3. Providing sufficient empowerment and other means for personnel to excel
4. Removing the sources of job stress and burnout
5. Providing continuous coaching for personnel
6. Providing for participation in departmental planning
7. Providing the opportunity to interact with customers (both external and internal)
8. Providing a variety of forms of reward and recognition

Retaining superior operations personnel, particularly in the fast-paced operations environment, is clearly important to achieve quality goals. It means hire the best people, give them the tools they need, train them, and reward them in tangible and intangible ways.

ORGANIZATIONAL FORMS ON THE OPERATIONS FLOOR

Many firms organize around functional departments having a well-defined management hierarchy. This applies both to the major functions (e.g., Operations, Marketing, Product Development) and also to sections within a functional department such as Operations.

Step 1	Step 2				
Identify Abilities	**Establish Training Priorities**				
	RELATIVE IMPORTANCE	EMPLOYEE NOW	PLAN FOR IMPROVEMENT	INDEX OF IMPROVEMENT (PLAN - NOW)	PRIORITY WGHT. (Importance Index)	PRIORITY WGHT. AS A PERCENTAGE
Coordinate Educational Offerings	9	9	9	0	0	0%
Develop Presentation Materials	6	8	9	1	6	3%
Employee Benefit Tracking	6	1	7	6	36	19%
Team Participation & Support	7	4	6	2	14	7%
Future H.R. Projects	8	2	7	5	40	21%
Payroll Back-up	9	1	7	6	54	29%
Design & Layout of Communications	5	3	5	2	10	5%
Facilitate Marketing Efforts	10	6	8	2	20	11%
Dvlp rltnshp w/ printers, ad agent, hotels	8	7	8	1	8	4%

FIGURE 22.12 Training priorities. (*Stampen and Stampen 1995.*)

Organizing by function has certain advantages—clear responsibilities, efficiency of activities within a function, and so on. But this organizational form also creates "walls" between the departments. These walls—sometimes visible, sometimes invisible—often cause serious communication barriers. The outcome can be efficient operations *within* each department but with a less-than-optimal result delivered to external (and internal) customers.

Clearly, the participation of the work force in planning and improvement has become a way of life. It seems likely that self-managing teams will replace the Taylor system (see Section 15, under Empowerment and Commitment: Self-Regulating Team).

The "organization of the future" will be influenced by the interaction of two systems that are present in all organizations: the technical system (equipment, procedures, etc.) and the social system (people, roles, etc.)—thus the name *sociotechnical systems* (STSs).

Much of the research on sociotechnical systems has concentrated on designing new ways of organizing work, particularly at the work force level. For example, supervisors are emerging as "coaches"; they teach and empower rather than assign and direct. Operators are becoming "technicians"; they perform a multiskilled job with broad decision making rather than a narrow job with limited decision making. Team concepts play an important role in these new approaches. Some organizations now report that within a given year, 40 percent of their people participate on a team; some organizations have a goal of 80 percent. Permanent teams (e.g., process team, self-managing team) are responsible for all output parameters, including quality; ad hoc teams (e.g., a quality project team) are typically responsible for improvement in quality. A summary of the most common types of quality teams is given in Table 22.10.

The literature on organizational forms in operations and other functions is extensive and increases continuously. For a discussion of research conducted on teams, see Katzenbach and Smith (1993). Mann (1994) explains how managers in process-oriented operations will need to develop skills as coaches, developers, and "boundary managers."

CONCEPT OF CONTROLLABILITY; SELF-CONTROL

When work is organized in a way that enables a person to have full mastery over the attainment of planned results, that person is said to be in a state of *self-control* and therefore can be held responsible for the results. Self-control is a universal concept, applicable to a general manager responsible for running a company division at a profit, a plant manager responsible for meeting the various goals set for that plant, a technician running a chemical reactor, or a bank clerk processing checks. The concept also applies to work teams.

To achieve self-control, people must be provided with a means for

1. Knowing what they are supposed to do, e.g., the product specification or the work procedure.

2. Knowing what they are actually doing, e.g., instruments to measure process variables or the amount of output conforming to quality requirements.

3. Regulating the process, e.g., the authority and ability to regulate the work process.

TABLE 22.10 Summary of Types of Quality Teams

	Quality project team	Quality circle	Business process quality team	Self-managing team
Purpose	Solve cross-functional quality problems	Solve problems within a department	Plan, control, and improve the quality of a key cross-functional process	Plan, execute, and control work to achieve a defined output
Membership	Combination of managers, professionals, and work force from multiple departments	Primarily work force from one department	Primarily managers and professionals from multiple departments	Primarily work force from one work area
Basis of and size of membership	Mandatory; 4–8 members	Voluntary 6–12 members	Mandatory; 4–6 members	Mandatory; all members in the work area (6–18)
Continuity	Team disbands after project is completed	Team remains intact, project after project	Permanent	Permanent
Other names	Quality improvement team	Employee involvement group	Business process management team; process team	Self-supervising team; semiautonomous team

The three basic criteria for self-control make possible a separation of defects into categories of "controllability," of which the most important are

1. *Worker-controllable:*   A defect or nonconformity is worker-controllable if all three criteria for self-control have been met.

2. *Management-controllable:*   A defect or nonconformity is management-controllable if one or more of the criteria for self-control have not been met.

The theory behind these categories is that only the management can provide the means for meeting the criteria for self-control. Hence any failure to meet these criteria is a failure of management, and the resulting defects are therefore beyond the control of the workers. This theory is not 100 percent sound. Workers commonly have the duty to call management's attention to deficiencies in the system of control, and sometimes they do not do so. (Sometimes they do, and it is management who fails to act.) However, the theory is much more right than wrong.

Whether the defects or nonconformities in a plant are mainly management-controllable or worker-controllable is a fact of the highest order of importance. To reduce the former requires a program in which the main contributions must come from the managers, supervisors, and technical specialists. To reduce the latter requires a different kind of program in which much of the contribution comes from the workers. The great difference between these two kinds of programs suggests that managers should quantify their knowledge of the state of controllability before embarking on major programs.

An example of controllability study is given in Table 22.11. A diagnostic team was set up to study scrap and rework reports in six machine shop departments for 17 working days. The defect cause was entered on each report by a quality engineer who was assigned to collect the data. When the cause was not apparent, the team reviewed the defect and, when necessary, contacted other specialists (who had been alerted by management about the priority of the project) to identify the cause. The purpose of the study was to resolve a lack of agreement on the causes of chronically high scrap and rework. It did the job. The study was decisive in obtaining agreement on the focus of the improvement program. In less than 1 year over $2 million was saved, and important strides were made in reducing production backlogs.

Controllability also can be evaluated by posing specific questions for each of the three criteria of self-control. (typical questions that can be posed are presented below.) Although this approach does not yield a quantitative evaluation of management-controllable and worker-controllable defects, it does show whether the defects are primarily management-controllable or worker-controllable.

TABLE 22.11   Controllability Study in a Machine Shop, %

Management-controllable	
Inadequate training	15
Machine inadequate	8
Machine maintenance	8
Other process problems	8
Materials handling	7
Tool, fixture, gauge (TFG) maintenance	6
TFG inadequate	5
Wrong material	3
Operation run out of sequence	3
Miscellaneous	5
Total	68
Worker-controllable	
Failure to check work	11
Improperly operated	11
Other (e.g., piece mislocated)	10
Total	32

In my experience, defects are about 80 percent management-controllable. This figure does not vary much from industry to industry but varies greatly among processes. Other investigators, in Japan, Sweden, the Netherlands, and Czechoslovakia, have reach similar conclusions.

While the available quantitative studies make clear that defects are mainly management-controllable, many industrial managers do not know this or are unable to accept the data. Their long-standing beliefs are that most defects are the result of worker carelessness, indifference, and even sabotage. Such managers are easily persuaded to embark on worker-motivation schemes which, under the usual state of facts, aim at a small minority of the problems and hence are doomed to achieve minor results at best. The issue is not whether quality problems *in industry* are management-controllable. The need is to determine the answer *in a given plant.* This cannot be answered authoritatively by opinion but requires solid facts, preferably through a controllability study of actual defects, as in Table 22.11.

The concept of self-control draws attention to the importance of manufacturing planning. Manufacturing planning for quality is the means of *prevention* of both management- and worker-controllable defects on the manufacturing floor.

Collins and Collins (1993) provide six examples from the manufacturing and service sectors illustrating problems that were originally blamed on people but which really were management-controllable (often called *systems-controllable*). A similar situation is found in the service sector. Berry, Parasuramen, and Zeithmal (1994) identified 10 lessons learned in improving service quality. Three of these are service design ("The real culprit is poor service system design"), employee research (Ask employees why service problems occur and what they need to do their jobs), and servant leadership (Managers must serve by coaching, teaching, and listening to employees). Note that these three lessons are directly related to the concept of self-control.

Often in practice the three criteria are not fully met. For example, some specifications may be vague or disregarded (the first criterion); feedback of data may be insufficient, often vague, or too late (the second criterion); and people do not know how to correct a process (the third criterion).

The section on operations focuses on the factory floor and backroom operations in service firms. The concept of self-control, however, also applies to operations activities that involve extensive front-line customer contact.

The freedom provided to individuals working in a state of self-control inspires initiative, creativity, and a sense of well-being, all leading to self-development of the individual. Designing—and maintaining—work activities to meet the three criteria of self-control is a prerequisite to motivating personnel to achieve quality goals. Only management can create and maintain the conditions for self-control. If jobs are designed for self-control, management might hear a chorus of appreciation from the work force—followed by a smash hit of success on quality. Self-control is related to the broader concept of democracy in the workplace [see Rubinstein (1993) for elaboration)]. The three criteria for self-control are discussed below.

KNOWLEDGE OF "SUPPOSED TO DO"

This knowledge commonly consists of the following:

1. The product standard, which may be a written specification, a product sample, or other definition of the end result to be attained.

2. The process standard, which may be a written process specification, written process instructions, an oral instruction, or other definition of "means to an end"

3. A definition of responsibility, i.e., what decisions to make and what actions to take (discussed earlier in this section)

Product Specifications.   The ideal source of knowledge is the use required by the user. In most situations this is translated into a product specification. In developing these product specifications, some essential precautions must be observed.

Provide Unequivocal Information.   Two obstacles to proper knowledge can exist:

1. The specification may be vague. For example, when fiberglass tanks are transported in vehicles, the surface of the supporting cradles should be smooth. It was recognized that weld spatter would be deposited on the cradle surface, so an operation was specified to scrape the surface "smooth." However, there was no definition of "how smooth," and many rejections resulted.

2. There may be conflicting specifications. The supervisor's "black book" has had a long, durable career. Changes in specifications may fail to be communicated, especially when there is a constant parade of changes. In one instance, an inspector rejected product that lacked an angle cut needed for clearance in assembly. It was discovered that the inspector was using drawing revision D, the production floor had used revision B, and the design office had issued revision E just 3 days before.

Provide Information on Seriousness.   All specifications contain multiple characteristics, and these are not equally important. When workers are informed of the vital few characteristics, their emphasis is better placed.

Explain the "Why."   Explanation of the purposes served by the product and by the specification enlarges the knowledge of "supposed to do" and provides motivation through the resulting feeling of participation.

For example, a specification on weight called for a nominal value of 40.0 g with a tolerance of ±0.5 g. Although the total tolerance of 1.0 was being met, most of the tolerance range was being used up, and this created some problems later in assembly. A process capability study showed that the process capability was 0.10 g—far better than the tolerance of 1.0 g. But why was most of the tolerance range being used? Discussion revealed that (1) workers had not been told of the impact of inconsistent weights on later assembly, and (2) workers had not been instructed on centering the process to the nominal specification value.

Provide Standards.   In those cases where the specification cannot be quantitative, physical or photographic standards should be provided. There is an extensive array of needs here, especially on widely prevailing characteristics such as product appearance. (For years, enormous numbers of electrical connections were soldered in the absence of clear standards for an acceptable soldered connection.) If these standards are not provided by the managers and engineers, then, by default, the standards will be set by the inspectors and workers.

Process Specifications.
Work methods and process conditions (e.g., temperature, pressure, time cycles) must be unequivocally clear. A steel manufacturer uses a highly structured system of identifying key process variables, defining process control standards, communicating the information to the work force, monitoring performance, and performing diagnosis when problems arise. The process specification is a collection of process control standard procedures. A procedure is developed for controlling each of the key process variables (variables that must be controlled in order to meet specification limits on the product). The procedure answers the following questions:

1. What are the process standards?
2. Why is control needed?
3. Who is responsible for control?
4. How is measurement made?
5. When is measurement made?
6. How are routine data reported?
7. Who is responsible for data reporting?
8. How is audit conducted?

9. Who is responsible for audit?

10. What is done with product that is out of compliance?

11. Who developed the standard?

Often, detailed process instructions are not known until workers have experience with the process. Updating of process instructions based on job experience can be conveniently accomplished by posting a cause-and-effect diagram (see Section 5, under Formulation of Theories, Arrangement of Theories) in the Operations Department and inviting employees to attach index cards to the diagram. Each card recommends additional process instructions based on recent experience.

The Primester Division of Eastman Chemical immediately communicates changes in product and process specifications electronically to operations, and the software includes checks for understanding, assimilation, and retention of the changes.

Ford and Leader (1989) explain experiences in integrating group dynamics, communication skills, conflict management, and other "human dynamics" issues in a statistical process control activity. Newberg and Nielsen (1990) explain an approach to "operator control" in which operators participate to remove barriers (to operator control), develop process controls, and receive specific job training for a process producing soup. This participation includes operator use of flow diagrams to establish "critical control points" for the process.

Checklist for Manufacturing.

The preceding discussion covers the first criterion of self-control; people must have the means for knowing what they are supposed to do. To evaluate adherence to this criterion, a checklist of questions can be created, including the following:

1. Are there written product specifications, process specifications, and work instructions? If written in more than one place, do they all agree? Are they legible? Are they conveniently accessible to the worker?

2. Does the specification define the relative importance of different quality characteristics? Are advisory tolerances on a process distinguished from mandatory tolerances on a product? If control charts or other control techniques are to be used, is it clear how these relate to product specifications?

3. Are standards for visual defects displayed in the work area?

4. Are the written specifications given to the worker the same as the criteria used by inspectors? Are deviations from the specification often allowed?

5. Does the worker know how the product is used?

6. Has the worker been adequately trained to understand the specification and perform the steps needed to meet the specification? Has the worker been evaluated by test or other means to see if he or she is qualified?

7. Does the worker know the effect on future operations and product performance if the specification is not met?

8. Does the worker receive specification changes automatically and promptly?

9. Does the worker know what to do with defective raw material and defective finished product?

10. Have the responsibilities in terms of decisions and actions been clearly defined?

(A checklist for self-control as applied to manufacturing operations was originally presented by L. A. Seder in the second edition of this handbook.)

The manufacturing sector has a long history of documenting quality and other requirements in the form of product and process specifications, work procedures, and other forms of written information. In the service sector, the formalization of quality requirements and associated documentation is now evolving. Highly detailed product specifications and process specifications are not yet common documents in service firms. Nevertheless, providing personnel in the service sector with the knowledge of what they are supposed to do is essential for self-control.

A framework starts with identifying control subjects. Control subjects are the features (or characteristics) that must be addressed to meet customer needs. Control subjects are a mixture of

Features of the product: Some control is carried out by evaluating features of the work product itself (e.g., the time to process an application or the completeness of a report). In manufacturing, these features are described in a product specification.

Features of the process: Much control consists of evaluating those features of the work process which directly affect the product features and therefore customer needs (e.g., the availability of equipment, the staffing levels for a service desk, the frequency of "out of stock" conditions, etc.). In manufacturing, a "process specification" describes these features. Such a specification is translated into procedures for use by operations personnel. Gass (1994) explains an approach for preparing and implementing procedures that encourages the use of the procedures on the operations floor. For service processes, Pyzdek (1994) describes a framework of service systems engineering.

Side effects: Some features that do not affect the work product directly but which may create troublesome side effects (e.g., irritations to employees, offense to the neighborhood, or threats to the environment) also can be control subjects.

Examples of control subjects and their relation to products and processes are shown in Table 22.12. To choose control subjects requires these steps: identify the major work process, identify the process objective, describe the work process, identify customers of the process, discover customer needs, and finally, select the control subjects. For elaboration, see Section 3, under Step 6: Develop Process Controls.

For self-control, these control subjects should be quantified and measured using appropriate units of measure and sensors. This quantification involves two kinds of indicators that must be made explicit for those running the process:

1. *Performance indicators:*   These measure the output of the process and its conformance to customer needs as defined by the unit of measure for the control subject.

2. *Process indicators:*   These measure activities or variation within the process that affect the performance indicators.

For clarity to personnel running a process, these indicators should have target values and maximum and minimum limits, where appropriate.

TABLE 22.12   Control Subjects

Major work product	Major work process	Control subjects
Photo developing	Film processing	Maintenance of chemicals
		Accuracy of placement of film on spool
Medical insurance	Claim processing	Accuracy of claim form
		Completeness of supporting documentation
Printing	Billing process	Accuracy of invoices
		Maintenance of customer information
Over-the-counter cold medications	Packaging of bottles	Safety seals
		Number of tablets per bottle
Catering services	Food preparation	Freshness of ingredients
		Oven temperature
Industrial tubing	Manufacture of tubing	Speed of intrusion machine
		Heat of machine
24-Hour banking services	Maintenance of ATM machines	Availability of cash
		Number of service people available

Checklist for Services.   Based on research (Shirley and Gryna 1998) with personnel in backroom operations of the financial services industry, the following questions can help to evaluate if personnel "know what they are supposed to do":

Work Procedures

1. Are job descriptions published, available, and up to date?
2. Do personnel know who their customers are? Have they ever met them?
3. Do personnel who perform the job have any impact on the formulation of the job procedure?
4. Are job techniques and terminologies consistent with the background and training of personnel?
5. Are there guides and aids (e.g., computer prompts) that lead personnel to the next step in a job?
6. Are there provisions to audit procedures periodically and make changes? Are changes communicated to all affected personnel?
7. Are there provisions for deviations from "home office" directives to meet local conditions?
8. Are procedures "reader friendly"?
9. Does supervision have a thorough knowledge of the operations to provide assistance when problems arise?
10. Do procedures given to personnel fully apply to the job they do in practice?
11. Have personnel responsibilities been clearly defined in terms of decisions and actions?
12. Do personnel know what happens to their output in the next stage of operations and understand the consequences of not doing the job correctly?
13. If appropriate, is job rotation used?

Performance Standards

14. Are formal job standards on quality and quantity needed? If "yes," do they exist. Are they in written form?
15. Have personnel been told about the relative priority of quality versus quantity of output? Do personnel really understand the explanation?
16. Are job standards reviewed and changed when more tasks are added to a job?
17. Do personnel feel accountable for their output, or do they believe that shortcomings are not under their control?
18. Does information from a supervisor about how to do a job always agree with information received from a higher level manager?

Training

19. Are personnel given an overview of the entire organization?
20. Is there regularly scheduled training to provide personnel with current information on customer needs and new technology?
21. Do personnel and their managers provide input to their training needs?
22. Does training include the "why," not just the "what"?
23. Does the design of the training program consider the background of those to be trained?
24. Do the people doing the training provide enough detail? Do they know how to do the job?
25. Where appropriate, are personnel who are new to a job provided with mentors?

KNOWLEDGE OF "IS DOING"

This is the second criterion for self-control. For self-control, people must have the means of knowing whether their performance conforms to standard. This conformance applies to

1. The product in the form of specifications on product characteristics
2. The process in the form of specifications on process variables

The knowledge is secured from three primary sources: measurements inherent in the process, measurements by production workers, and measurements by inspectors.

Measurement Inherent in the Process.

Many processes are engineered to include much instrumentation. The resulting information provides a feedback to enable the workers to close the loop. Even where the feedback is into an automated system, the data are usually available to human workers acting as monitors.

Measurements by Workers

Where the worker is to use the instruments, it is necessary to provide training in how to measure, what sampling criteria to use, how to record, how to chart, and what kinds of corrective action to take. The difficulty of motivating the workers to follow these instructions is so widespread a problem that many companies go to great lengths to minimize the need for worker action by providing instruments that require little or no human effort to measure, record, and control.

When these instruments are provided to workers, it is also necessary to ensure that these instruments are compatible with those used by inspectors and in other operations later in the progression of events.

On one construction project, the "form setters" were provided with carpenter levels and rulers to set the height of forms prior to the pouring of concrete. The inspectors were provided with a complex optical instrument. The differences in measurement led to many disputes.

Control of the process is strengthened if the worker is provided with the type of gauge that provides numerical measurements on a characteristic rather than providing accept-reject information.

A problem arises when the measurement necessary to control a process must be made in a laboratory off the production floor. The time required to send a sample to the laboratory, to have the analysis made, and to have the data relayed back to production can result in a delay to proper control of a process. One solution is the development of auxiliary measuring devices that can be used on the production floor by the worker and thereby provide immediate feedback. An example comes from a process used to control the concentration of chloride in a corn product derivative. Traditionally, the raw material undergoes centrifuging, a sample of the product is sent to a laboratory for analysis, the test results are forwarded to Production, and any necessary changes are then made in the centrifugal loads. (Chloride level, for the most part, is dependent on the load size of crystallized liquor being spun in the centrifugals.) Under the new setup, the worker takes a spot sample at the surge bin and analyzes the product for parts per million chloride on an ion analyzer and thereby directly regulates the process. Total time between processing a batch and obtaining a measurement plunges from 90 to 20 minutes. As a result, the amount of inferior product due to delayed process adjustment is greatly reduced.

Parker (1981) describes how the use of on-line gauges overcame problems in obtaining adequate sampling of product at a paper mill.

Measurements by Inspectors.

When an Inspection Department makes measurements that are to serve as a basis for action by Operations, the feedback usually goes to both workers and supervisors.

Criteria for Good Feedback to Workers.   The needs of production workers (as distinguished from supervisors or technical specialists) require that the data feedback read at a glance deals only with the few important defects, deals only with worker-controllable defects, provides prompt information about symptom and cause, and provides enough information to guide corrective actions. Criteria of good feedback are

1. *Read at a glance:*   The pace of events on the factory floor is swift. Workers should be able to review the feedback in stride.

Where the worker needs information about process performance over time, charts can provide an excellent form of feedback, provided they are designed to be consistent with the assigned responsibility of the worker (Table 22.13). It is useful to use visual displays to highlight recurrent problems. A problem described as "outer hopper switch installed backwards" displayed on a wall chart in large block letters has much more impact than the same message buried away as a marginal note in a work folder. Carlisle (1981) describes the effectiveness of such a system.

2. *Deal only with the few important defects:* Overwhelming workers with data on all defects will result in diverting attention from the vital few.

3. *Deal only with worker-controllable defects:* Any other course provides a basis for argument which will be unfruitful.

4. *Provide prompt information about symptom and cause:* Timeliness is a basic test of good feedback the closer the system is to "real time" signaling, the better.

5. *Provide enough information to guide corrective action:* The signal should be in terms that make it easy to decide on remedial action.

Software helps to collect, analyze, and display process data on a real-time basis. The control chart in Figure 22.13 shows an example of operator feedback in printed wiring assembly manufacture at Group Technologies. The unit of measure is defects per million opportunities (DPMO); the "Alarm line" is the computed average DPMO. Depending on the color of this line, the operator receives guidance on controlling the process. If the color is black, the process is acceptable, and the operator maintains the process under current conditions; a yellow color alerts the operator to exercise caution; a red color directs the operator to stop the process and seek help from a supervisor or a "reaction team." Limits for each of the zones are set by the process engineer based on customer specifications.

TABLE 22.13 Worker Responsibility versus Chart Design

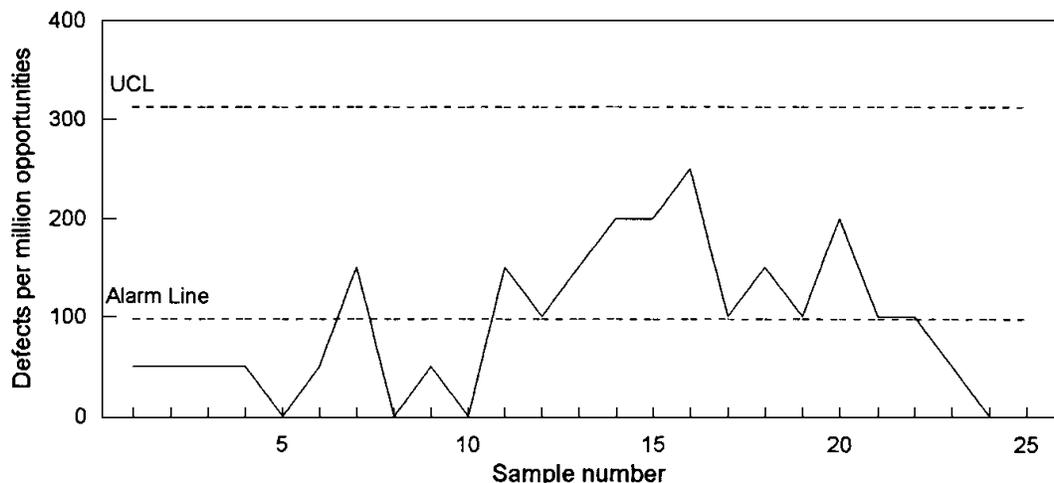
Responsibility of the worker is to	Chart should be designed to show
1. Make individual units of product meet a product specification	The measurements of individual units of product compared to product specification limits
2. Hold process conditions to the requirements of a process specification	The measurements of the process conditions compared with the process specification limits
3. Hold averages and ranges to specified statistical control limits	The averages and ranges compared to the statistical control limits
4. Hold percent nonconforming below some prescribed level	Actual percent nonconforming compared to the limiting level


FIGURE 22.13 Operator feedback chart. (*Group Technologies Corporation internal document.*)

The control chart is just one of the many tools of statistical process control (SPC). SPC provides an arsenal of tools that operations people need to understand and apply. For elaboration, see Section 45, Statistical Process Control.

Feedback Related to Worker Action.   The worker needs to know what kind of process change to make to respond to a product deviation. Sources of this knowledge are

1. The process specification
2. Cut-and-try experience by the worker
3. The fact that the units of measure for product and process are identical

Lacking all these, the workers can only cut and try further or stop the process and sound the alarm.

Sometimes it is feasible for the data feedback to be supplemented with other graphic information that enables process personnel to decide on and take appropriate action on the process. Foster and Zirk (1992) explain how complex research and development information can be converted into "multiple curve plots" for use by process workers. An illustration is given in Figure 22.14. In a hydrocarbon cracking process, two of the operator-controlled variables are fuel capacity and burner air opening (BAO). The graphs serve as operating guides for workers to adjust the two variables.

Feedback to Supervisors.   Beyond the need for feedback at the workstations, there is need to provide supervisors with short-term summaries. These take several forms.

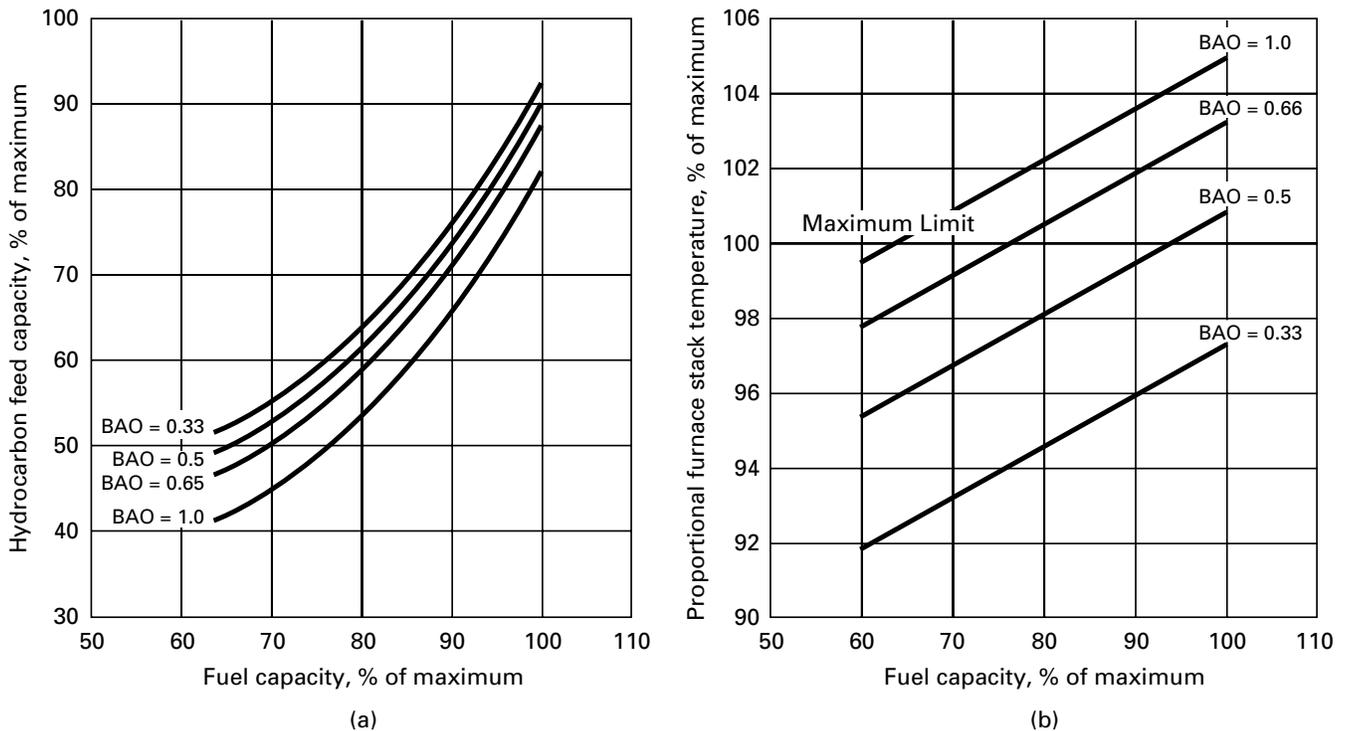
Matrix Summary.   A common form of matrix is workers versus defects; i.e., the vertical columns are headed by worker names and the horizontal rows by the names of defect types. The matrix makes clear which defect types predominate, which workers have the most defects, and what the interaction is. Other matrices include machine number versus defect type, defect type versus calendar week, and so on.


FIGURE 22.14   (*a*) Hydrocarbon feed capacity. (*b*) Proportional furnace stack temperature. [Parameter: burner air opening, area fraction; fixed condition: furnace draft = 0.065 inches H_2O.] (*Foster and Zirk 1992.*)

When the summary is published, it is usual to circle the matrix cells to highlight the vital few situations that call for attention. An elaboration of the matrix is to split the cell diagonally, permitting the entry of two numbers, e.g., number defective and number produced.

Pareto Analysis.   Some companies prefer to minimize the detail and provide information on the total defects for the day plus a list of the top three (or so) defects encountered and how many of each. Increasingly, supervisors can monitor processes by reviewing summarized and detailed process data on a personal computer (PC) in their office. One manufacturer even makes data available on a PC at the homes of people who are "on call" to assist on process problems.

Special Graphing of Multiple Parameters.   Traditionally, individual parameters are tracked in a process. The single-measure approach can lead to focusing on the numbers and not on the practices that drive desired performance. Madigan (1993) describes a chart that provides a "holistic approach to understanding operations." First, measures are identified that describe factors that are critical to the success of the operation. For example, in a building services operation, the measures relate to training, cleaning area, safety, wages, and absentee rate. Data are gathered from four plants. For each measure, the plant with the best result serves as a benchmark. The *measures matrix chart* consists of concentric circles that plot the data from all five measures and provide a profile of the average values and a profile of each plant. The approach is used in both service and manufacturing applications at Eastman Kodak. For further explanation, see Madigan (1993).

Automated Quality Information.   Production volume and complexity are important factors in determining the role of the computer. However, the role can be important even in relatively simple processes. For example, in a fast-food franchise, the elapsed time in filling a customer order is visibly shown (the goal is 45 seconds); the number of calls waiting to be answered in an insurance service center is clearly displayed. Section 10, Computer Applications in Quality Systems, explains the role of computers in analyzing and reporting data during production and other phases of the product life cycle.

Checklist for Manufacturing   A checklist to evaluate the second criterion of self-control includes questions such as

1. Are gauges provided to the worker? Do they provide numerical measurements rather than sort good from bad? Are they precise enough? Are they regularly checked for accuracy?

2. Is the worker told how often to sample work? Is sufficient time allowed?

3. Is the worker told how to evaluate measurements to decide when to adjust the process and when to leave it alone?

4. Is there a check to see that the worker does follow instructions on sampling work and making process adjustments?

5. Are inspection results provided to the worker, and are these results reviewed by the supervisor with the worker?

Examples of the second criterion of self-control also can be found in the service sector. These focus on identification and measurement of service indicators. A credit card provider has identified 18 key processes covering all activities: 2 business processes, 6 support processes, 10 product and service production and delivery processes. Two examples of production processes are credit screening and payment processing. For the total of 18 processes, over 100 internal and supplier process measures were defined. (In addition, external customer satisfaction research is conducted.) Daily and monthly performance results are available through video monitors and are also posted. Each morning, the head of operations meets with senior managers to discuss the latest results, identify problems, and propose solutions. Employees can access a summary of this meeting via telephone or electronic mail.

To emphasize the importance of quality, the measurement system is linked to compensation by a daily bonus system that provides up to 12 percent of base salary for nonmanagers and 8 to 12 percent for managers. For elaboration, see Davis et al. (1995).

Hestand (1991) explains how a bank uses a "report card" to measure the services provided to internal customers. Performance on specific quality measures is rated from A (excellent) to F (fails to meet requirements). At each participating branch, ratings are provided by a branch manager (BR MAN), an operations manager (OP MAN), and a customer service representative (CSR). A sample of the results for two measurements is presented in Table 22.14. Thus, for the accuracy of proof item encoding measurement, the total frequency of grades reported ranged from 2 A's, to 38 B's, to 0 F's. (The letter grades are also expressed in numerical form.) Further detail is automatically provided on D and F grades along with a procedure on follow-up toreport action taken.

One fast-food firm creates teams of "crew members" (workers at one location) who are trained to manage the site without a full-time manager (Harvard Business School 1994). Not only does this mean installing on-line technology such as the time to prepare an order, but it also means providing crew members with the same operating and financial information provided to a restaurant general manager to run the site. At these "team-managed units," the crew members make decisions on such matters as ordering food. Thus knowledge that long separated "brain workers" from "hand workers" now resides in a computer on the operations floor.

Lochner (1995) explains the use of a balanced set of measures in health care activities and makes the distinction between process measures (room occupancy rate) versus results measures (waiting time at admissions). Latzko (1993) explains the use of quality measurements to identify key potential "quality deviations" in a retail lending function at a bank. Early (1989) provides guidance on developing quality measures in the service sector.

Checklist for Services.   A checklist developed from discussions with personnel in backroom operations in financial service is provided below (Shirley and Gryna 1998):

Review of Work

1. Are personnel provided with the time and instructions for making self-review of their work?
2. Can errors be detected easily?
3. Are independent checks on quality needed? Are they performed? Are these checks performed by peer personnel or others?

TABLE 22.14   Examples of Quality Measurements from Internal Customers: Proof Department

72. Promptness of responses to special requests

	A	B	C	D	F	N/A	?	
Total	7	26	30	5	0	22	3	2.51
BR MAN	1	7	10	2	0	11	0	2.35
OP MAN	3	9	12	1	0	6	0	2.56
CSR	3	10	8	2	0	5	3	2.61

73. Accuracy of proof item encoding for transactions received by branch

	A	B	C	D	F	N/A	?	
Total	2	38	23	3	0	26	0	2.59
BR MAN	1	10	6	1	0	13	0	2.61
OP MAN	1	20	9	0	0	1	0	2.73
CSR	0	8	8	2	0	12	0	2.33

Source: Hestand (1991).

4. Is a review of work performed at various checkpoints in a process, not just when work is completed? Is the sample size sufficient?

5. Is there an independent audit of an entire process to ensure that individual work assignments are integrated to achieve process objectives?

6. Where appropriate, are detailed logs kept on customer contracts?

Feedback

7. Do upper management and supervision both provide the same message and actions on the importance of quality versus quantity?

8. If needed, do standards exist on making corrections to output?

9. Where appropriate, is feedback provided to both individuals and a group of personnel? Is time provided for discussion with the supervisor, and does the discussion occur?

10. Is feedback provided to those who need it? Is it timely? Is it personnel specific?

11. Does feedback provide the level of detail needed particularly to correct problem areas? Have personnel been asked what detail is needed in the feedback?

12. Is feedback provided from customers (external or internal) to show the importance of the output and its quality?

13. Does feedback include information on both quality and quantity?

14. Is positive in addition to negative (corrective) feedback provided?

15. Is negative (corrective) feedback given in private?

16. Do personnel receive a detailed report of errors by specific type of error?

17. Where appropriate, are reports prepared describing trends in quality (in terms of specific errors)? Is this done for individual personnel and for an entire process performed by a group of people?

18. Are there certain types of errors that are tracked with feedback from external customers? Could some of these be tracked with an internal early indicator?

ABILITY TO REGULATE

This is the third criterion for self-control. Regulating the process must always include both the authority to regulate and the ability to regulate. Regulation depends on a number of conditions, including

1. *The process must be capable of meeting the specifications:* (See above under Process Capability.)

2. *The process must be responsive to regulating mechanisms in a predictable cause-and-effect relationship (this is essential to minimize variation):* In a process for making polyethylene film, the workers were required to meet multiple product parameters. The equipment had various regulating devices, each of which could vary performance with respect to one or more parameters. The workers, however, could not "dial in" a predetermined list of settings that would meet all parameters. Instead, it was necessary to cut and try in order to meet all parameters simultaneously. During the period of cut and try, the machine produced nonconforming product to an extent that interfered with meeting standards for productivity and delivery. The workers were unable to predict how long the cut-and-try process would go on before full conformance was achieved. Consequently, it became the practice to stop cut and try after a reasonable amount of time and to let the process run, whether in conformance or not.

Skrabec (1991) describes how a cause-and-effect diagram can be combined with a process flow diagram to relate key input variables to key output variables. The result provides a guide for making process changes.

3. *The worker must be trained in how to use the regulating mechanisms and procedures:* This training should cover the entire spectrum of action: under what conditions to act, what kind and extent of changes to make, how to use the regulating devices, and why these changes need to be done.

Of three qualified workers on a food process, only one operated the process every week and became proficient. The other two workers were used when the primary worker was on vacation or was ill, and thus they never became proficient. Continuous training of the relief people was considered uneconomical, and agreements with the union prohibited their use except under the situations cited. This problem is management-controllable; i.e., additional training or a change in union agreements is necessary.

4. *The act of adjustment should not be personally distasteful to the worker, e.g., should not require undue physical exertion:*   In a plant making glass bottles, one adjustment mechanism was located next to a furnace area. During the summer months, this area was so hot that workers tended to keep out as much as possible.

When the regulation consists of varying the human component of the operation, the question of process capability arises in a new form: Does the worker have the capability to regulate? This important question is discussed in Section 5, under Technique Errors, which includes some examples of discovering worker "knack."

5. *The process must be maintained sufficiently to retain its inherent capability:*   Without adequate maintenance, equipment breaks down and requires frequent adjustments—often with an increase in both defects and variability around a nominal value. Clearly, such maintenance must be both preventive and corrective. The importance of maintenance has given rise to the concept of total productive maintenance (TPM). Under this approach, teams are formed to identify, analyze, and solve maintenance problems for the purpose of maximizing the uptime of process equipment. These teams consist of production line workers, maintenance personnel, process engineers, and others as needed. Problems are kept narrow in scope to encourage a steady stream of small improvements. Examples of improvement include a reduction in the number of tools lost and simplification of process adjustments.

Process Control Tools.   The tools selected are often related to one of five forms of dominance in a process: setup, time, component, worker, and information. For a listing of specific process control tools related to each form, see above under Planning Process Controls.

Checklist for Manufacturing.   A checklist to evaluate the third criterion of self-control typically includes such questions as the following:

1. Has the quality capability of the process been measured to include both inherent variability and variability due to time? Is the capability periodically checked?

2. Has the worker been told how often to reset the process or how to evaluate measurements to decide when the process should be reset?

3. Is there a process adjustment that the worker can make to eliminate defects? Under what conditions should the worker adjust the process? When should the worker shut down the machine and seek more help? Whose help?

4. Have the worker actions that cause defects, and the necessary preventive action, been given to the worker, preferably in the written form?

5. Is there an adequate preventive maintenance program on the process?

6. Is there a hidden knack possessed by some workers that needs to be discovered and transmitted to all workers?

Following a brief discussion of empowerment, a similar checklist will be provided for the service sector.

Empowerment.   In providing sufficient authority for process regulation, the concept of empowerment plays an important part. *Empowerment* is the process of delegating decision-making authority to lower levels within the organization. Particularly dramatic is empowerment of the work force. But empowerment goes far beyond delegating authority and providing additional training. It means encouraging people to take the initiative and broaden their scope; it also means being supportive if they make mistakes.

As employees become more empowered in their work, the feeling of ownership and responsibility becomes more meaningful. Further, the act of empowering employees provides evidence of management's trust. Additional evidence is furnished when management shares confidential business information with employees. For many organizations, such steps are clearly a change in the culture.

The concept of empowerment applies both to individuals and to groups of workers. Self-managed teams (see Section 15, under Empowerment and Commitment: Self-Regulating Team) provide an illustration of empowerment for groups of workers. With empowerment comes the need to redefine the basic roles of upper management, middle management, and the work force. One model at a bank looks like this:

> *Upper managers* act as shapers and coaches. As shapers, they create, communicate, and support the organization's mission. As coaches, they help when asked but avoid entering into the day-to-day problems of middle management.
>
> *Middle managers* not only run their areas of responsibility but also work as a group to integrate all parts of the organization. In addition, they support the work force by eliminating obstacles to progress.
>
> The *workers* are the primary producers of the output for customers. Their closeness to and knowledge about their work means that they uses their empowerment to determine how the work can best be done.

Dramatic illustrations of empowerment of the work force from authorizing a worker to stop the production line to authorizing clerks to make check-cashing decisions span all industries. Shay et al. (1991) trace the history, approach, and results of empowerment at an unusual firm—a century-old manufacturing plant with seven unions. The new system uses self-managing teams with new roles for supervisors, operators, and inspectors. Hayes (1994) shows how an employee questionnaire can be developed to learn the extent of empowerment within a firm. Simons (1995) explains how in an environment of empowering personnel, a firm may be exposed to some business risks that can be minimized by following four approaches, which he describes.

Checklist for Services.   A checklist for the third criterion, developed from discussions with personnel in backroom operations of financial service, is provided below (Shirley and Gryna 1998).

Job Design

1. Is the process (including procedures, equipment, software, etc.) given to personnel capable of meeting standards on quality and quantity of output? Has this capability been verified by trial under normal operating conditions?
2. Has the design of the job made use of the principles of error-proofing?
3. Does the job design minimize monotonous or unpleasant tasks?
4. Have provisions been made in the job design to anticipate and minimize errors due to normal interruptions in the work cycle?
5. Can special checks be created (e.g., balancing of accounts) to detect errors?
6. Can steps be incorporated in data entry processes to reject incorrect entries?
7. Does the job design include provisions for action when wrong information is submitted or information is missing as an input to a job?
8. Is paperwork periodically examined and obsolete records destroyed to simplify working conditions?

9. When volume of work changes significantly, are there provisions for adjusting individual responsibilities or adding resources?

10. Are there external factors (e.g., no account number on a check, cash received instead of a check, etc.) that hinder the ability to perform a task?

11. Are some personnel cross-trained for different tasks to provide an adequate supply of experienced personnel for filling in when needed?

12. If appropriate, is a "productive hour" scheduled each day in which phone calls and other interruptions are not allowed, thus providing time to be away from the work location to attend to other tasks?

13. Has equipment, including any software, been designed to be compatible with the abilities and limitations of personnel?

14. Is there an adequate preventive maintenance program for computers and other equipment used by personnel?

15. Is there a hidden knack possessed by some personnel that needs to be discovered and explained to all personnel?

16. For a job requiring special skills, have personnel been selected to ensure the best match of personnel skills and job requirements?

Changes in Job Design

17. Are proposed changes limited by technology (e.g., address fields on forms)?

18. Can personnel institute changes in a job when they show that the change will provide benefits? Are personnel encouraged to suggest changes?

19. What levels of approval by management are required for proposed changes to be instituted? Could certain types of changes be identified as not needing any level of management approval?

20. Do management actions confirm that they are open to recommendations from all personnel?

Handling Problems

21. Have personnel been provided with the time and training to identify problems, analyze problems, and develop solutions? Does this include diagnostic training to look for patterns of errors and determine sources and causes?

22. Are personnel permitted to exceed permitted process limits (e.g., maximum time on a customer phone call) if they believe it is necessary?

23. When personnel encounter an obstacle on a job, do they know where to seek assistance? Is the assistance conveniently available?

Use of Checklists on Self-Control. The checklists presented have several applications in operations:

1. *The design of new jobs and redesign of old jobs to assist in the prevention of errors and to place personnel in a state of self-control:* The checklist can serve as a tool to evaluate all quality-related aspects of the job, e.g., clarity of formal requirements and job instructions, adequacy of feedback to control the job, capability of the process itself, and the means of regulating the process. When a re-engineering effort is in progress, the design of specific jobs within a process using self-control criteria ensures that the job requirements and the needs of personnel are in harmony.

2. *Analysis and diagnosis of current jobs that have quality problems:* The search for root causes of current quality problems can be difficult and time-consuming. The checklist can help identify potential causes by providing an exhaustive list of candidate areas.

3. *Use by supervisors to discuss jobs with personnel:* In reviewing both general job performance and current job problems, the checklist can focus on specific aspects of the job—some of which

are under control of the person and some of which are not—and help the supervisor to function as a coach. Similarly, the checklist can be beneficial to self-managing teams.

4. *Getting prepared for auditors on financial transactions:*   Auditors check output and procedures in many financial areas, e.g., moving money from one account to another. The checklist can help to prepare for the auditing process.

5. *Help to focus on a broad improvement strategy:*   Use of the checklists for reviewing current jobs may reveal that many job designs have basic weaknesses such as lack of clarity in quality requirements or job instructions, timely and relevant feedback on output, or capability of the process itself. Why not ask personnel to review the checklist and then prioritize the specific problem areas?

6. *Use in training classes in quality:*   The concept of self-control helps to plan new jobs and to analyze quality problems on current jobs. Exercises on the three elements of self-control can be made part of a training class. Checklists developed by the participants or the checklists in this section can serve as a basis for discussion by the participants.

You might wish to refine the checklists or develop your own to meet the needs of your organization. This could be done by circulating the checklist internally and asking for additions to the list, identification of critical items, or any input that would make the list more useful. Additional ideas also could be generated by using the list for an exercise and discussion in a training class on quality.

TROUBLESHOOTING

Chronic versus Sporadic Troubles.   Quality troubles exist in two different forms: chronic and sporadic. *Chronic* troubles go on and on because no way has ever been found to eliminate them. For example, a process has for years operated at 10 percent nonconforming. No one has succeeded in reducing this level, so we learn to live with it.

Sporadic troubles are the result of some sudden adverse change. For example, a process that is usually at 10 percent nonconforming suddenly goes to 25 percent. Such a change sets off a number of alarm signals that demand prompt action to restore the status quo (to go back to the usual 10 percent). *Troubleshooting* (also called *firefighting*) is the process of dealing with the sporadic and restoring quality to the original level. Section 5, The Quality Improvement Process, discusses a structured approach for dealing with chronic problems; Section 4, The Quality Control Process, presents a structured approach for sporadic problems.

For organizations that do not have a formal effort to reduce chronic and sporadic problems, operations managers often spend 30 percent of their time on troubleshooting; for the supervisors reporting to these managers, the time consumed frequently exceeds 60 percent.

Responsibility for Troubleshooting.   While Operations Department responsibility for troubleshooting is fairly clear, the ability to carry out this responsibility varies. The main variables are the *complexity* of the adverse change and the *extent* to which operations personnel are trained in the tools of diagnosis.

A complex adverse change can require an extent of data collection and analysis that goes beyond the training and experience of operations personnel. This same complexity also can require extensive time for data collection and analysis—time that is not available to Operations Department supervisors.

In such complex cases, a team approach may be needed. The team is usually drawn from the following:

Operations personnel to supply theories and authorize data collection

Technicians to carry out data collection

Diagnosticians to design the data plan and to analyze the subsequent data

"Outsiders" as the needs arise

The responsibility for creating such a team rests with the Operations Department.

The trend is to train operations personnel to become self-sufficient in troubleshooting. If non-supervisors are trained to do troubleshooting within their own work areas, the supervisors will have more time to participate on the cross-functional project teams that typically are needed for chronic troubles. The training needed is common to that needed by operations personnel for dealing with quality problems generally. The problem-solving training provided to quality teams is useful (see Section 5, under The Diagnostic Journey). At each step of the journey, the tools and techniques mentioned are candidates for training topics.

SELF-INSPECTION

Once goods or services have been produced, there arises the question: Do they conform to specification? In manufacturing industries, the activity to determine conformance is called *inspection* or *test* (see Section 23, Inspection and Test). In the service sector, typical terms used are *checking, examination, review,* and *reconciliation.*

In the manufacturing sector in the United States, the responsibility for making the conformance decision often rests with full-time inspectors in an independent Inspection Department but this is changing fast to in-process inspection by the worker with an audit inspection by an independent inspector. In the service sector, output is checked by the person creating the output, and typically no independent check occurs. Often the only independent check is by the customer (internal or external).

Under the concept of self-inspection, the worker who made the product also measures the product and decides whether it conforms to specifications. (Special or complex tests are performed by a separate department.)

Note that the worker is *not* given the responsibility for determining the disposition of any non-conforming product. Also, self-inspection does *not* involve transfer of full-time inspectors to the Production Department. It involves abolishing the jobs of full-time inspectors and having the inspection done on a part-time basis by the production workers. Provision is made for an audit (see below under Audit of Decisions).

Self-inspection has decided advantages over the traditional delegation of inspection to a separate department:

1. Production workers are made to feel more responsible for the quality of their work.

2. Feedback on performance is immediate, thereby facilitating process adjustments. Traditional inspection also has the psychological disadvantage of using an "outsider" to report the defects to a worker.

3. The costs of a separate Inspection Department can be reduced.

4. The job enlargement that takes place by adding inspection to the production activity of the worker helps to reduce the monotony and boredom that are inherent in many jobs.

5. Elimination of a specific station for inspecting all products reduces the total manufacturing cycle time.

The current emphasis on downsizing in organizations, coupled with the benefits of self-inspection, has resulted in pressures to reduce the size of inspection departments in manufacturing. Sometimes the reduction in independent inspection activities has been premature.

Criteria for Self-Inspection.   Before self-inspection can be adopted, some essential criteria must be met:

1. Quality is the number 1 priority within an organization. If this is not clear, the worker may succumb to schedule and cost pressures and classify as acceptable products that should be rejected.

2. There is mutual confidence between managers and workers. Managers must have sufficient confidence in the work force to be willing to entrust to them the responsibility of deciding whether the product conforms to specification. In turn, workers must have enough confidence in management to be willing to accept this responsibility.

3. The criteria for self-control are met. Failure to eliminate the management-controllable causes of defects suggests that management does not view quality as a high priority, and this may bias the workers during inspections.

4. Workers are trained to understand the specifications and perform the inspection. In some companies, "certification" (for making product conformance decisions) is issued only to those workers who demonstrate their competence.

5. Specifications are unequivocally clear.

6. Workers understand the use that will be made of the products (internally and externally) in order to grasp the importance of a conformance decision.

7. The process permits assignment of clear responsibility for decision making.

Several references provide elaboration on these criteria: Ziegler (1995) discusses six elements common to successful self-inspection; Whittingham (1987) explains some implementation details, including use of a "work conditions questionnaire" (to evaluate the criteria of self-control) and the importance of feedback to workers.

Sequence for Instituting the Self-Inspection Concept. The many benefits of self-inspection suggest that steps be taken to successfully apply it broadly. However, the criteria listed above are not easy to meet. In practice, it is unlikely that the criteria could be met for all products, all operations, and all personnel. It is best to apply the concept only to products and processes that are stabilized and meet product specifications and to personnel who have demonstrated their competence.

This competence can be verified by a trial period during which workers make conformance decisions while duplicate decision making is done by inspectors. The purpose of this duplication is to discover, through data, which workers consistently make good product-conformance decisions.

Audit of Decisions. During the trial period, the inspection is conducted for two purposes:

1. Product approval, lot by lot

2. Comparison of inspector results with worker results

As the comparison establishes validity of the worker's decisions, the duplicate inspections are reduced in frequency until their prime purpose is to determine whether the worker continues to make good decisions (hence the name *audit of decisions*). At this stage, any knowledge of the product is incidental. If an audit reveals that wrong decisions were made by the workers, then the product evaluated since the last audit is suspect and must be investigated.

Results of Self-Inspection. In a coning operation of textile yarn, the traditional method of inspection often resulted in finished cones sitting for several days in the inspection department, thereby delaying any feedback to production. Under self-inspection, the worker received immediate feedback and could more promptly get machines repaired and setups improved. Overall, the program reduced nonconformities from 8 to 3 percent. An audit inspection of the products that were classified by the workers as "good" showed that virtually all of them were classified correctly. In this company, workers also can classify product as "doubtful." In one analysis, worker inspections classified 3 percent of the product as doubtful, after which an independent inspector reviewed the doubtful product and classified two-thirds of it as acceptable and one-third as nonconforming.

A pharmaceutical manufacturer employed a variety of tests and inspections before a capsule product was released for sale. These checks included chemical tests, weight checks, and visual inspections of the capsules. A 100 percent visual inspection traditionally had been conducted by an Inspection Department. Defects ranged from "critical" (e.g., an empty capsule) to "minor" (e.g., faulty print). This inspection was time-consuming and frequently caused delays in production flow. A trial experiment of self-inspection by machine operators was instituted. Operators performed a visual inspection on a sample of 500 capsules. If the sample was acceptable, the operator shipped the full container to the warehouse; if the sample was not acceptable, the full container was sent to the Inspection Department for 100 percent inspection. During the experiment, both the samples and the full containers were sent to the Inspection Department for 100 percent inspection with reinspection of the sample recorded separately. The experiment reached two conclusions: (1) the sample inspection by the operators gave consistent results with the sample inspection by the inspectors, and (2) the sample of 500 gave consistent results with the results of 100 percent inspection.

The experiment convinced all parties to switch to the sample inspection by operators. Under the new system, good product was released to the warehouse sooner, and marginal product received a highly focused 100 percent inspection. In addition, the level of defects *decreased.* The improved quality level was attributed to the stronger sense of responsibility by operators (they themselves decided if product was ready for sale) and the immediate feedback received by operators from self-inspection. However, there was another benefit—the inspection force was reduced by 50 people and these 50 people, were shifted to other types of work, including experimentation and analysis activities on the various types of defects. Inspectors became analysts.

Schilling (1994) provides a sobering explanation of the importance of inspection and its relationship to acceptance sampling, acceptance control, and process control.

In the service sector, relatively little use is made of full-time independent personnel who check work output. Workers check their own work, with perhaps a sampling check by a supervisor. Thus an operations supervisor in a bank money transfer department spends about 1.5 hours a day in 10-minute segments going from clerk to clerk and examining the last piece of work completed, and a housekeeping supervisor in a hotel samples a number of rooms to verify the quality of the work performed by the maids.

The lack of extensive checking and inspection activity in the service sector certainly does not mean that all output conforms to service requirements or goals. Particularly in backroom activities, service processes have many rework loops. One example of extensive rework is the department of 32 people in a regional office of a utility. The sole purpose of this department is to detect errors in internal billing charges received from other units of the company. The budget of this department can easily be justified by the savings achieved in detecting the errors. Two obvious questions are (1) Was there any form of inspection by those who generated the charges? and (2) Are there any plans to prevent these errors?

AUDIT OF OPERATIONS QUALITY

A *quality audit* is an independent evaluation of various aspects of quality performance for the purpose of providing information to those in need of assurance with respect to that performance. Application to manufacturing has been extensive and includes both audit of activities (systems audits) and audit of product (product audit). For products (e.g., medical, financial) that are subject to government regulations, audits are often concerned with compliance to these regulations.

Systems Audit.   Systems audits (sometimes called *process audits*) can be conducted for any activity that affects the final quality of goods or services. The audit is usually made of a specific activity against a specific document, such as process operating instructions, employee training manuals, certification of personnel for critical operations, and quality provisions in purchasing docu-

ments. The checklists presented earlier in this section for the three criteria of self-control can suggest useful specific subjects for audits. Priority is assigned to subjects that affect customer satisfaction. Adherence to existing procedures is often emphasized, but systems audits often uncover situations of inadequate or nonexistent procedures.

Peña (1990) explains an audit approach for processes. Two types of audits are employed: engineering and monitor. The *engineering process audit* is conducted by a quality assurance engineer and entails an intense review of all process steps, including equipment parameters, handling techniques, and statistical process control. Table 22.15 shows the audit checklist. The *monitor process audit* is conducted by a certified auditor; it covers a broad range of issues, e.g., whether specifications are correct and whether logs are filled in and maintained. Discrepancies (critical, major, or minor) are documented and corrective action is required in writing. Critical defects must be corrected immediately; majors and minors must be resolved within 5 working days.

McDonald's Corporation conducts a system evaluation of restaurants using visits (announced and unannounced) by a trained consultant. The evaluation includes quality, service, cleanliness, and sanitation. Highly detailed audit items include numerical standards on food-processing variables. Key questions for the overall systems evaluation cover training, ordering, scheduling, production control, equipment, and leadership. An overall grade (A, B, C, or F) encompasses operational standards and customer expectations.

A major airline employs audits to evaluate service in three areas: airport arrival and departure, aircraft interior and exterior, and airport facilities. Forty-seven specific activities are audited periodically, and then performance measurements are made and compared with numerical goals. Two examples on the aircraft are the condition (appearance) of carpets inside the planes and the adhesion of paint on the planes.

Dedhia (1985) describes an audit system for an electronics manufacturer. The audit consists of 14 subsystems each having an audit checklist. Routine audits are performed by quality audit personnel on a scheduled basis. For selected activities, annual audits are conducted by a team from

TABLE 22.15   Audit Checklist

---

1. Is the specification accessible to production staff?
2. Is the current revision on file?
3. Is the copy on file in good condition with all pages accounted for?
4. If referenced documents are posted on equipment, do they match the specification?
5. If the log sheet is referenced in specifications, is a sample included in the specification?
6. Is the operator completing the log sheet according to specifications?
7. Are lots with out-of-specification readings authorized and taken care of in writing by the engineering department or the proper supervisor?
8. Are corrections to paperwork made according to specification?
9. Are equipment time settings according to specifications?
10. Are equipment temperature settings according to specification?
11. Is the calibration sticker on equipment current?
12. Do chemicals or gases listed in the specification match usage on line?
13. Do quantities listed in the specification match the line setup?
14. Are changes of chemicals or gases made according to specification?
15. Is the production operator certified? If not, is this person authorized by the supervisor?
16. Is the production operating procedure according to specification?
17. Is the operator performing the written cleaning procedure according to specification?
18. If safety requirements are listed in the specification, are they being followed?
19. If process control procedures are written in the specification, are the actions performed by process control verifiable?
20. If equipment maintenance procedures are written in the specification, are the actions performed verifiable? according to specification?

Source: Peña (1990).

Manufacturing, Quality Engineering, Test Engineering, Purchasing, and other departments. The system includes a numerical audit rating based on classifying each discrepancy as major or minor. A rating below 90 percent requires an immediate corrective action response. Craner (1994) explains how managers (and others) conduct audits at a medical device firm. Lane (1989) relates how a micro-electronics firm reduced redundant inspection and shifted the resources to a defect-prevention effort that included audits of broad systems, individual process, and products.

Who Performs the Audits?   There are several categories of personnel to whom systems audits may be delegated:

Production Management: In this situation, the middle or upper operations managers undertake the audit of execution versus plan. Because most production activities are highly visible, skilled observers can learn much from shop tours. Generally, operations managers possess these skills and, in addition, put a high value on direct observation.

Inspectors: Some inspections are conducted not to measure the product but to observe the process (see, for example, Section 23, under Patrol Inspection). Such observations are themselves a review of execution versus plan. It is often feasible to extend these patrol inspections to review other aspects of execution.

Independent auditors: For critical work, the auditing preferably should be done by those who are not a part of the Inspection Department. Usually such auditors review the practices of inspectors as well as production workers.

The independent audit tends to be more completely planned than an audit by operations management or by inspectors. In addition, the entire concept of the independent audit has the support of upper management, which receives the audit reports for review. For further discussion, see Section 11, under Quality System Certification/Registration.

A self-audit and an independent audit can be combined to provide a two-tier audit each with an audit plan, execution, and report. Advantages include using the expertise of the person responsible for the activity, ensuring objectivity with an independent auditor, and minimizing some of the human relationship issues. The aim of both the self-audit and the independent audit is to build an atmosphere of trust based on the reputation of the auditors, the approach used during the audit, and an emphasis on being helpful to the activity audited.

There are two trends in auditing worth noting. First, the scope of audits often goes beyond determining compliance with specific procedures and requirements to include broader issues such as the effectiveness, efficiency, and adaptability of processes (see Section 6, Process Management). Second, audits increasingly emphasize helping operational areas to meet customer expectations and needs. Myers and Heller (1995) provide an illustration of how the broader scope (modeled after the Baldrige Award) helps to align business processes with customer needs and also recognize employees' efforts. Audits having a broad companywide scope are often called *assessments*.

The audit of decisions discussed previously requires a regular examination (product audit) of product conformance along with the associated documentation. This cannot be done readily by the independent auditors who are on the scene so infrequently. Instead, it is assigned to a special category of auditor created at the time of delegating conformance decisions to production workers.

Product Audit.   This form of audit provides information on the extent of product conformance to specification and fitness for use. For elaboration, see Section 11.

OVERALL QUALITY MEASUREMENT IN OPERATIONS

The management of key work processes must include provision for measurement. In developing units of measure, the reader should review the basics of quality measurement discussed in Section 9, Measurement, Information, and Decision Making.

Table 22.16 shows examples for manufacturing activities and for backroom operations in the service sector. Note that the measurements cover both output from operations and input to operations. Also note that the examples include early indicators, concurrent indicators, and lagging indicators of performance.

The units in Table 22.16 become candidates for data analysis using statistical techniques such as control charts. More important, the selection of the unit of measure and the periodic collection and reporting of data demonstrate to operating personnel that management regards quality as having priority importance. This helps to maintain a focus on improvement, which we will discuss below.

Many control subjects for quality measurement are forms of work output. In reviewing current units in use, a fruitful starting point is the measure of productivity. *Productivity* is usually defined as the amount of output related to input resources. Surprisingly, some organizations still mistakenly calculate only one measure of output—the total (acceptable *and* nonacceptable). Clearly, the pertinent output measure is that which is usable by customers, *acceptable output*).

MAINTAINING A FOCUS ON CONTINUOUS IMPROVEMENT

Historically, the operations function always has been involved in troubleshooting sporadic problems (see above under Troubleshooting). As chronic problems were identified, these were addressed using various approaches, such as quality improvement teams (see Section 5, The Quality Improvement Process). Often the remedies for improvement involve quality planning or replanning (see Section 3, The Quality Planning Process). These three types of actions are summarized in Table 22.17.

Global competitive pressures and other forces will result in an even stronger emphasis on improvement. Continuous improvement in the future will need to

1. Draw on many sources of information to identify improvement opportunities that go beyond nonconformance to specifications. These sources of information include studies on the cost of poor quality (see Section 8, Quality and Costs), market research on customer satisfaction and loyalty (see Section 18, Market Research and Marketing), assessments of quality culture (see Section 15, Human Resources and Quality), and broad assessments using, for example, Baldrige Award criteria (see Section 14, Total Quality Management).

2. Address process improvement in terms of effectiveness, efficiency, adaptability, and cycle time (see Section 6, Process Management).

TABLE 22.16 Examples of Quality Measurements in Operations

Quality of output from operations
Percentage of output meeting specifications at initial inspection ("first-time yield")
Percentage of output meeting specifications at intermediate and final inspections
Amount of scrap, rework (quantity, cost, percentage, etc.)
Percentage of invoices returned due to errors
Average cycle time to fill customer orders for products or documentation
Warranty and adjustment costs due to errors in operations
Overall measure of quality (defects per million, weighted defects per unit, variability in units of standard deviation, etc.)

Quality of input to operations
Percentage of incoming material meeting specifications
Percentage of incoming data that is complete and error-free
Amount of downtime of manufacturing equipment, computer systems, and other support equipment
Percentage of critical operations with certified employees
Percentage of specifications or process instructions requiring changes after release

TABLE 22.17 Three Types of Action

Type of action to take	When to take action	Basic steps
Troubleshooting (part of quality control)	Performance indicator outside control limits Performance indicator in clear trend toward control limits Performance indicator normally meets target but does not now Process indicator outside target range or control limits Process indicator trend toward target or control limits	Identify problem Diagnose problem Take remedial action
Quality improvement	The control limits are so wide that it is possible for the process to be in control and still miss the targets Performance indicator frequently misses its target	Identify project Establish project Diagnose the cause Remedy the cause Hold the gains
Quality planning	Many performance indicators for this process miss their targets frequently Customers have significant needs that the work product does not meet	Establish project Identify customers Discover customer needs Develop product Develop process Design controls

Source: Adapted from Juran Institute (1995, pp. 5–7).

3. Pursue radical forms of improvement ("re-engineering") in addition to incremental forms (see Section 6, Process Management).

4. Effectively and quickly capture, share, and take action on experience-based information. A fast-food firm is creating an "intellectual network" of computer bulletin boards of information that include best practices information. Personnel will be able to use the system 24 hours a day, 7 days a week. Rethmeier (1995) explains how an alliance of 300 hospitals uses a "learning center" to create and transfer knowledge for continuous improvement. See also the *Harvard Business Review* (September–October 1994) for a special section on "regaining the lead in manufacturing." This section is based on a 4-year study of 20 development projects and identifies 7 elements of learning (core capabilities, guiding vision, organization and leadership, ownership and commitment, "pushing the envelope," prototypes, and integration).

5. Apply all the tools of improvement—technical and behavioral, simple and sophisticated. Increasingly, savings from improvement projects have "skimmed the cream off the top." The next round will require deeper analysis.

Many sections of this handbook present both methodologies and case examples on quality improvement; see particularly Section 5, The Quality Improvement Process, and Section 45, Statistical Process Control. The general literature is replete with examples from operations in virtually every industry. For examples in manufacturing see Kitamura et al. (1994) for a discussion of the Toyota production system; also, Hays and Gander (1993) explain how yield and turn-around time were improved on a printed circuit board production line. For examples in the service sector, see Aubrey and Gryna (1991) to learn about the experiences of over 1000 quality teams at a bank; also, Anderson et al. (1995) describe experiences (including advantages and disadvantages) in applying computer simulation to achieve improvement in claims processing and other activities in a health insurance firm.

QUALITY AND OPERATIONS CULTURE

For an organization to become superior in quality, it needs an unusual marriage:

1. Technologies to create products and processes that meet customer needs. Part of this is the design of individual jobs (that meet the criteria of self-control).
2. A culture throughout the organization that continually views quality as a primary goal. Quality culture is the pattern—the emotional scenery—of human habits, beliefs, and behavior concerning quality. Designing and maintaining jobs to meet the criteria of self-control are essential prerequisites to achieving a positive quality culture.

Some companies have a strong—but negative—quality ethic. Examples are legion: hide the nonconforming product, e.g., bury the rejected paint in the ground; and finesse the inspector, e.g., keep producing defective product and wait until an inspector discovers the situation. Such negative actions are often taken in order to achieve other objectives such as production quotas. To build a strong quality culture requires two steps: (1) collect information to determine the present quality culture and (2) take the steps necessary to change the culture.

Determining the Quality Culture.   Learning about the present quality culture in a firm can be accomplished by a carefully planned attitude survey on quality for various levels of operations supervision and the work force. However, be prepared for some sobering results. For a general discussion of quality culture, see Section 15. For a discussion of the results of a survey (20 questions) given to both American and Russian factory workers, see Pooley and Welsh (1994). Yavas and Burrows (1994) used 33 questions to compare the attitudes of American and Asian manufacturing managers on quality. Tabladillo and Canfield (1994) describe a 25-question survey employed at a hospital. Turner and Zipursky (1995) describe a survey of 20 questions that measure "employee commitment." The analysis of the results made use of several tools, including cause-and-effect diagrams, analysis of means on performance versus importance of factors, regression analysis, interrelation digraph, and quality function deployment. The road to developing a positive quality culture is lengthy and difficult—though essential for survival. The general approach of Section 15 to organizing for quality, the manager's role, and so on is germane to quality culture.

Changing the Quality Culture.   Developing a positive quality culture involves five key elements [for elaboration, see Juran and Gryna (1993, Chap. 8)]:

1. Create and maintain an awareness of quality. This means we must create and disseminate information on our current status of quality. The message must go to upper management, middle and lower management, and all other personnel—using languages that fit each territory.
2. Provide evidence of management leadership on quality. This is not only cheerleading but serving on a quality council, doing strategic planning for quality, providing resources for quality, and doing a host of other tasks to plan and deploy quality goals.
3. Provide for self-development and empowerment. This includes designing jobs for self-control, selection and training for jobs, organizing work using approaches for self-development such as self-managing teams, and encouraging personal commitment for quality.
4. Provide participation as a means of inspiring action. The forms of participation are almost endless: serve on a quality council, a quality circle, or an improvement team; be a process owner; take part in a product or process design review; or make presentations on quality.
5. Provide recognition and rewards. These expressions of esteem play an essential role in inspiring people on quality. Recognition takes the form of public acknowledgment for great performance on quality. Rewards are tangible benefits (salary increases, bonuses, promotions, etc.) for quality. Aside from these specifics, some countries that are moving toward democracy in the workplace

must address basic "quality of life" issues (e.g., clean bathrooms and other working conditions) before attempts at changing the quality culture will succeed.

Creating a positive culture is an important factor in building loyalty and retaining key personnel in operations. Reichheld (1993) explains the importance of loyal employees in achieving loyal customers.

SECTION 23
INSPECTION AND TEST[1]

E. F. "Bud" Gookins

---

[1]In the Fourth Edition, the material on inspection and test was prepared by Joseph J. Zeccardi.

INTRODUCTION

Inspection and testing activities always involve the evaluation of a characteristic as it relates to a specific requirement. The requirement can be in the form of a standard, a drawing, a written instruction, a visual aid, or any other means of conveying the characteristic specification.

Inspection and testing functions can be done automatically, manually, or both in a sequential manner. The evaluation process consists of the following steps applied to each characteristic (Juran 1945, p. 23):

1. Interpretation of the specification

2. Measurement of the quality of the characteristic

3. Comparing 1 with 2

4. Judging conformance

5. Processing of conforming items

6. Disposition of nonconforming items

7. Recording of data obtained

These steps apply to both product and service items.

The inspection and testing evaluation can be determined by using the intrinsic senses of the human being (i.e., smell, taste, sight, hearing, and touch), or it can be made using a nonvariable gage, a nonvariable electronic or laser instrument, a nonvariable chemical or physical testing device, or any other method in which a decision is made based on simply an "accept" or "reject" determination. Such inspection is commonly referred to as *attribute inspection.*

The inspection and testing evaluation that is determined by using any measurement device, be it mechanical, electronic, laser, chemical, or any other method that will display data generated by physically measuring the characteristic, in which a decision is made based on actual value readout, is commonly referred to as *variable inspection.*

The primary purpose of inspection and testing is to determine whether products or services conform to specification. This purpose is often called *acceptance inspection* and *acceptance testing.* The components of the inspection and testing function can be broken down further into subclassifications. The most salient are listed in Table 23.1.

People engaged full time in inspection work commonly carry the title of *inspectors* but often are recognized as product appraisers, product auditors, and product verifiers for organizations that produce a manufactured item. For organizations engaged in nonmanufactured goods or services, the

TABLE 23.1 Subclassifications for Manufacturing Products and Service

Type	Prime function
Receiving (or incoming) inspection and testing	To ensure that incoming product is not used or processed until it has been inspected or tested and found to be conforming to specified requirements
In-process inspection and testing	To ensure that in-process product is not moved forward until it has been inspected or tested and found to be conforming to specified requirements
Final inspection and testing	To ensure that finished component and/or product is not dispatched until all the activities have been satisfactorily completed
Layout inspection and functional testing	To ensure that all customer engineering material and performance standards have been appraised prior to production
Shipping inspection and testing	To ensure that all shipped products are conforming to specified requirements
Qualification inspection and testing	To judge the service capability of the product and the possible extreme applications of the product
Dock inspection and auditing	To ensure that the product and its testing (product-related packaging, identification, information, etc.) are released to the customer conforming to all requirements
Service inspection (health inspector, environmental inspector, etc.)	To ensure that all specified requirements are met and to evaluate and measure nonconformancies found in the system
Nonproduction inspection and testing	To evaluate a specific task requested by quality assurance i.e., gage repeatability and reproducibility, process capability, 100% appraisal, etc.
Initial sample inspection request (ISIR)	To assure the customer that the first production run will be in conformance with all their designated characteristics and to submit those actual characteristic measurements and attributes to the customer for verification and approval
Production part approval process (PPAP)	A request by the customer indicating the level of inspection to conduct first production run checking all characteristics and indicating actual dimensions, gage repeat-ability and reproducibility studies, capability studies, material verification, or any other outside processing; e.g., heat-treating, plating, etc., and submit to the customer for approval (used primarily by the auto industry)

inspection work is identified pertaining to that particular function, e.g., safety inspectors, environmental inspectors, health inspectors, etc. People engaged in part-time inspection work are commonly referred to by the title of their major activities, e.g., machine operators, setup people, assemblers, welders, platers, foundry people, etc. The people engaged full time in the testing function commonly carry the title of *tester* but often are recognized as assaying technicians, laboratory technicians, chemists, metallurgists, etc.

Today, many manufacturing organizations have moved toward total automated inspection and testing or semiautomated inspection or testing augmented by productive operation appraisal. Within this movement of proactive product acceptance, the inspection and testing become integrated into the operational function and verified usually by a new breed of inspectors called *audit inspectors.*

PURPOSE OF INSPECTION AND TEST

The purpose of inspection and test is to determine the conformance of the product or service to the standard or specific requirements and to disposition the product or service based on the results of the evaluation. This determination involves three main decisions (Juran and Gryna 1980):

Conformance decision: To judge whether the product conforms to specification

Fitness-for-use decision: To decide whether nonconforming product is fit for use

Communication decision: To decide what to communicate to outsiders and insiders

The Conformance Decision.   Except in small companies, the number of conformance decisions made per year is simply huge. There is no possibility for the supervisory body to become involved in the details of so many decisions. Hence the work is organized in such a way that the inspectors or production workers can make these decisions. To this end, they are trained to understand the products, the standards, and the instruments. Once trained, they are given the job of making the inspections and of judging conformance. (In many cases the delegation is to automated instruments.)

Associated with the conformance decision is the disposition of conforming product; the inspector is authorized to identify the product ("stamp it up") as an acceptable product. This identification then serves to inform the packers, shippers, etc. that the product should proceed to its next destination (further processing, storeroom, customer). Strictly speaking, this decision to "ship" is made not by the inspectors but by management. With some exceptions, a product that conforms to specification is also fit for use. Hence the company procedures (which are established by the managers) provide that conforming products should be shipped as a regular practice.

The Fitness-for-Use Decision.   In the case of nonconforming product, a new question arises: Is this nonconforming product fit for use or unfit? In some cases the answer is obvious—the nonconformance is so severe as to make the product clearly unfit. Hence it is scrapped or, if economically repairable, brought to a state of conformance. However, in many cases the answer as to fitness for use is not obvious. In such cases, if enough is at stake, a study is made to determine fitness for use. This study involves securing inputs such as those shown in Table 23.2.

Once all the information has been collected and analyzed, the fitness-for-use decision can be made. If the amount at stake is small, this decision will be delegated to a staff specialist, to the quality manager, or to some continuing decision-making committee such as a material review board. If the amount at stake is large, the decision usually will be made by a team of upper managers.

The Communication Decision.   Inspection and test serve two purposes: to make decisions on the products and to generate data that provide essential information for a wide variety of uses, such as those listed in Table 23.1. The conformance and fitness-for-use decisions likewise are a source of essential information, although some of this is not well communicated.

Data on nonconforming products are usually communicated to the producing departments to aid them in preventing a recurrence. In more elaborate data-collection systems there may be periodic summaries to identify "repeaters" or the "top 10," which then become the subject of special studies.

When nonconforming products are sent out as fit for use, there arises the need for two additional categories of communication:

1. *Communication to "outsiders":*   They (usually customers) have a right and a need to know. All too often the manufacturing companies neglect to inform their customers when shipping nonconforming products. This may be as a result of bad experience; i.e., some customers will seize on such nonconformances to secure a price discount despite the fact that use of the product will not add to their costs. Usually, the neglect indicates a failure even to face the question of what to communicate. A major factor here is the design of the forms used to record the decisions. With rare excep-

TABLE 23.2   Inputs Required for Fitness-for-Use Decision

Input	Usual sources
Who will be the user?	Marketing
How will the nonconforming product be used?	Marketing, client
Are there risks to human safety or structural integrity?	Product research and design
What is the urgency?	Marketing, client
What are the company's and the users' economics?	All departments, client
What are the users' measures of fitness for use?	Market research, marketing, client

tions, these forms lack provisions that force those involved to make recommendations and decisions on (a) whether to inform the outsiders and (b) what to communicate to them.

2. *Communication to insiders:* When nonconforming goods are shipped as fit for use, the reasons are not always communicated to the inspectors and especially not to the production workers. The resulting vacuum of knowledge has been known to breed some bad practices. When the same type of nonconformance has been shipped several times, an inspector may conclude (in the absence of knowing why) that it is just a waste of time to report such nonconformances in the first place. Yet in some future case the special reasons (which were the basis of the decision to ship the nonconforming goods) may not be present. In like manner, a production worker may conclude that it is a waste of time to exert any effort to avoid some nonconformance that will be shipped anyway. Such reactions by well-meaning employees can be minimized if the company faces squarely the question: What shall we communicate to the insiders?

PREPRODUCTION EVALUATION

The inspection and testing functions are key elements of the production process. Without accurate and specific criteria for determining that the manufacturing or service product meets the customer's requirements, we expose the organization to uncontrolled, inefficient, and expensive processing as well as negative perceptions from customers. These resulting performances can be minimized—if not eliminated—by preproduction and service evaluations.

The approach to inspection and test planning follows closely the principles of quality planning as set out in Section 3, The Quality Planning Process. Application of these principles to the inspection job has been studied extensively, and good tools are available to facilitate inspection planning.

The Nature of "Lots" of Product. It is useful here to define what is meant by *lot* and expand briefly on the term as applied to inspection and test. A *lot* is usually associated with physical product, especially in connection with sample inspection and test. Usually the product submitted for decision on conformance to standard consists of a lot. The true lot is an aggregation of product made under a common system of causes. When this ideal is met, the lot possesses an *inherent uniformity derived from the common system of causes.* The extent to which the lot conforms to this ideal greatly influences the approach to the product conformance decision and especially the kind and extent of sampling.

In its simplest form, the true lot emerges from one machine run by one operator processing one material batch, all under a state of statistical control, e.g., a single formulation of a drug product or a run of screw-machine parts turned from one piece of rod on one machine. A great deal of industrial production consists of true lots.

However, a great deal of other production consists of product mixtures that, in varying degrees, fall short of the ideal lot definition. Product made from several material batches, on several machines, or by several operators may be dumped into a common container. In shop language, this mixture is a "lot," but in more precise language it is only a "mixture." In continuous processes or in conveyor production, the process may well be common and constant, but the input materials may not be.

For precise and economic product conformance decisions, it is most helpful to *preserve the order.* This means that product is kept segregated in true lots or at least identified as to common cause. In addition, for those processes which exhibit a time-to-time variation or "drift" (e.g., the solution gradually becomes dilute. The tool gradually wears), preserving the order includes preserving the time sequence during which various portions of the lot were made. Any loss of order of manufacture also becomes a loss of some prior knowledge as to inherent uniformity. (See Section 22, Operations, under Process Capability: The Concept, Process Mixture, for a discussion of the effect of product mixture on process improvement, including application in services.)

Some products are naturally fluid and develop a homogeneity through this fluidity. Homogeneity from this new cause also can qualify the product as a true lot, with important implications for the sampling process.

When several true lots are combined for the purposes of acceptance, the combination is known as a *grand lot*. Such mixtures are very common, e.g., product from multiple cavities of molding operations or from multiple spindles of screw-machine operations. The two categories of single elements of product (e.g., discrete units and specimens) have their counterparts in two categories of lots.

The Lot as a Collection of Discrete Units.   Here the lot consists of numerous bolts, teacups, or refrigerators, each one of which is governed by the product specification. In batch production, the lot is usually determined by the obvious boundaries of the batch. In continuous production, the lot is usually defined as an arbitrary amount of production or as the amount produced during an arbitrary time span, e.g., a shift, a week.

The Lot as Coalesced Mass.   Here the lot also may consist of a batch, e.g., the melt of steel. In continuous production, the lot is again based on some arbitrary selection, e.g., 1 ton or a day's production.

The Inspection and Test Requirement Review.   Some organizations produce a standard or proprietary product that lends itself to very little change in configuration, materials, or processing, whereas some organizations are driven by ongoing changes or modifications to their products or services, and even some organizations are a "job shop" type, producing a product specifically to a customer's requirements and specifications. Regardless of the frequency or type of change to existing inspection and testing requirements, however, a review should be made prior to first production release or any subsequent revisions.

This review should examine any measurement parameter that would require special gaging and testing equipment that is different from that presently used as the method of measurement. It also should include any other input that would provide assurance that the customer's requirements will be met or that preproduction appraisal exceptions have been resolved.

The Inspection and Test Planner.   The planning can be done by anyone who understands the fitness for use of the product being inspected. Usually, however, the planning is done by a quality assurance staff planner, an inspection or test supervisor, and in some situations even the inspector or tester.

Where planning is done by a staff planner, it is recommended that his or her proposal be accepted by the inspection or testing supervisor before the plan becomes effective. The staff planner also is assigned a scope of responsibility within which to work. This scope determines which aspects of inspection or test planning are to be covered: inspection instructions, instrumentation, cost estimates, space and workplace design, documentation, etc. In large organizations, the planning is sometimes divided among specialists rather than being assigned by project. In smaller organizations, the planning may be done by the head of quality or assigned to an inspector or tester.

If the inspection or testing planning is service-oriented, it is usually conducted by the functioning individual conducting the inspection/testing or an immediate supervisor. If the inspection or testing planning is manufacturing-oriented, it is usually broken down into five categories:

1. Components completed within a single department, small series production—conducted by inspector/tester.

2. Components completed within a single department, large series production—conducted by inspection/testing supervision.

3. Simple components and services, purchased or in-house heat-treating, plating, casting—conducted by inspection/testing supervision.

4. Complex units, small series production (machine tools)—conducted by inspection/testing supervision.

5. Components produced by multiple department progression, subsystem test, or interdepartment units—conducted by quality planner.

Developing the Inspection and Test Plan.   For each inspection station, the planner lists the quality characteristics to be checked. To determine these, the planner considers the various sources of pertinent product information:

- The needs of fitness for use
- The product and process specifications as published by the engineers
- The customer's order, which references the product specification but may call for modifications
- The applicable industry standards and other general-use sources

For test stations, the planner must consider the functional and reliability parameters, such as

- The industrial standards
- Third-party requirements
- Application environments
- Customer expectations

For the service application, the planner must consider the characteristic criteria for the checklist method of evaluation, such as

- The needs of the customer
- Service industry standards
- The objectives and goals of the organization.

The specification information is seldom sufficient for the inspector/tester to meet the realities to be faced. The inspector/tester planner can help to bridge this gap in several ways:

1. *Clear up the meaning of the words used.*   Terminology for describing sensory qualities is often confusing. In one company, the term *beauty defects* was used generally to describe blemishes on the products. Some of these blemishes (scratches in the focal plan of an optical instrument) made the product unfit for service. Other blemishes, though nonfunctional, could be seen by the customers and were objectionable for aesthetic reasons. Still other nonfunctional blemishes could be seen by the company inspectors but not by consumers. However, because the multiple meanings of the term *beauty defect* had not been clarified, the inspectors rejected all blemishes. Data analysis showed that most of the blemishes were both nonfunctional and nonoffensive to customers. Hence new terminology was created to make the distinctions needed to describe the effect of blemishes. The clarification of terminology improved yields and opened the way to improvement in manufacturing processes as well. [Based on the consulting experience of J. M. Juran. For some added examples, see Juran (1952).]

2. *Provide supplemental information.*   Make it available on matters for which the specification is vague or silent, e.g., workmanship. Usually this can be done for entire commodity or component classes, with minimum individual analysis. The greatest needs for supplemental standards arise in new and rapidly changing technology; in such cases it is common to find that vague standards are provided to the inspectors. Vague standards create confusion among departments as well as among companies. Refer to Miller (1975) for a discussion on specifying test methods and specifications.

3. *Classify the characteristics for seriousness.*   This will help place the emphasis on the most important features of the product. (See Seriousness Classification, later in this section.) In the case of process characteristics, make use of the concept of dominance, as discussed in Section 22, Operations, under Planning Process Control.

4. *Provide samples, photographs, or other reference aids.*   This will help explain the meaning of the specification. The greatest single need is for visual standards (see below).

Inspection and Test Equipment.   Each product type requires a review of the gages and test equipment required prior to production. Many specifications can be satisfied in the inspection or testing

appraisal using standard inspection and testing equipment. However, some characteristics require gaging and testing equipment that must be designed specially. The planner must make this decision and schedule the equipment prior to production. The preproduction assessment should be verified prior to production release, and any discrepancy should be corrected immediately, before first-piece acceptance.

Inspection and Test Locations.   Inspection and test stations usually are placed

At movement of goods between companies, usually called *supplier inspection or test*

Before starting a costly or irreversible operation, usually called *setup inspection*

At movement of goods between departments, usually called *process inspection* or *process testing*

As an integration of automatic inspection or testing within the process

On completion of the product, usually called *finished-goods inspection* or *final-product testing.*

For complex products, acceptance may require tests of mechanical compatibility, electrical mating, product performance under specified environmental conditions, and final configuration. These are usually called *systems tests.*

These general rules do not decide all questions of inspection and test stations. Complex supplier relations may require an inspection location at the supplier's plant. Some process operations may require a "station" from which the inspector patrols a large area. Other process operations may be sufficiently well in hand that no inspection stations are used between departments; instead, there is a station after completion of all operations. In assembly lines, inspection stations may be located on the line as well as at the end of the line. In still other situations there may be an added station after packing or at the customer's premises.

For each inspection location, instruct the inspector (or tester) what to inspect for and how to do it:

Just what the mission of that inspection or test station is, i.e., which qualities to check

How to determine whether a unit of product conforms to standard or not

How to determine whether a lot of product is acceptable or not (*lot criteria*)

What to do with conforming and nonconforming products

What records to make

While these categories of instruction are quite similar from one job to another, the degree of detail varies enormously.

In allocating the inspection work among the various inspection stations, the planner should be alert to the presence of "self-policing" operations. Some oversize parts will not enter tools or fixtures for further processing or cannot be assembled. Some parts are subjected to greater stresses during manufacture than during use. Some electrical circuit tests identify deficient components. Oil-pressure tests identify some undersize parts. [Refer to Trippi (1975) for a discussion on the optimal allocation of inspection resources; Ballou and Pazer (1982) for the optimal placement of inspection stations; and Eppen and Hurst (1974) for the optimal location of inspection stations in multistage production processes.]

INSPECTION AND TEST DOCUMENTED INFORMATION

As products have developed in complexity and technological advances, consistent and repetitive information properly documented is essential. The ability to appraise the product or service item the same exact way each and every time is imperative if acceptance or rejection criteria are to be cogently and enforceably judged.

Inputs into the Control Plan.   The final results of inspection and test planning are reduced to writing in one of several ways.

Inspection and Test Procedure.   This is a tailor-made plan for a specific component or product type. It always lists the characteristics to be checked, the method of check (e.g., visual, gage, etc.), and the instruments to be used. It may, in addition, include the seriousness classification of characteristics, tolerances and other piece criteria, list of applicable standards, sequence of inspection operations, frequency of inspection, sample size, allowable number of defects, and other lot criteria, as well as inspection stamps to be applied.

Inspection and test procedures are widely used in industry. In companies making complex systems or undergoing frequent design changes, these procedures become very numerous and consume extensive staff resources to prepare them.

The planner also should be alerted to the need for locating inspection stations at such operations as materials handling, storage, packing, and shipping. The fact that the departments doing these operations are not a part of production is of no consequence if product quality is affected.

Aspects that may require inspection planning include

- *Internal handling:*   Use of correct containers and other handling facilities; product protection against corrosion, contamination, etc.
- *Internal storage:*   Adequate identity and traceability
- *Packing:*   Product identification, lot numbers, traceability; protection against adverse environments; protection against damage due to handling, shipping, and unpacking; presence of incidental small parts and information circulars
- *Shipping:*   Care in loading; special markings required by customers

Once the planner has prepared the procedure, the interested departmental supervisors can be convened to reach agreement on who is to carry out which part of the inspection plan.

Inspection Data Planning.   The planner also determines the data-recording needs for each inspection station. In many cases the standard inspection report forms will meet the recording needs. For finished products, a special test document is usually provided. In addition, the planner makes provision for any special recording needed for frequency distribution, control charts, certification, traceability, etc.

The concept of separating inspection planning from execution has great value if properly applied. If planning is underapplied, there is increased risk of catastrophic product failure. If overapplied, the result is excess cost and much internal friction. Striking a sound balance requires periodic reappraisal of the major forces in contention as well as analysis of the conventional alarm signals, e.g., rising staff costs or abrasion between departments. In addition, the changing job situations influence the extent of formal planning needed, notably (1) the education, experience, and training of the work force, (2) the stability of the processes, and (3) the severity of the product requirements.

Error-Proofing.   The planner faces two responsibilities related to inspection error: (1) avoiding built-in sources of error and (2) providing positive means of foolproofing the inspection against error. See, for a detailed discussion, Inadvertent Inspector Errors, under Inspection Errors, below.

Overplanning.   In some companies, the writing of inspection plans is done extensively. New customer orders, new product designs, new process changes, new regulations, and so on, are all occasions for scrutiny by the quality engineers, who issue inspection plans accordingly. As this goes to extremes, the cost of planning rises, and the excess formality increases the training time for inspectors, the attention to trivia, the documentation, and the control effort generally. Error rates tend to increase, with adverse effects on inspection costs and inspector morale.

Dealing with excess planning costs takes several forms. One technique is to do the planning by computer or by other means of mechanizing much of what the engineers otherwise do manually. A second approach is to minimize the amount of tailor-made planning by extending the use of inspection and test manuals that have broad application. See Instruction Manual, below.

A third approach is to delegate some of the planning itself to the inspection supervisors and the inspectors. To do this usually requires preparation of a manual on inspection planning plus training the inspection force to do the planning for all except the vital few characteristics, which are reserved for the staff planners. Still another device is to agree, case by case, on the amount of detailed planning needed.

Human, Machine, and System.

A major decision in all planning is the extent to which tasks will be assigned to people or to machines and the related decision regarding delegation of tasks to people or to systems. Machines are superior for doing deeds that can be clearly defined and which require exacting attention to repetitive detail.

Table 23.3 is a list contrasting intellectual activities and proposes a division between person and machine as applied to inspection and test. (See also Thompson and Reynolds 1964.)

The study of the interrelationship of people, machines, and system masquerades under a variety of names: human factors, biomechanics, human engineering, ergonomics, and industrial psychology. Industrial managers, including quality managers, are commonly amateurs in the understanding of human capacities and especially human behavior. The behavioral scientists are the "professionals," but the subject is as yet hardly a science. In addition, communication between the practicing managers and the behavioral scientists is severely limited by differences in dialect and, especially, cultural background.

Procedure Manual (Includes Flow Diagram)

The Flow Diagram.   The more complex the product, the greater is the need to prepare a flow diagram showing the various materials, components, and processes that collectively or sequentially turn out the final product. To prepare the flow diagram, the planner visits the various locations, interviews

TABLE 23.3   Assignment to Machines Versus People

Lower intellectual activities	Higher intellectual activities
Things that can be expressed exactly	Things that cannot be expressed exactly
Decisions that can be made in advance	Decisions that cannot be made in advance
Arithmetic, algebraic, and and chesslike symbolic logic	Pattern recognition, judgment, creativity, foresight, leadership, and such thinking
Highly repetitive and, therefore menial	Random, having many degrees of freedom, never exactly the same
Can be reduced to logic and therefore programmed exactly into a machine	Cannot be programmed exactly but can use heuristic approximations as an aid
Those a small machine can handle completely, faster and more positively	A machine cannot handle completely and it becomes excessively large and uneconomical in attempting to do so
Design and programming require a high level of intelligence but, once done, the mental activity need not be repeated	This problem is never exactly the same and it must be reconsidered, that is, rethought out for each new decision
Involves decisions as to what is right or wrong; the person guesses and the machine monitors to prevent him or her from making a mistake; it does this positively enough for use in safety systems	People use the display which is driven by the machine and possibly a separate computer to assist them in making the choice type of decisions as to what is best, using the most advanced mathematical techniques
Requires a high degree of orderliness	Takes care of matters which cannot be arranged into any sort of orderly procedures
Includes the decisions that must be made rapidly by the machine in periods of congestions and in emergencies	Involves situations that develop more slowly, that will, sooner or later, require a considered decision.

the key people, observes the activities, and records findings. The planner simplifies the picture by good use of symbols. One common set of symbols is

○	Operation	D	Delay
⇨	Transportation	∇	Storage
☐	Inspection	◻○	Combined activity

(See also Section 3, The Quality Planning Process, for another view of flow diagraming.) In addition, the planner prepares proposals for improvement, sends copies of the diagram to all concerned, and then is ready to convene them for discussion of the diagram and the proposals.

   Procedures for the inspection and testing activities to verify that specified requirements for the products are met are collected and organized in the inspection and testing procedures manual. A flow diagram should be incorporated into the procedure contents and should reflect the path the product takes and the types of inspection required along this path. Any changes to the procedures should be so noted by an ongoing document change system. All aspects of the throughput should be described in subsequent procedures with a clearly defined documentation trail back to the main or general procedure. Each organization should examine its flow diagram to determine if receiving, in-process (sometimes referred to as *patrol inspection*), final inspection (sometimes referred to as *finished-goods acceptance, dock auditing*), or special inspection (such as magnetic particle inspection, Zyglo, etc.) is applicable.

   It is not uncommon to incorporate the in-process inspection function within the responsibility of the operators or even to integrate it into the machine or process. If so, this consolidation also should be spelled out as a procedure.

Instruction Manual.   The instruction manual elaborates the work of each discipline in the inspection and testing functions, including detailed instructions on how to do specific work. The document should spell out the proper method of inspecting and/or testing and should be detailed as to how to fill out an inspection or test log, report, and any other record of data retention. All detailed information should be clearly defined, with the documentation trail extending bilaterally between the quality systems manual and the inspection and test instructions.

CRITERIA FOR INSPECTION AND TEST DEVELOPMENT

The factors for determining the methods and evaluation functions of appraising products or services are based on knowledge available from multiple sources.

Prior Knowledge of Product or Service Performance.   In some cases, the concept of "audit of decisions" has been put to work so that suppliers, independent laboratories, workers, and so on have been qualified as able to give reliable product conformance decisions and in addition have accepted this very lot. In such cases, no further product inspection is necessary (beyond that inherent in "audit of decisions"). See, in this connection, Section 22, Operations, under Audit of Decisions.

Prior Knowledge of the Process.   To illustrate, a press operation stamps out 10,000 pieces. If the first and last pieces contain certain specified holes of correct size and location, it follows that the intervening 9998 pieces also carry holes of correct size and in the correct locations. Such is the inherent nature of press dies. In statistical language, the sample size is two pieces, and the number of allowable defects is zero. Yet despite the tiny sample size, this is a sound way to do the inspection for these characteristics in the example given.

The press example is rather simple. In more complex cases, there is need to measure process capability and to arrange specially to take the samples with knowledge of the order of production. One organized form of this is the conventional control chart method used for process control. For product conformance, the approach is less well organized.

Prior knowledge of the "process" as used here includes knowledge of the qualifications of the suppliers and workers who run the process. Workers who have qualified for licenses require less rigorous inspection of their work than operators who have not qualified. Suppliers who have established a record of good deliveries need not be checked as severely as suppliers who lack such a record.

Product Homogeneity.   When the product is a fluid, this fluidity contributes to homogeneity. The extent of this homogeneity can be established by taking multiple specimens and computing the dispersion (another form of study of process capability). The presence of uniformity through fluidity greatly reduces the need for random sampling and thereby greatly reduces the sample sizes.

Even when the product is a solid, the inspection planner should be alert to the possibility that it possesses homogeneity through former fluidity. For example, a centrifugal casting process was used to cast metal cylinders that were then destroyed during testing for strength. However, it was then found that the dispersion of several strength tests all made on one ring was not different from the ring-to-ring dispersion. This discovery made it possible to reduce the amount of product destroyed during test.

Economic Impact.   When it is important to allocate limited testing resources to those parts which cost the most to replace, unique testing strategies can be designed that use past test, line, and field history. [See Wambach and Raymond (1977) for a discussion of this application for reliability-critical parts.]

Input from Outside Inspection and Test Functions.   The "prior knowledge" does not automatically come to the inspection planner or the inspector. Some of this knowledge is already in existence as a byproduct of other activities and hence can be had for the procedural cost of retrieval. Other knowledge is not in existence and must be created by additional effort. However, this added effort is usually a one-time study, whereas the benefits then go on and on.

THE DEGREE OF INSPECTION AND TESTING NEEDED

It is evident that a determination of "How much inspection?" should be made only after there has been an evaluation of the other inputs to product knowledge. This evaluation can then dictate any of several levels of inspection.

No Inspection.   There is already adequate evidence that the product or service conforms, and hence no further inspection is needed.

Skip Lot.   There is already adequate evidence that the product or service conforms, but because of the nature of the characteristics being checked or the customer's requirement for some type of verification, a need to spot check the lots in batches every so often is conducted. This skip lot will remain effective until a nonconformance occurs; then the inspection or test reverts back to lot sampling.

Sampling Plans.   Where there is little or no prior knowledge and no product fluidity, the main source of product knowledge becomes product inspection through *random sampling*. The amount of this inspection can be determined "scientifically" once the tolerable level of defects in accepted product has been defined clearly. However, choice of these levels—using the sampling parameters AQL (acceptable quality level), AOQL (average outgoing quality level), etc.—is largely arbitrary

and usually is determined by negotiation. In theory, the sampling parameters can be determined from economic considerations, i.e., the cost of detecting unsatisfactory lots versus the cost of failing to detect them. In practice, the "cost of detecting" is fairly easy to determine, but the cost of "failing to detect" is difficult to determine. For intangibles such as customer goodwill, there is no way known to make the determination with any useful precision.

One Hundred Percent Inspection and Test.   This alternative is usually used for final test of critical or complex products. In very critical cases, it is used to provide redundancy against the unreliability of 100 percent inspection. In these cases the amount may be 200 percent or over. In cases where "zero defects" constitute the objective or requirement, 100 percent automated inspection is required. [See Nygaard (1981) and the discussion on machine-vision systems later in this section.] In some cases, 100 percent inspection is required to satisfy legal or political requirements (Walsh 1974). In other cases, 100 percent inspection is the most cost-effective approach. [See Walsh et al. (1976) and (1978) for examples where 100 percent inspection is the cost-effective alternative in high-volume production and in testing hardness of finished steel wheels.]

One hundred percent inspection also may be used when process capability is inherently too poor to meet product specifications. Sampling is of no avail in such cases, since the accepted lots are usually no better than the rejected lots, i.e., the difference is merely the result of statistical variations in the respective samples. This does not apply in cases where the process is highly erratic so that some lots are truly conforming and others are not merely the result of statistical accidents. For such processes, sampling can be a useful way to separate the conforming lots from the nonconforming ones.

Whatever the motivation for selecting the 100 percent alternative, effective implementation goes beyond choosing the inspection methodology or test equipment. Physical arrangements and personnel procedures must be changed. In many cases, attitudes of in-house and vendor personnel must be changed through reeducation. [See Walsh et al. (1979*b*).]

With the advent of computer-based testing, 100 percent inspection is becoming more practical (Schweber 1982). However, it is not clear that it is cost-effective in all cases, even if the technology is readily available (Walsh et al. 1979*a*). This is especially true if the total costs of quality are considered (Gunter 1983).

Check List Inspection.   Where there is not a hardware sort of product that requires an assessment of the dimension, appearance, or testing parameters, the main source of evaluation is the check list type. Such service industries as hotels, restaurants, banks, and health care require only evidence of compliance or no compliance to a specific standard.

OTHER TYPES OF CONFORMANCE INSPECTIONS

Faced with the objective to minimize inspection costs and achieve maximum quality control, management must be sensitive to nontraditional types of conformance decision-making inspections.

Simulation.   With advancement of the digital computer, system-simulation techniques are used as an alternative to the experimental or analytical approach (Wang et al. 1981). Examples of application:

   Receiving inspection simulation

   Printed circuit board assembly inspection simulation

   Camera subassembly and final inspection simulation

Automated Inspection and Test.   The first large-scale applications of automated testing were very likely done by the Western Electric Company during the 1920s. Current developments in

microcomputers, artificial intelligence (AI), integrated computer-aided manufacturing (ICAM), robotics, and software are making automated inspection practical and cost-effective. [See "An Outlook for 3D Vision" (1984) and "ASD's Quality Assurance Program Rates in Top 10" (1984); also see the discussion on 100 percent inspection above and that on Machine Vision, in Human Factors in Inspection, below.]

Automated inspection and testing are used to reduce costs, improve precision, shorten time intervals, alleviate labor shortages, and avoid inspection monotony, among other advantages. In some industries, the labor problems now seem insoluble in the absence of automated inspection. Already in widespread use, automated inspection is still expanding, with no end in sight.

The economics of automation involve a substantial investment in special equipment to secure a reduction in operating costs. The crux of justifying the investment lies in the amount of repetitive work the equipment will be called on to perform. This estimate of the anticipated volume of testing therefore should be checked out with great care.

A common starting point in discovering opportunities for automated inspection is to make a Pareto analysis of the kinds of inspections and tests being conducted. The vital few types are identified. Estimates are then made of the personnel, costs, and other current problems associated with these tests. The economics of automation are then estimated, and the comparable figures are an aid in deciding on the feasibility of successful conversion. For complex equipment involving depot storage and field maintenance, the question of use of automated testing is itself highly complex and requires a tailor-made study of some magnitude.

Technologically, the "machine" poses many problems. It is less adaptable than the human being it replaces, so some changes may need to be made in the product to offset this rigidity. For example, the machine may hold the units to be tested by grasping certain surfaces whose dimensions were previously unimportant. Now these surfaces may need to be held to close dimensions because the machine is not as adaptable as the human inspector. Alternatively, the product design may need to be changed to provide for adequate location.

Beyond the work of original design, construction, and prove-in, the machine must be set up specially for each job. However, modular construction master test pieces and taped programs have considerably reduced setup time while improving reproducibility. Reliability generally has been high, and use of printed circuit cards and other modular components has so reduced the "mean time to repair" that downtime is generally below 5 percent for well-designed machines.

Automated gaging and testing are used extensively in the mechanical industries. They are also widely used in the electronics industries, especially for electronic components, where the problem of making connections to the automated test equipment is so severe that the original product design must provide especially for this.

In the chemical industries, the corresponding development has been the *autoanalyzer*. This already has made possible some extensive cost reductions and solutions of otherwise forbidding problems of recruitment of laboratory technicians. The autoanalyzer makes use of some equipment common to all tests—sensors, transducers, recorders, and computers. However, each type of analysis has its unique procedure for converting the material under test into a form suitable for sensing.

The rapid evolution from numerically controlled (NC) machines to computer numerical control (CNC) has brought with it related new technologies. Machines now available are capable of continuously informing the operator of the machine's state of adjustment. Specification data stored in the computer's database are compared with the continuous stream of workpiece measurements provided by the measurement sensors to warn the operator when an adjustment is needed and even, in some cases, make the adjustment automatically. This new control technology, with its programmable logic, simplifies the operator's task. In reducing the degree of nonconformance at the source and providing a richer stream of information for the inspector, it also holds the promise of reducing the volume of inspections necessary and making the inspector function much more reliable. Applying programmable logic to the control of tool cutter wear compensation makes possible longer tool life and products of higher grade and greater consistency.

These new CNC machines also can function in a "lights out" manufacturing setting, in which a single machine or machining cell can operate for long periods and many machine cycles without human intervention, like an airplane flying on automatic pilot. Technology now under development

will incorporate setup approval as an integral part of the setup process and then retain in memory a record of the setup as a mode of objective evidence documentation. Only when the setup is approved does the software release the machine for production; if the setup is rejected, the software does not respond to a "run" command. This technology will allow manufacturing organizations to create a totally paperless system and still meet the requirements of ISO 9000 standards.

As we move into the next century, we will see machines that will be programmed to react to voice recognition with output able to make tool adjustments automatically, without operator intervention. All these technologies will contribute to increased consistency and productivity; equally important, they will help to improve product quality as well.

There are many recent and successful stories of how automated gaging and testing have improved defect detection and product reliability and even reduced the overall cost per unit of inspection and reject rate. Usually custom-built and highly engineered, these automated systems are best suited for application where certain conditions exist:

- Steady production output
- History of process control
- History of low reject rate
- Where products need individual appraisal

Automated inspection and test may be categorized into five main types: postprocess gaging, in-process gaging, testing, inspection, and assembly and test systems (Quinlan 1996). In all five types of inspection and testing, the automation or semiautomated concept provides high-confidence repeatability and a faster analytical mode that can be interfaced directly to a machine or process to display visually or audibly the statistical process variance above or below the control limits and signal the immediate need for process corrective action.

Strong advancements also have been made in high-speed visual inspection processes, where automated electronic inspection stations are either integrated or slightly off line from manufacturing operations. High-speed cameras capture the image displayed on a monitor, and in microseconds each part passing under the "eye" or segment of a continuous process automatically can undergo multi-characteristic checks. At the end of the inspection cycle, a computer monitor tells the operator if the part or strip passed. The monitor also can indicate why parts are rejected, while updating quality process statistics.

Prior inspection methods could spot only 85 to 90 percent of critical defects. With the new high speed visual automation, virtually all defects are caught. This advanced technology has resulted in increased productivity, reduced waste, and fewer defective parts passing through to the customer (Lincoln 1996).

Integrated Process Inspection and Test. More and more companies are developing inspection and/or testing equipment that can be integrated into the process directly. Instead of having to physically transport the part to the inspection station, certain characteristics or testing parameters can be evaluated directly on machine or process equipment. For example, one company integrated a measurement system comprising a standard gage linked to a statistical analyzer and coupled with some specially made fixturing. This method allowed the company to make an appraisal decision without having to spend abundant amounts of time on transporting the product to the inspection station and inspection time for setup. This cost savings can be realized in productivity gains by closing the gap between manufacturing and inspection. The shorter the time required for appraisal, the more time is available for production and the greater is the impact of generating larger amounts of quality product.

Specialty gaging and control monitoring equipment has been developed to integrate directly into certain types of machinery and sold as an accessory or an attachment to an existing machine. See, for example, Figure 23.1, which shows a process-control monitor integrated into a coldforming machine for continuous monitoring of process variation. If a force load value falls outside specified parameters, the instrument signals a shutdown of the machine, and only after a quality evaluation is

conducted and conformance is determined can the monitor be reactivated by the insertion of a key—usually under quality assurance ownership.

Computer-Aided Inspection.   The marriage of computer and inspector provides benefits to inspection in the form of (1) information or (2) assistance to enhance the conformance decision for almost any inspection situation, or both. The marriage of computers and inspectors takes the form of (1) providing information and/or (2) providing assistance to enhance the conformance decision for almost any inspection situation. This is especially applicable to inspecting precision machine parts and assembly inspection [see Holmes (1974) and Linn (1981) for further discussion]. The selective use of computer-aided inspection (CAI) techniques can minimize the more menial, repetitive inspection tasks and direct the human resource (the inspector) to preventive quality control.

Voice Entry.   Another unique enhancement of computer-aided technology is the voice data-entry system (VDES). VDES can be applied to incoming, in-process, and final inspection functions, as

FIGURE 23.1   Process control monitor.

well as some testing operations. Yet, somewhat embryonic in its applications, VDES will continue to develop in providing the inspection and testing desciplines with many practical benefits, such as

- Saving time by eliminating manual entry
- Reducing labor requirements
- Providing instantaneous response
- Accepting multiple languages and all speakers
- Allowing for remote control
- Permitting on-line, real-time control

Video Entry.   Video inspection techniques used to augment typical video applications called *Moiré contouring* are emerging as a viable method for inspection. Using an optical head with a projection system and camera, a monitor, and a computer equipped with an image-processing board, Moiré allows the operator to obtain a very dense collection of *X, Y, Z* measurements. This depth-information technology is used to find surface defects at various dimension and contours of the part.

The Moiré sensor has been used in several companies for visual enhancement of warping, to inspect hard-to-measure locations, and to examine other machining features with no sharp edges or lighting contrasts to define such shapes as bevels, tapers, etc.

Because Moiré fringe data are already separated into two dimensions (2D) and the depth information is encoded into a 2D line drawing, computer analysis is easier. Also, inspection applications let the manufacturer use the high-density *X, Y, Z* data to detect random part flaws and warpage, and the process can move from high-speed off-line inspection to high-speed on-line inspection and in-process control (see Kennedy 1996).

Optical Sensing.   Optical sensing also can be designed for some applications that may require greater sensing capabilities than would otherwise be possible. This optical scanning technology can measure dimensions by counting the number of beams blocked by an object passing through the scanned region.

Optical scanning systems typically consist of three components: a transmitter, a receiver, and a controller. The transmitter includes a series of light-emitting diodes (LEDs) in a linear array. The controller sequentially switches each LED to the "on" state in succession to generate a sequence of parallel beams of infrared light.

The receiver, with a corresponding linear arrangement of phototransistors, is modulated by the same controller (multiplexed) so that each phototransistor only detects light from its corresponding LED in the transmitter. When something changes the state of one of the receivers, the controller can generate an analog, parallel digital, or serial output (Strack 1996).

INSPECTION AND TESTING FUNCTIONS

Inspection functions are usually staffed by full-time inspectors or testers responsible to the Inspection Department. This is by no means universal. Some final inspection or test functions are staffed by full-time inspectors responsible to production. Many process inspection stations are staffed by production workers whose principal job is production.

Receiving (Incoming) Inspection and Testing.   The extent of inspection of products received from suppliers depends largely on the extent of prior planning for supplier quality control. In the extreme case of using surveillance and audit of decisions, there is virtually no incoming inspection except for identity. At the other extreme, many "conventional" products are bought under an arrangement that relies primarily on incoming inspection for control of supplier quality.

The inspectors and their facilities are housed in the receiving area to provide ready collaboration with other supplier-related activities, i.e., materials receiving, weighing, counting, and storage. Depending on the physical bulk and tonnage of product, entire shipments or just samples are brought to the inspection floor. The documentation routines provide the inspectors with copies of the purchase orders and specifications, which are filed by supplier name.

Inspection planning is conventional, as discussed under Inspection Data Planning above. However, there is usually a lack of prior knowledge of process capability, order of manufacture, etc. Consequently, the sampling plans involve random and (often) large samples, employing standard random inspection tables. Randomness becomes a severe problem in the case of large shipments, whether bulk or not. However, special arrangements can be made with the supplier. Setting acceptable quality levels (AQLs) has been a troublesome problem to such an extent that some industry standards have been worked up. In the absence of such standards, the AQLs are established based on precedent, past performance, or just arbitrarily. Then, as instances of rejection arise, the negotiations with vendors result in adjustment to the AQLs or other acceptable sampling criteria. Data feedback to vendors follows conventional feedback practice.

Process Inspection and Testing.   This commonly serves two purposes simultaneously:

1. *Provides data for making decisions on the product*; e.g., does the product conform to specification?

2. *Provides data for making decisions on the process;* e.g., should the process run or stop?

Because of the interrelation between process and product variables, process inspection involves observation of process variables as well as inspection of the product. These observations and inspections are made by both production and inspection personnel.

Product acceptance of work in process may be done in any of several stages or by a combination of them. These stages include the following.

Setup Inspection.   Some processes are inherently so stable that if the setup is correct, the entire lot will be correct, within certain limits of lot size. For such processes, the setup approval also can be used as the lot approval. Where a good deal is at stake, it is usual to formalize the setup inspection and to require that the process may not run until the inspector has formally approved the setup, e.g., by signing off, by stamping the first pieces, etc. (Garfinkel and Clodfelter 1984).

Patrol Inspection.   For processes that will not remain stable for the duration of the lot, it is usual to provide for periodic sampling to be conducted during the progression of the lot, making use of various techniques described in Section 24. The numerous plans in use consist mainly of variations of the following four types:

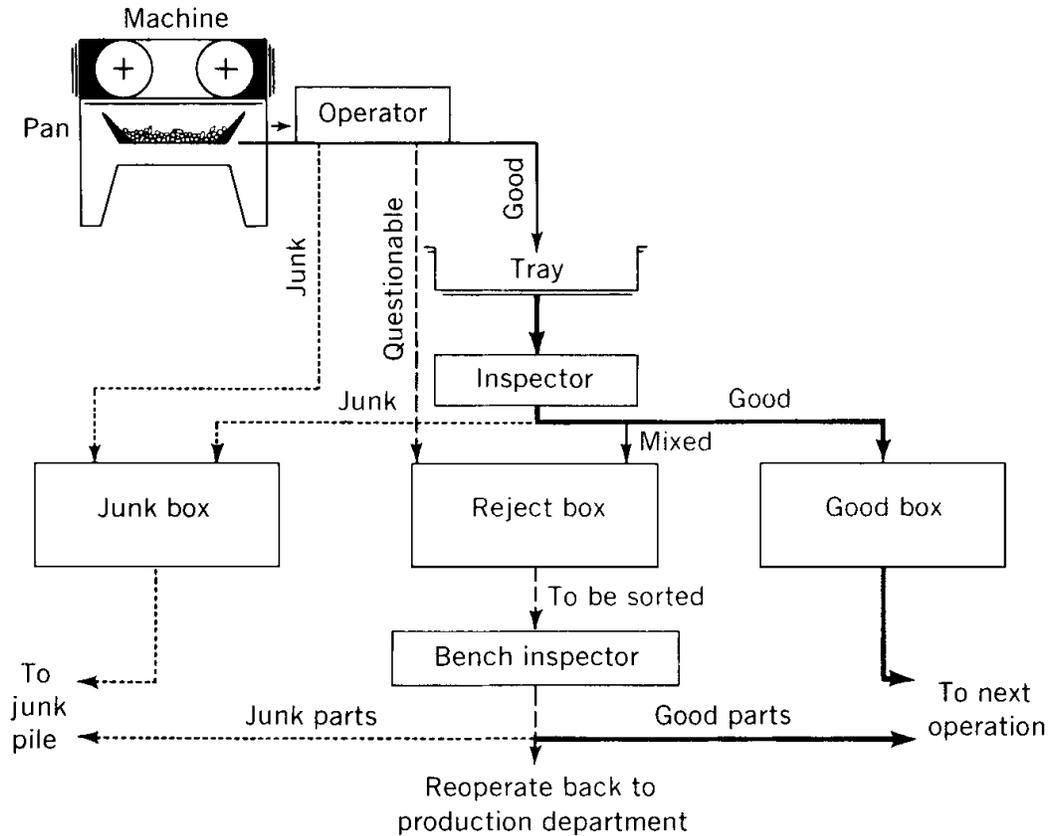
1. Preserve the order of manufacture under an arrangement such as is depicted in Figure 23.2. In this example, the machine discharges its production into a small container called a *pan.* The production operator periodically empties the pan into one of three larger containers:
   a. Into the junk box if the parts are junk.
   b. Into the reject box if the parts are questionable or are mixed good and bad.
   c. Into the tray if the parts are presumably good.
   The patrol inspector comes to the machine and checks the last few pieces being made. (He or she also may sample the tray.) Based on this check, the tray is disposed of in one of three ways:
   a. Into the junk box if the parts are junk.
   b. Into the reject box if the parts are questionable or are mixed good or bad.
   c. Into the good box if the parts are acceptable. The good box goes on to the next operation.
   Only the inspector may dispose of the tray, and only the inspector may place any product in the good box. The reject box is gone over by a sorter, who makes three dispositions:
   a. Junk to the Junk Department.
   b. Reoperate back to the Production Department.
   c. Good parts on to the next operation.


FIGURE 23.2   Patrol inspection plan based on preserving the order.

2. This method is similar to the first, but the inspection data from the last few pieces are posted to a control chart. If the process remains in control, all product made since the last check is accepted.

3. The accumulated product (e.g., in the tray of Figure 23.2) is sampled at random using some standard sampling plan, and acceptance is based on the sampling criteria.

4. The process variables are checked against a process specification, and the product is accepted provided the process conforms to specification. This method is usually restricted to cases in which there is to be a direct check on the product at later stages.

Tollgate Inspection.   This is a lot-by-lot product-acceptance procedure. Commonly it is done after the Production Department has concluded its operations. Sometimes the product is moved physically to an inspection area, where it waits its turn to be inspected. Sampling is at random, using standard sampling tables.

Tollgate inspection reduces congestion at the machines and clarifies departmental responsibility. The price paid is in added material handling, added floor space, loss of order of production, and greater difficulty in fixing individual responsibility.

Finished-Goods Inspection.   Most finished products are tested 100 percent for minimal simulation of use. Tests are often automated, as are the data recordings. Testing may be done either at inspection stations on the production line or in separate inspection areas.

Shipping Inspection.   For processes that are continuous and stable and/or do not require multiple operations before enclosure into a container, a shipping inspection and/or test will provide assurance of conformance before the containers are sealed.

Dock Audit.   This is an inspection of a random selection of product that is ready to be shipped. Such audits may be made daily, weekly, semiweekly, biweekly, etc. Whatever the frequency, it is important to check not only the product characteristics but also the labeling, shipping and handling methods, and many other requirement criteria.

Destructive Test.   A product that has been deemed stable and by its functional nature requires a lot or batch destruction test on its components or assemblies is subject to a random destructive evaluation. If any failure occurs, the lot or batch is automatically quarantined to future analysis.

QUALITY STANDARDS

The cornerstone of quality control is the specification. Specifications embody the minimum and maximum values (see also Bader 1980). However, they are usually *incomplete.* They tend to ignore *visual quality characteristics,* or they treat characteristics labeled as *workmanship* superficially. [Refer to the discussion of visual quality characteristics below; and see also Dodds (1967) and Alaimo (1969) for further discussion on workmanship standards.]

Seriousness Classification.   Some quality characteristics and defects are very important to fitness for use; others are not. The village artisan and the small-shop proprietor, with their first-hand knowledge of fitness for use, are able to concentrate their efforts on the most important qualities. In modern, large, complex organizations, the workers, inspectors, and many of the supervisors lack complete knowledge of fitness for use and thus are not fully clear on where to place their emphasis and how to make their decisions.

For example, one company studying the fabrication and inspection of machine parts divided the quality characteristics into four classes. Table 23.4 shows the effect of this classification on product tolerances and on the number of dimensions checked. The inspection time was reduced from 215 to 120 minutes. In addition, there were greater savings through lower rework costs, lower tooling costs, and lower engineering costs for disposition of nonconforming product (see also Allen 1959).

The seriousness classification takes into consideration information from a variety of sources:

The specification: This is the primary source. Because the specifications rarely reflect the most current input from customers and other sources, it is important that the team proactively seek current information from the sources listed here.

TABLE 23.4   Results of Seriousness Classification of Characteristics

Characteristic classification	Effect of classification on design tolerance	Effect of classification on amount of inspection	Number of dimensions checked Before classification	Number of dimensions checked After classification
Critical	None	None	154	154
Major	None	None	110	110
Minor A	Tolerance was increased by a specified amount (doubled, etc.) provided the part assembled satisfactorily	Inspection was made normally, but to wider tolerances	66	15
Minor B	Tolerance was ignored provided the part assembled satisfactorily	Inspection was eliminated	352	0
Total			682	279

Customer input: The classification is an even more useful guide to decision making when the team broadens the information base to include direct preproduction input from the whole range of customers—the purchaser, the end user, the various internal departments involved in manufacture, inspection, packaging, shipping, and so on. Then the classification can reflect more accurately the customer's needs and expectations of the product.

Manufacturing experience with the product: Problems and inadequacies, including evidence of nonconformance during manufacturing, help identify troublesome features.

Life testing and functional testing: When these functions are part of the production cycle, they should be included in the classification process and in structuring a formal classification model. The test results are useful input to classification decisions. Where there exists the possibility of product misuse—which, for a variety of unanticipated reasons, too frequently replaces the customer's originally intended use—the tests can help anticipate and prevent such misuse or at least help mitigate its effects. The proper classification ensures that the affected features will receive proper attention.

Failure during use: Field failure is the ultimate undesirable quality outcome. Any feature for which a causal link can be established to field failure is, by definition, a critical feature.

Seriousness classification is useful input both to the control plan and the overall quality plan. Some quality characteristics are multileveled in their seriousness criteria. For example, a shaft diameter specified as "1.000 ± 0.001" gives rise to two defects: oversize and undersize. These defects may be assigned different degrees of seriousness depending on the extent and effect of nonconformance. Some extensive defect lists, e.g., the list for glass bottles, have little resemblance to the list of characteristics set out in the specifications.

Some companies use the same system of classification for both characteristics and defects. However, there is enough uniqueness about each of the two lists to suggest that adoption of a single system should be preceded by a positive examination of the nature of the two lists. For example, the effect of seriousness classification on design decisions can be quite different from the effect on inspection decisions, as is evident from Table 23.4.

Formal systems of seriousness classification were evolved originally to serve specialized purposes. (The Bell System pioneered by developing a system to permit rating of quality of finished product. The U.S. Army developed systems to simplify the administration of acceptance of goods purchased from contractors.) However, as the systems came into being, they were found to have application to the entire progression of product from design through use: in quality specification, manufacturing planning, supplier relations, tooling, production, salvage, product auditing, and executing reporting. Vital qualities could now be identified with greater confidence, and it also became feasible to delegate class decisions and actions on a broad scale. For example, all class C defects could be assigned a common sampling plan, thereby avoiding the need for publishing numerous individual plans.

The multiple uses of seriousness classification systems make it desirable that the job of developing such a system be guided by an interdepartmental committee that has the responsibility for drafting a plan, modifying it, and recommending it for adoption. Such a committee has a series of tasks:

1. Determining the number of strata or classes of seriousness to use.

2. Defining each class.

3. Classifying each defect into one of the classes.

Number of Levels or Strata.   In theory, this number may be large; e.g., a defect may have any weight from 1000 down to 1. In practice, such a large number of weights is too complex to administer. The actual plans in use consist of only several classes. While choice of the actual number of classes is arbitrary, extensive experience has shown that three or four classes suffice for a wide variety of situations.

Definitions for the Classes.   These will differ with the nature of the product, process, etc. However, plans in existence tend to show striking similarity in definition, the result in part of the

influence of the Bell System classification plan [see also Dodge (1928) and Dodge and Toreey (1956)]. Not only was this pioneering plan uncommonly well reasoned out; the men who devised it were later consultants to some of the U.S. armed services during World War II, and their thinking influenced the classification plans adopted by these services. These plans, in turn, influenced the plans adopted by the contractors to the armed services.

The standard definitions adopted by the Bell System [see also Dodge and Torrey (1956)] are shown in Table 23.5. Study of these definitions discloses that there is an inner pattern common to the basic definitions (Table 23.6).

A composite of definitions used in food industry companies is shown in Table 23.7. It is evident that there are industry-to-industry differences in products, markets, and so on that require a tailor-made wording for each industry. In addition, the lists are not static. The growth of government regulation has further influenced the definition, as has the problem of repairs and guarantees for long-life products.

It is also evident that the classifications must simultaneously take into account multiple considerations such as functional performance, user awareness, and financial loss. For example, the effects and awareness of a radio receiver's defects may be as follows:

Defect	Effect	User awareness
Open circuit in power supply	Set is inoperative	Fully aware
Short circuit in resistor	Excess power consumption	Seldom aware
Poor exterior finish	No effect	Usually aware
Poor dress or internal wiring	No effect	Seldom aware

Classifying the Defects.   This essential task is time-consuming, since there are always many defects to be classified. If the class definitions have been well drawn, the task becomes much easier.

During classifying, much confusion is cleared up. It is found that the seriousness of important visual defects depends not so much on whether the inspector can see them as on whether the consumer can see them. It is found that some words describing defects must be subdivided; i.e., a *stain* may be placed in two or three classes depending on severity and location. In many ways, the work of classifying defects is rewarding through clearing away misconceptions and giving a fresh view to all who participate.

Classification of Characteristics.   In some companies the formal "seriousness" classification is not of defects but of characteristics in the specifications. The classification may be in any of several alternatives:

1. *Functional or nonfunctional.*   Where a single set of drawings carries both functional ("end use") requirements and nonfunctional ("means to an end") requirements, it is important to make clear which is which. (This is not to be confused with mechanical, chemical, or electrical functioning. In products such as jewelry or textiles, the most important functional requirement is *appearance*.) The purposes served by these two classes are generally alike throughout industry:

Functional requirements are intended to	*Nonfunctional requirements are intended to*
Ensure performance for intended use	Inform the shop as to method of manufacture
Ensure long, useful life	Reduce cost of manufacture
Minimize accident hazards	Facilitate manufacture
Protect life or property	Provide interchangeability in the shop
Provide interchangeability in the field	Provide information to toolmakers
Provide competitive sales advantage	

TABLE 23.5 Serious Classification of Defects (Bell System)

Class A: Very serious (demerit value, 100)

1. Will surely cause an operating failure of the unit in service that cannot be readily corrected in the field, e.g., open relay winding, or
2. Will surely cause intermittent trouble, difficult to locate in the field, e.g., loose connection, or
3. Will render unit totally unfit for service, e.g., dial finger wheel does not return to normal after operation, or
4. Liable to cause personal injury or property damage under normal conditions of use, e.g., exposed part has sharp edges.

Class B: Serious (demerit value, 50)

1. Will probably cause an operating failure of the unit in service that cannot be readily corrected in the field, e.g., protective finish missing from coaxial plug, or
2. Will surely cause an operating failure of the unit in service that can be readily corrected in the field, e.g., relay contact does not make, or
3. Will surely cause trouble of a nature less serious than an operating failure, such as substandard performance, e.g., protector block does not operate at specified voltage, or
4. Will surely involve increased maintenance or decreased life, e.g., single contact disk missing, or
5. Will cause a major increase in installation effort by the customer, e.g., mounting holes in wrong location, or
6. Defects of appearance or finish that are extreme in intensity, e.g., finish does not match finish on other parts, requires refinishing.

Class C: Moderately serious (demerit value, 10)

1. May possibly cause an operating failure of the unit in service, e.g., contact follow less than minimum, or
2. Likely to cause trouble of a nature less than an operating failure, such as substandard performance, e.g., ringer does operate within specified limits, or
3. Likely to involve increased maintenance or decreased life, e.g., dirty contact, or
4. Will cause a minor increase in installation effort by the customer, e.g., mounting bracket distorted, or
5. Major defects of appearance, finish, or workmanship, e.g., finish conspicuously scratched, designation omitted or illegible.

Class D: Not serious (demerit value, 1)

1. Will not affect operation, maintenance, or life of the unit in service (including minor deviations from engineering requirements), e.g., sleeving too short, or
2. Minor defects of appearance, finish, or workmanship, e.g., slightly scratched finish.

TABLE 23.6 Inner Pattern: Seriousness Classification System

Defect class	Demerit weight	Cause personal injury	Cause operating failure	Cause intermittent operating trouble difficult to locate in field	Cause substandard performance	Involve increased maintenance or decreased life	Cause increase in installation effort by customer	Appearance, finish, or workmanship defects
A	100	Liable to	Will surely*	Will surely				
B	50		Will surely		Will surely	Will surely	Major increase	
C	10		May possibly		Likely to	Likely to	Minor increase	Major
D	1		Will not		Will not	Will not	Minor increase	Minor

*Not readily corrected in the field.

TABLE 23.7   Composite Definitions for Seriousness Classification in Food Industry

Defect	Effect on consumer safety	Effect on use	Consumer relations	Loss to company	Effect on conformance to government relations
Critical	Will surely cause personal injury or illness	Will render the product totally unfit for use	Will offend consumer's sensibilities because of odor, appearance, etc.	Will lose customers and will result in losses greater than value of product	Fails to conform to regulations for purity, toxicity, identification
Major A	Very unlikely to cause personal injury or illness	May render the product unfit for use and may cause rejection by the user	Will likely be noticed by con-sumer, and will likely reduce product salability	May lose customers and may result in losses greater than the value of the product; will sub-stantially reduce production yields	Fails to conform to regulations on weight, volume, or batch control
Major B	Will not cause injury or illness	Will make the product more difficult to use, e.g., removal from package, or will require impro-vision by the user; affects appearance, neatness	May be noticed by some consumers, and may be an annoyance if noticed	Unlikely to lose customers; may require product replacement; may result in loss equal to product value	Minor nonconformance to regulations on weight, volume, or batch control, e.g., completeness of documentation
Minor	Will not cause injury or illness	Will not affect usability of the product, may affect appearance, neatness	Unlikely to be noticed by con-sumers, and of little concern if noticed	Unlikely to result in loss	Conforms full to regulations

"Which is which" becomes important because it directs the priorities of process design and many aspects of economics of manufacture, as well as the jurisdiction over waivers. When the engineers make this classification, they commonly add a designation such as *E* (for engineering) to the functional characteristics. All others are then assumed to be nonfunctional.

A comparable situation prevails in process specifications, where the need is to distinguish manda-tory from advisory requirements, which correspond roughly to functional and nonfunctional require-ments as applied to the product. However, the process specifications seldom make this distinction. (For further discussion, see Section 22, Operations, under Knowledge of "Supposed to Do.")

2. *Seriousness classification.*   When this method is used, it parallels closely the classification into critical, major, and minor as used for classification of defects. (The contention is often raised that the tolerances on the specifications are an automatic form of seriousness classification, i.e., any-thing with assigned tolerances must be met and is "therefore" critical. An alternative contention is that the closeness of the tolerances is a key to seriousness classification; i.e., the narrowest tolerances are assigned to the most critical characteristics. When these contentions are examined more closely, they are found to contain too many exceptions to serve as firm rules for classifications.)

The resulting classifications then become a supplement to the specification or are shown on the drawings themselves by some code designation, for example:

    Critical   ⊕

    Major A   ①

    Major B   ○

    Minor   Not marked

One large automotive company differentiates between regulatory and nonregulatory critical characteristics by the use of two different symbols.

3. *Segregation of functional requirements.* Place in a separate document, such as an "engineering specification" or a "test specification."

4. *Shop practice tolerances versus special tolerances.* This method is based on preparation of a shop practice manual that sets out general-use tolerances derived from the process capability of general-use machines and tools. Once published, these shop practice tolerances govern all characteristics not specially toleranced.

Who Classifies? For defect classification, an interdepartmental committee is the ideal choice. This provides each department with the benefits derived from the process of active review, and it also produces a better final result (sometimes the committee goes further and establishes a plan for product rating, including demerit weights for each class; see Section 8, under Appraisal Costs). However, some companies assign a staff specialist to prepare a proposed classification, which is then reviewed by all interested departments. The specialist is usually a quality control engineer.

When the classification is limited to specified characteristics, e.g., functional versus nonfunctional, the designer usually prepares the draft.

SENSORY QUALITIES

Sensory qualities are those for which we lack technological measuring instruments and for which the senses of human beings must be used as measuring instruments. (For some special purposes, e.g., tests of toxicity, the test panel may consist of animals.) Sensory qualities may involve

- Technological performance of the product, e.g., adhesion of a protective coating, friction of a sliding fit
- Esthetic characteristics of consumer products, e.g., taste of food, odor of perfume, appearance of carpets, noise of room air conditioners

In common with other qualities, sensory qualities require:

1. Discovery of which characteristics are required and in what degree to meet the needs of fitness for use

2. Design of products that will possess these characteristics

3. Establishment of product and process standards and of tests that will simulate fitness for use

4. Judgment of conformance to the product and process standards

This multiplicity of tasks requires a corresponding multiplicity in type of sensory test panel used, choice of test design, and so on.

Customer Sensitivity Testing. In this form of test, the purpose is to discover the "threshold" level at which customers can detect the presence of sensory qualities. The qualities under test may be "desirable." For example, if an expensive ingredient is used in a product blend, it is very useful to know the threshold concentration level that ensures customer recognition of the ingredient. The qualities under test may be "undesirable." For example, a product exhibits varying degrees of visual blemish. It is very useful to know the threshold degree of defectiveness that makes the customer respond negatively to the product.

In customer-sensitivity testing, a graduated set of samples is prepared, each exhibiting a progressively greater extent of the quality or deficiency under investigation. These samples are submitted to a customer panel as part of an organized study.

For example, in two companies—one making sterling silverware and the other making costume jewelry—studies were conducted to discover customer sensitivity to visual defects. In both companies, a committee of key people (from Marketing, Design, Manufacture, and Quality) structured a plan of study as follows:

1. An assortment of product was chosen to reflect the principal visual defects, the principal products in the product line, and the principal price levels.

2. These samples were inspected in the factory by the regular inspectors to determine the severity of the defects as judged by the frequency with which the inspectors rejected the various units of product.

3. The assortment of products was then shown to a number of customer panels chosen from those segments of the buying public which constituted important customer classes, e.g., suburban women, college students, etc. These panels reviewed the products under conditions that simulated use of the product, e.g., silverware in place settings on a dining room table. The customers were instructed (by printed card) somewhat as follows: "Assume you have previously bought these products and they have been delivered to you. Naturally, you will want to look them over to see that the merchandise is satisfactory. Will you be good enough to look it over, and if you see anything that is objectionable to you, will you please point it out to us?"

The resulting data showed that the customer panels were highly sensitive to some defects. For such defects, the strict visual standards were retained. For certain other defects, the customer sensitivity was far less than factory-inspector sensitivity. For such defects, the standards were relaxed. In still other instances, some operations had deliberately been omitted, but the customers proved to be insensitive to the effect of the omission. As a result, the operations were abolished.

Customer sensitivity testing is an extension of the principle that "the customer is right." This principle may be subdivided as follows:

1. The customer is right as to qualities he or she can sense. As to such qualities, the manufacturer is justified in taking action to make such qualities acceptable to the customer.

2. The customer is also right as to qualities he or she *cannot* sense. The manufacturer is not justified in adding costs to create an esthetic effect not sensed by the customer.

3. Where, for a given quality, the customer is sensitive to a limited level but not beyond, the manufacturer should take action to make the quality to that level but not beyond.

The intermediate marketing chain sometimes interferes with these principles. Sales clerks are proficient in emphasizing product differences, whether important or not. In turn, dealers are alert to seize on such differences to wring concessions out of competing manufacturers. A frequent result is that all manufacturers are driven to adopt wasteful standards, resulting in a needlessly high cost, e.g., finishes on nonworking or nonvisible surfaces. Elimination of such perfectionism commonly requires that the manufacturer secure data directly from consumers and then use the data to convince the distribution chain. These same data may be needed to convince other nonconsumers who exhibit perfectionist tendencies: upper management, designers, salespeople, inspectors, etc.

Visual Quality Characteristics.   These constitute a special category of sensory qualities. (Visual inspection remains the largest single form of inspection activity.) For these characteristics, the written specifications seldom describe completely what is wanted, and often inspectors are left to make their own interpretation. In such cases, inspectors are really making two judgments simultaneously:

1. What is the meaning of this visual characteristic of the specification, e.g., what is the standard?

2. Does this unit of product conform to the standard?

Where inspectors understand fitness for use, they are qualified to make both these judgments. If a particular inspector lacks this knowledge, he or she is qualified to make only judgment 2, no mat-

ter how long on the job. Extensive experience has shown that inspectors who lack this knowledge differ widely when setting standards and, in addition, do not remain consistent. (As an example, from the consulting experience of J. M. Juran, in an optical company, study of the methods used by 18 different inspectors, engineers, and so on disclosed the existence of six methods of counting the number of "fringes of irregularity.") Several methods are available to planners to clarify the standard for visual characteristics.

Visual Inspection and Test Standards.
The most elementary form of visual standard is the *limit sample*—a unit of product showing the worst condition acceptable. In using this standard, the inspector is aided in two ways:

1. The sample conveys a more precise meaning than does a written specification.
2. The inspection is now made by comparison, which is well known to give more consistent results than judgment in the absence of comparison.

A more elaborate form of visual standards involves preparation of an exhibit of samples of varying degrees of defects ranging from clearly defective to clearly acceptable. See, for an example involving solder connections, Leek (1975 and 1976), who describes how the companies Martin Marietta and Northrup supported series or "ranges" to provide manufacturing latitude in processing material while at the same time identifying minimum and maximum limits on visual attributes. This exhibit is used to secure the collective judgments of all who have a stake in the standard—consumers, supervisors, engineers, and inspectors. Based on these judgments, standards are agreed on, and limit samples are chosen. (It is also feasible to estimate, by sampling, what would be the yield of the process, and thereby the cost of defects, for any one of the various degrees of defectiveness.)

In products sold for esthetic appeal, appearance becomes a major element of fitness for use and commonly a major element of cost as well. In such cases, an exhibit of samples with varying degrees of defects intermingled with perfect units of product becomes a means of measuring consumer sensitivity (or insensitivity) to various defects. Use of consumer panels to judge such mixtures of product invariably confirms some previous concepts but also denies some long-standing beliefs held by managers as well as by the inspectors.

In the sterling silverware case mentioned earlier, consumers were quite sensitive to several types of defects—they held out 22 percent of the defects present. However, for the bulk of defects, the consumers were quite insensitive and found only 3 percent of such defects. The salespeople generally found twice as many defects as consumers but still considerably fewer than factory inspectors.

A further use of samples of various defects is to establish *grades* of defects. The concept of different grades is vital when a plant makes products that, while outwardly similar, are used in widely different applications, e.g., ball bearings used for precision instruments and those used for roller skates, lenses for precision apparatus and lenses for simple magnifiers, or sterling silverware and plated silverware. Unless the grades are well defined and spelled out in authoritative form, the risk is that the inspectors will apply one standard to all grades.

Once limit samples have been agreed to, there remains a problem of providing working standards to the inspection force. Sometimes it is feasible to select duplicates for inspection use while retaining the official standard sample in the laboratory. An alternative is to prepare photographs (sometimes stereoscopic) of the approved standards and to distribute these photographs instead.

Standardizing the Conditions of Inspection and Test.
Visual inspection results are greatly influenced by the type, color, and intensity of illumination, by the angle of viewing, by the viewing distance, and so on. Standardizing these conditions is a long step in the direction of securing uniform inspection results. In the case of esthetic visual qualities, the guiding rule for conditions of inspection is to simulate the conditions of use, but with a factor of safety.

Establish a *fading distance.* In some products the variety of visual defects is so great and the range of severity so wide that the creation of visual standards becomes prohibitively complex. An

alternative approach is to standardize the conditions of inspection and then to establish a fading distance for each broad defect class. The definition for a defect becomes "anything that can be seen at the fading distance." (This technique appears to have been evolved in 1951 by N. O. Langenborg of St. Regis Paper Company. See also Riley 1979.)

Sensory Tests: Design and Analysis.   There are numerous designs of sensory tests, some of them quite complex. Some of the basic forms are described below.

Tests for Differences or Similarities.   These include

1. *The paired-comparison test.*   Product is submitted to members of a panel in pairs of samples. One sample is identified to each panelist as the standard or "control"; the other is the test sample. The panelist is asked to judge and record the difference on a scale of differences (such as no difference, slight difference, or pronounced difference). Some of the pairs have no difference; i.e., both are "controls."

2. *The triangle test.*   The panelist is asked to identify the odd sample in a group of three, two of which are alike. He or she also may be asked to estimate the degree of difference and to describe the difference between the odd sample and the two like samples.

3. *The duo-trio test.*   The panelist is asked to identify which of two samples is like the "control" to which she or he has been subjected previously. For example, in liquor manufacture, the aim is to make each batch indistinguishable in taste from past batches. The duo-trio test is used as a product-acceptance test. Each panelist tastes the "control," which he or she is told comes from previous product. Then each panelist tastes the two remaining samples, one of which is "control" and the other of which is the batch under test. However, the panelists are not told which is which. If the data make clear that the panel cannot distinguish the new batch from the control, the batch is accepted. Otherwise, it is reblended.

4. *Ranking test.*   Coded samples are submitted to each panelist, who is asked to rank them in the order of concentration.

Creating New Instruments to Measure Sensory Qualities.   Many sensory qualities formerly judged by human perception are now measured by instruments. This development of new instrumentation goes on apace using essentially the following approach (based on a procedure set out by Dr. Amihud Kramer 1952; see also Hains 1978):

1. Define precisely what is meant by the quality characteristic under discussion. This must be done with participation of all interested parties.

2. Discover, through analytical study, the subcharacteristics, and define them in a way that permits, in theory, measurement by some inanimate instrument.

3. Search the literature to become informed about methods already in existence or under the development for measuring these subcharacteristics. This search will disclose a number of such possible measurement methods.

4. Choose or create product samples that vary widely for the subcharacteristics. Test a limited number (10 to 50) of samples with each of the various measurement methods, and correlate these tests with evaluation by panels of human testers. The human evaluation here aims not to measure personal preferences but to rate the degree to which the samples possess the variable under study. Hence the main requirement of the panel is that it be able to discriminate the subcharacteristics under study. Discard those measurement methods which lack precision or which fail to reflect human evaluation.

5. For the remaining, more promising measurement methods, conduct tests on a larger number of samples (100 to 1000) also chosen to reflect the entire range of quality variation. In addition, conduct tests of duplicate samples using evaluation by human test panels.

6. Correlate the results of measurement against the human test panel evaluation; select the method that gives a high correlation. (Multiple correlation methods may be necessary.)

7. Improve and simplify the selected measurement method through further tests and correlations.

8. Establish a scale of grades through use of a human sensory test panel. At this stage, the prime purpose of the human test panel is to state preferences along the scale of measure. Hence the main requirement of this panel is that it be representative of the producers and users of the product.

9. Weigh the various subcharacteristics in accordance with their rated performance [see also Montville (1983) and Papadopoulos (1983)].

10. Develop the sampling procedures needed to apply the resulting method of measurement.

MEASUREMENT QUALITY: AN INTRODUCTION

Conduct of the quality function depends heavily on qualification of product and process characteristics. This quantification is done through a systematic approach involving

1. Definition of standardized units called *units of measure* that permit conversion of abstractions (e.g., length, mass) into a form capable of being quantified (e.g., meter, kilogram).

2. *Instruments* that are calibrated in terms of these standardized units of measure.

3. Use of these instruments to quantify or *measure* the extent to which the product or process possesses the characteristic under study. This process of quantification is called *measurement.*

The word *measurement* has multiple meanings, these being principally

1. The *process* of quantification; e.g., "The measurement was done in the laboratory."

2. The resulting number; e.g., "The measurement fell within the tolerances."

Measurement rests on a highly organized, scientific base called *metrology,* i.e., the science of measurement. This science underlies the entire systematic approach through which we quantify quality characteristics.

MEASUREMENT STANDARDS

The seven fundamental units of the International System (SI) of measurement are defined as shown in Table 23.8. It is seen that except for the kilogram, all units are defined in terms of natural phenomena. (The kilogram is defined as the mass of a specific object.)

Primary Reference Standards.   In all industrialized countries there exists a national bureau of standards whose functions include construction and maintenance of *primary reference standards.* These standards consist of copies of the international kilogram plus measuring systems that are responsive to the definitions of the fundamental units.

In addition, professional societies (e.g., the American Society for Testing and Materials) have evolved standardized test methods for measuring many hundreds of quality characteristics. These standard test methods describe the test conditions, equipment, procedure, and so on, to be followed. The various national bureaus of standards, as well as other laboratories, then develop primary reference standards that embody the units of measure corresponding to these standard test methods.

Primary reference standards have a distinct legal status, since commercial contracts usually require that "measuring and test equipment shall be calibrated . . . utilizing reference standards . . . whose calibration is certified as being traceable to the National Institute of Standards and

TABLE 23.8 Definitions of Fundamental Units of the SI System

Unit	Definition
Meter, m	1/650 763.73 wavelengths in vacuo of the unperturbed transition $2_{p10} \rightarrow 5d_5$ in ^{36}Kr
Kilogram, kg	Mass of the international kilogram at Sevres, France
Second, s	1/31 556 925 974 7 of the tropical year at 12^h ET, 0 January 1900, supplementarily defined in 1964 in terms of the cesium F, 4; M, 0 to F, 3; M, 0, transition, the frequency assigned being 9 192 631 770 Hz
Kelvin, K	Defined in the thermodynamic scale by assigning 273.16 K to the triple point of water (freezing point, 173.15 K = 0°C)
Ampere, A	The constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular sections, and placed 1 m apart in a vacuum, will produce between these conductors a force equal to 2×10^{-7} mks unit of force per meter of length.
Candela, cd	1/60 of the intensity of 1 cm^2 of a perfect radiator at the temperature of freezing platinum.
Mole, mol	An amount of substance whose weight in grams numerically equals the molecular formula weight.

Technologies." In practice, it is not feasible for the U.S. National Institute of Standards and Technologies to calibrate and certify the accuracy of the enormous volume of test equipment in use in shops and test laboratories. Instead, resort is made to a hierarchy of secondary standards and laboratories, along with a system of documented certification of accuracy.

Hierarchy of Standards. The primary reference standards are the apex of an entire hierarchy of reference standards (Figure 23.3). At the base of the hierarchy there stands the huge array of *test equipment,* i.e., instruments used by laboratory technicians, workers, and inspectors to control processes and products. These instruments are calibrated against *working standards* that are used solely to calibrate these laboratory and shop instruments. In turn, the working standards are related to the primary reference standards through one or more intermediate secondary reference standards or *transfer standards.* Each of these levels in the hierarchy serves to "transfer" accuracy of measurement to the next lower level in the hierarchy.

Within the hierarchy of standards there are differences both in the physical construction of the standards and in their precision. The primary reference standards are used by a relatively few highly skilled metrologists, and their skills are a vital commitment to the high precision attained by these standards. As we progress down the hierarchy, the number of technicians increases with each level, until at the base there are millions of workers, inspectors, and technicians using test equipment to control product and process. Because of the wide variation in training, skills, and dedication among these millions, the design and construction of test equipment must feature ruggedness, stability, and foolproofing so as to minimize errors contributed by the human being using the equipment.

FIGURE 23.3 Hierarchy of standards.

Precision of measurement differs widely among the various levels of the hierarchy of standards. At the level of primary reference standards, the precision is determined by the state of the art. For example, Figure 23.4 shows the precision attained by the U.S. National Bureau of Standards (now

the National Institute of Standards and Technology) when weighing loads across the spectrum of 10^{-10} to 10^6 (National Bureau of Standards 1965).

At the base of the hierarchy, the precision of measurement is determined by the needs of fitness for use as reflected by the product and process tolerances. While some specialists urge that the test equipment be able to "divide the tolerance into tenths," this ideal is by no means always attained in practice. However, the tolerances themselves have been tightened drastically over the centuries, and this tightening generally has paralleled the advances made in the state of the art of measurement. For example, accuracy of measurement of a meter of length has progressed from an error of 1000 per million (at the end of the fifteenth century) to an error of 0.0001 per million as we move into the twenty-first century.

Allocation of measurement errors among the working and transfer standards has been discussed widely but has not been well standardized. The precision gap between primary reference standards and product test equipment may be anywhere from one to several orders of magnitude. This gap must then be allocated among the number of levels of standards and laboratories (transfer plus working) prevailing in any given situation. (Some models have been worked out to show the interrelation among the cost of developing greater precision in the primary reference standard, cost of attaining precision at each level of transfer laboratory, and number of laboratories at each level. See, for example, Crow 1966.) When this problem of allocation was first faced, there was a tendency to conclude that each level should have a precision 10 times greater than the level it was checking. More recently, there has been growing awareness of how multiple levels of precision combine; i.e., their composite is better represented by the square root of the sum of the squares rather than by the arithmetic sum. This new awareness has caused many practitioners to accept a ratio of 5:1 rather than 10:1 for precision of working standards to product tolerances. This same ratio also has been tolerated among transfer standards as well.

ERROR OF MEASUREMENT

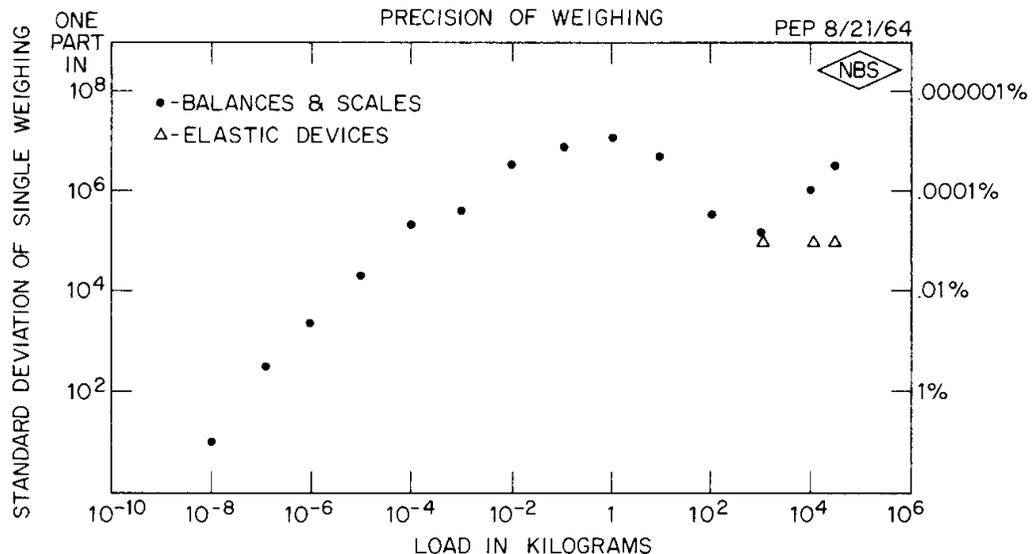
Product and process conformance is determined by measurements made by the test equipment at the bottom of the hierarchy of standards. Obviously, any error in these measurements has a direct bearing on the ability to judge conformance. On examination, the nature of measurement error is quite complex; even the terminology is confused. A clear understanding of the meaning of the


FIGURE 23.4 Precision of weighing.

measurements requires a minimal degree of understanding of the nature of measurement error. The starting point is to understand the nature of accuracy and precision. Figure 23.5 shows the meaning of these terms by example and by analogy. See, in this connection, ASTM 177-71 (listed in Appendix III) on use of the terms *precision* and *accuracy* as applied to measurement of the properties of materials. See also Mathur (1974) for a discussion on the influence of measurement variation in mass production of parts.

Accuracy.   Suppose that we make numerous measurements on a single unit of product and that we then compute the average of these measurements. The extent to which this average agrees with the "true" value of that unit of product is called the *accuracy* of the instrument or measurement system that was employed. The difference between the average and the true value is called the *error* (also *systematic error, bias,* or *inaccuracy*) and is the extent to which the instrument is out of calibration. The error can be positive or negative. The *correction* needed to put the instrument in calibration is of the same magnitude as the error but opposite in sign. The instrument is still considered *accurate* if the error is less than the *tolerance* or maximum error allowable for that grade of instrument.

   Accuracy and *error* are quantified as a difference between (1) the average of multiple measurements and (2) the true value. As will be seen, each of these is surrounded by a fringe of doubt. Consequently, the expression of accuracy must show the extent of these doubts if the full meaning of the numbers is to be conveyed.

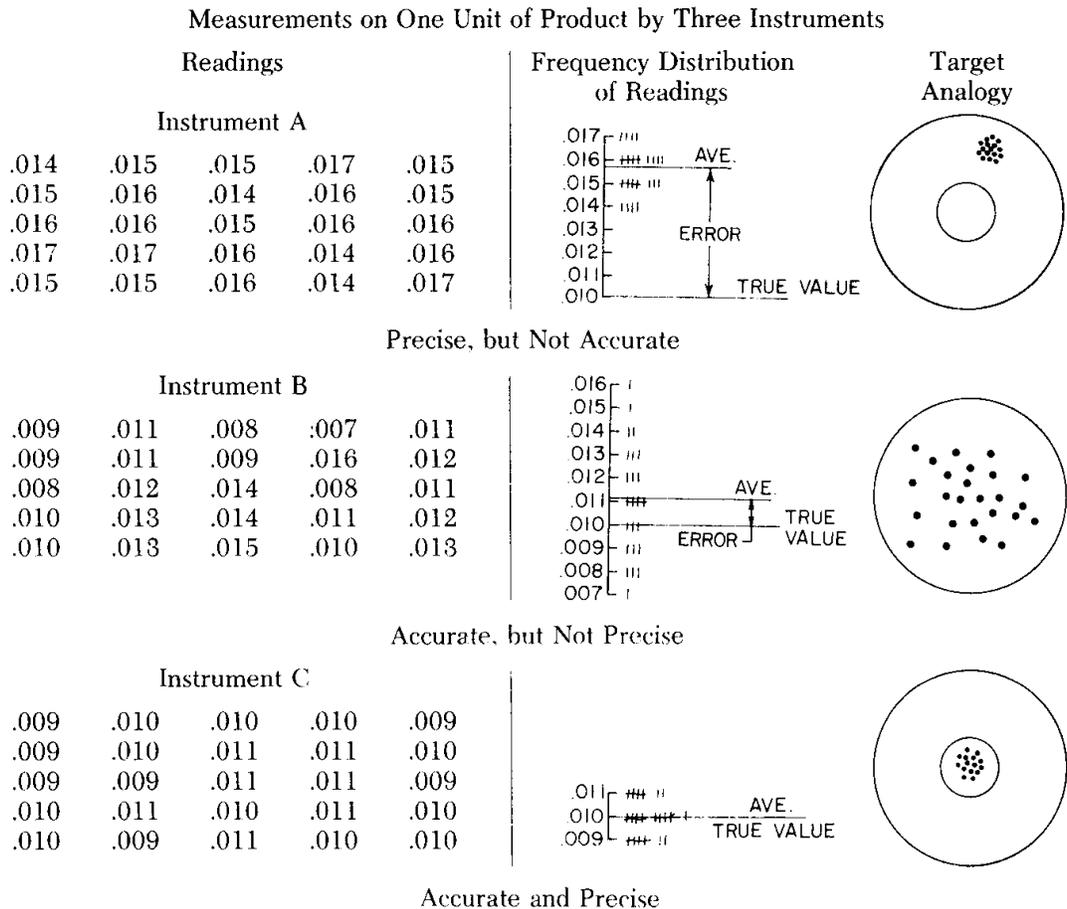
Precision.   Irrespective of accuracy of calibration, an instrument will not give identical readings even when making a series of measurements on one single unit of product. Instead, the measure-


FIGURE 23.5   Accuracy and precision.

ments scatter about the average, as exemplified in Figure 23.5. The ability of the instrument to reproduce its own measurements is called its *precision,* and this varies inversely with the dispersion of the multiple (*replicated*) measurements.

Experience has shown that any measurement system has an inherent dispersion that is itself reproducible, measurable, and therefore (once known) predictable. This inherent precision of measurement parallels the inherent process capability of a machine tool. (The parallel extends to the requirement that the system be in a state of statistical control.) Quantification of precision is in terms of the standard deviation of replicated measurements and is expressed by σ (sigma), the statistical symbol for standard deviation of a population.

Normally, recalibration can improve the accuracy of an instrument by reducing its error. However, recalibration normally does not improve the precision of the instrument, since this precision remains relatively constant over the working range.

Sources of Error.

Systematic error and dispersion of measurements have their origin in several well-known components of measurement error. (In some industries, e.g., chemical processes, the measurement problems are so severe that development of valid test procedures is a major step in the launching of a new product or process.)

Within-Operator Variation.   The same operator, inspector, or technician, even when using the same measuring system on the same unit of product, nevertheless will come up with a dispersion of readings. This variation is usually referred to as *within-operator variation.*

Between-Operators Variation.   When two operators use the same measuring system on the same products, they usually will exhibit differences traceable to differences in operator technique. These differences are called *between-operators variation* and can be exhibited both as systematic error and as differences in dispersion.

Materials Variation.   In many cases it is not feasible to conduct replicated tests on the same "unit of product"; i.e., the product is changed or destroyed by testing. In other cases, the standard itself is consumable (e.g., hardness test blocks), so material variation affects the standard as well. In these cases, where replicate testing is not feasible, the variations due to operator, equipment, and test method are composited with the materials variation. Sometimes it is feasible to resolve these composites into their components, and sometimes it is not. A further complication is the case of perishable materials, which may require use of calibrations that relate time elapsed to degradation suffered.

Test Equipment Variation.   Instruments are subject to numerous sources of error, both within a single instrument and between instruments: nonlinearity, hysteresis (e.g., gear backlash), drift due to temperature rise, and sensitivity to extraneous "noise" (e.g., magnetic, thermal, electrical fields). Each technology is subject to its own unique array of troubles. These instrument troubles are multiplied by the *fixturing* troubles of connecting the instruments into the larger test equipment units and of connecting the test specimens for tests. These fixturing troubles include such problems as making good electrical connections, fastening mechanical linkage, locating probes precisely, and so on.

Test Procedure Variation.   In those cases where more than one test procedure is available to conduct measurement, it is essential to determine the relative variations, since these comprise one of the criteria for judging the adequacy of the procedure used.

Between-Laboratories Variation.   This is a major problem both within companies and between companies. Some major programs must await resolution of this problem before they can be concluded, e.g., industry standardization of materials, test equipment, and test procedures. In like manner, variation between vendor and buyer laboratories may be at the root of a major quality problem. So extensive is the need to reduce between-laboratories variation that standard procedures have been evolved for the purpose (see *Quality Control Handbook,* 4th ed., Section 18, under Interlaboratory Test Programs).

Composite Errors.   The observed measurements are, of course, a resultant of the contributing variations. Generally this resultant or composite is related to the component variables in accordance with the formula

$$\sigma_{obs}^2 = \sigma_w^2 + \sigma_b^2 + \sigma_m^2 + \sigma_e^2 + \sigma_f^2 + \cdots$$

where σ_{obs} is the standard deviation of the observed measurements and σ_w, σ_b, σ_m, σ_e, σ_f, etc. are the standard deviations reflecting the size of the variables that affect precision, i.e., within operator, between operators, material used, in test equipment, in test procedure, etc., respectively.

This relationship is valid provided the variables are independent of each other, which they often are. Where two or more of the variables are interrelated, then the equation must be modified. If, for example, variables A and B are interrelated, then

$$\sigma_T^2 = \sigma_A^2 + \sigma_B^2 + \rho_{AB}\sigma_A\sigma_B$$

where σ_T^2 = total variance
σ_A^2 = variance of A
σ_B^2 = variance of B
ρ_{AB} = the correlation coefficient (ρ) of A and B

In many cases it is feasible to quantify the effect of some component sources of variation by simple designs of experiment. When an instrument measures a series of different units of product, the resulting observations will have a scatter that is a composite of (1) the variation in the system of measurement and (2) the variation in the product itself. This relationship can be expressed as

$$\sigma_{obs} = \sqrt{\sigma_{prod}^2 + \sigma_{meas}^2}$$

where σ_{obs} = σ of the observed data
σ_{prod} = σ of the product
σ_{meas} = σ of the measuring method

Now, solving for σ_{prod},

$$\sigma_{prod} = \sqrt{\sigma_{obs}^2 - \sigma_{meas}^2}$$

It is readily seen that if σ_{meas} is less than one-tenth σ_{obs}, then the effect on σ_{prod} will be less than 1 percent. This is the basis of the rule of thumb that the instrument should be able to divide the tolerance into about 10 parts.

To illustrate, in one shop the validity of a new type of instrument was questioned on the ground that it lacked adequate precision. The observed variation σ_{obs} was 11 (coded). An experiment was conducted by having the instrument make replicate checks on the same units of product. The σ_{meas} was figured out to be 2. Then, since

$$\sigma_{prod}^2 = \sigma_{obs}^2 - \sigma_{meas}^2$$

$$\sigma_{prod} = \sqrt{121 - 4} = \sqrt{117} = 10.8$$

This was convincing proof that the instrument variation did not significantly inflate the product variation.

In another instance involving the efficiency of an air-cooling mechanism, the observed variation σ_{obs} was 23, and the variation on retests σ_{meas} was 16. Thereupon,

$$\sigma_{prod} = \sqrt{23^2 - 16^2} = \sqrt{529 = 256} = \sqrt{273} = 16$$

This showed that the measurement variation was as great as the product variation. Further study disclosed that the measurement variation could be resolved into

Variable	σ of that variable	σ^2
A	14	196
B	5	25
All other	7+	52
		273

It became clear that real progress could be made only by improving variable *A,* and the engineers took steps accordingly.

To quantify the individual components of variation requires still more elaborate analysis, usually through a special design of experiment (see Section 47, Design and Analysis of Experiments). [See also McCaslin and Grusko (1976) for a discussion on an attribute gage study procedure and Ezer (1979) for statistical models for testing vial-to-vial variation in medical laboratories.]

Statement of Error.   In publishing results, it is necessary to make clear the extent of error in those results. Lacking clear conventions or statements, those who review the results simply do not know how to evaluate the validity of the data presented. To make clear the extent of error present in the data, metrologists have adopted some guidelines that are ever more widely used.

Effect of Reference Standards.   Accuracy of an instrument is expressed as the difference between T, the "true" value, and $\overline{X}_m$, the average of the replicated measurements. The reference standard used is *assumed* to be the true value, but of course, this is not fully valid; i.e., the standards laboratory is able to make only a close approximation. In theory, the "true" value cannot be attained. However, the extent of error can be ascertained through the use of replication and other statistical devices. As long as the systematic error of the standard is small in relation to the error of the instrument under calibration (the usual situation), the error of the standard is ignored. If there is some need to refer to the error of the standard, the published measurements may include a reference to the standard in a form similar to "as maintained at the National Institute of Science and Technology."

Effect of Significant Systematic Error.   When the systematic error is large enough to require explanation, the approved forms of explanation consist of sentences appended to the data, stating (for example), "This value is accurate within $\pm x$ units," or "This value is accurate within $\pm y$ percent." [See National Bureau of Standards (1965).] If necessary, these statements may be further qualified by stating the conditions under which they are valid, e.g., temperature range.

It is a mistake to show a result in the form $a \pm b$ with no further explanation. Such a form fails to make clear whether b is a measure of systematic error, an expression of standard deviation of replicate measurements, or an expression of probable error, etc.

Effect of Imprecision.   The quantification of precision is through the standard error (standard deviation), which is the major method in use for measuring dispersion. In publishing the standard error of a set of data, care must be taken to clear up what are otherwise confusions in the interpretation.

1. Does the standard error apply to individual observations or to the average of the observations? Unless otherwise stated, it should be the practice to relate the published standard error to the published average, citing the number of observations in the average.

2. If uncertainty is expressed as a multiple of the standard error, how many multiples are used? An approved form of expression is "…with an overall uncertainty of ±4.5 km/s derived from a standard error of 1.5 km/s."

3. Is the standard error based solely on the data presented or on a broader history of data? To clarify this requires still more intricate wording, since a dispersion based solely on the current data is itself uncertain [see Eisenhart (1968)].

Effect of Combined Systematic Error and Imprecision.   In these cases the expression of the published result must make clear that both types of error are present and significant. Eisenhart (1968)

recommends a phraseology such as "…with an overall uncertainty of ±3 percent based on a standard error of 0.5 percent and an allowance of ±1.5 percent for systematic error."

Errors Negligible.   Results also may be published in such a way that the significant figures themselves reflect the extent of the uncertainty. For example, in the statement, "The resistance is 3942.1 Ω correct to five significant figures," the conventional meaning is that the "true" value lies between the stated value ±0.05 Ω.

CALIBRATION CONTROL

Measurement standards deteriorate in accuracy (and in precision) during use and, to a lesser degree, during storage. To maintain accuracy requires a continuing system of calibration control. The elements of this system are well known and are set out below.

(The terminology associated with *calibration control* is not yet standardized. To put an instrument into a state of accuracy requires first that it be tested to see if it is within its calibration limits. This test is often referred to as *checking* the instrument. If, on checking, the instrument is found to be out of calibration, then a *rectification* or *adjustment* must be made. This adjustment is called variously *calibration, recalibration,* or *reconditioning.* In some dialects, the word *calibration* is used to designate the combination of checking the instrument and adjusting it to bring it within its tolerances for accuracy.)

While the same system can be applied to all levels of standards, as well as to test equipment, there are some significant differences in detail of application. Transfer standards are exclusively under the control of standards laboratories staffed by technicians whose major interest is maintaining the accuracy of calibration. In contrast, test equipment and, to some extent, working standards are in the hands of those production, inspection, and test personnel whose major interest is product and process control. This difference in outlook affects the response of these people to the demands of the control system and requires appropriate safeguards in the design and administration of the system.

New-Equipment Control.   The control system regularly receives new elements in the form of additional standards, new units of test equipment, and expendable materials. These elements should be of proven accuracy before they are allowed to enter the system. The approach varies depending on the nature of the new item:

1. *Purchased precision standards.*   These include high-accuracy gage blocks, standard cells, etc. Control is based on the supplier's calibration data and on his or her certification that the calibration is traceable to the National Institute of Standards and Technology. Where such purchased standards represent the highest level of accuracy in the buyer's company, any subsequent recalibration must be performed by an outside laboratory, i.e., the supplier, an independent laboratory, or the National Institute of Standards and Technology.

2. *Purchased working standards.*   These are subjected to "incoming inspection" by the buying company unless the demonstrated performance of the supplier merits use of an audit of decisions (see Section 21).

3. *New test equipment.*   This equipment is intended for use in checking products and processes (Figure 23.6). However, it usually embodies measuring instruments of various sorts and may well include working standards as well, i.e., test pieces ("masters" for in-place check of calibration).

4. *Test materials.*   These include consumable standards as well as expandable supplies such as reagents or photographic film. Variability in such materials can affect the associated measurements and calibrations directly.

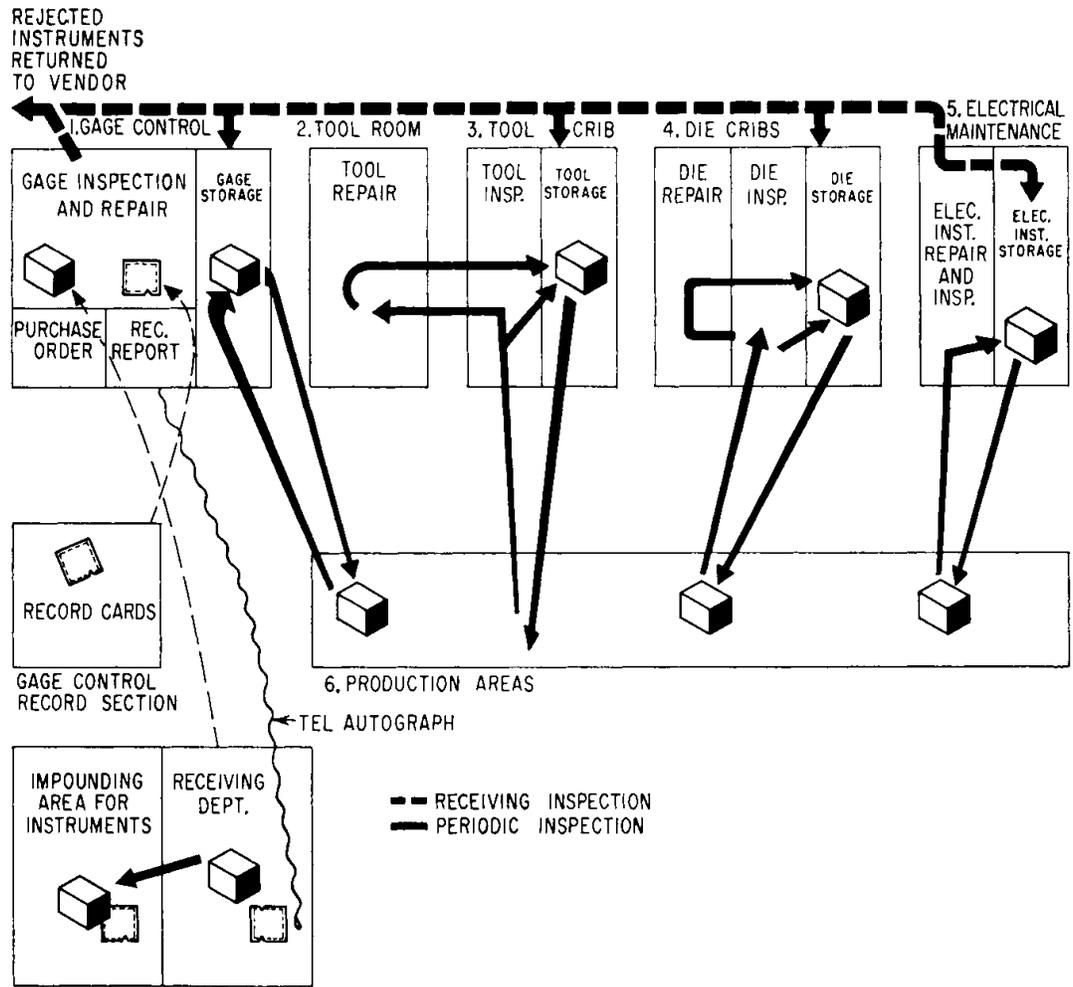
For example, a manufacturer of sandpaper needed a uniform material on which to test the abrasive qualities of the sandpaper. The engineer investigated the possibility of using plastic blocks and


FIGURE 23.6   Flow diagram for gage control.

found that the plastics manufacturer was using the same sandpaper as a means of testing the toughness of the plastic. For some of these materials, the suppliers could provide data on variability. For the rest, it was necessary to discover the variability through analysis, as discussed earlier under Error of Measurement.

Inventory and Classification.   A systematic approach to calibration control starts with a physical inventory of all standards, instruments, and test equipment. (Where tooling is used as one of the means of product inspection, such tooling is commonly included in the list of items to be systematically controlled for accuracy.)

For each item that is to enter the system, a database record is created. This record contains the historical origin of the item, its assigned serial number, the checking schedule, and related information. The record is also designed to accommodate information on the results of checking and the repairs needed [see also Woods (1978)]. The physical test equipment is also marked with an assigned serial number for identification and traceability in the system.

Calibration Schedules.   These are established by class of equipment and are varied to reflect precision, nature, and extent of use and still other factors. At the outset, these schedules are established by judgment and bargaining. Later, as data become available on the results of checking, it becomes feasible to change the schedules in the interest of greater effectiveness and economy.

The broad intent of calibration schedules is to detect deterioration beyond tolerable levels of accuracy. This deterioration takes place primarily though use and secondarily through the passage of time. As a result, the calibration schedules describe the extent of use or of elapsed time in several ways:

1. *Elapsed calendar time.*   This method is in widest use. It establishes a fixed calendar time, e.g., 3 months, as a checking interval. At the end of the 3 months, steps are taken to check the equipment in accordance with schedule.

2. *Actual amount of use.*   This is based on counting the actual use, e.g., number of units of product checked by the equipment. The count may be made (*a*) manually, by the inspectors, (*b*) through automatic counters installed in the equipment, or (*c*) by programming the computers to show the amount of testing performed based on production schedules.

3. *Test accuracy ratio* (*TAR*) *control.*   This is a systems approach that analyzes the degree to which interrelated parameters are identified and controlled within a *traceability cone.* Minimum TARs for each traceable parameter are measured and controlled [see also Tobey (1979)].

Adherence to Schedule.   This vital detail makes or breaks the entire system of calibration control. Generally, the transfer standards and most working standards pose no problem of adherence to schedule, since they are in the custody of a few standards laboratories and a relatively few associated technicians. In contrast, the test equipment (and some working standards) are widely scattered over numerous locations and are in the custody of thousands of workers, inspectors, and testers. Some of these individuals can be relied on to see that the checking schedule is followed, but many cannot.

In part, the problem is one of lack of knowledge of when the recalibration is due. The shop personnel require the aid of a memory system if they are to know which piece of equipment is due to be checked that day. They may recall what the checking intervals for each class of equipment are, but they cannot recall what the date of the last calibration was.

Some systems for adherence to schedule make use of ingenious color codes or labels that mark on each unit of equipment the date it was put back into service. (These codes are often extended to identify the grades of the standards themselves, whether primary, secondary, etc.) For large units, the expiration date also may be entered on a maintenance card that is attached to the unit. Such dates are an aid to personnel for adhering to the checking schedule.

However, an added problem is that of motivation. The numerous users of test equipment are quite concerned with recalibration when trouble is encountered but less concerned when things seem to be going smoothly. In these latter cases, interruptions for calibration can even be a nuisance.

The solution is to give responsibility (for adherence to schedule) to the standards laboratory rather than to the production, inspection, and test personnel. When this proposal is made to practicing managers, they seldom accept it purely on grounds of theory of organization. However, when it is proposed that a sample of instruments be taken at random and checked for calibration (as a test of the existing "system" of calibration control), these same managers are quite willing to conduct such a test. The resulting disclosure of the actual state of calibration of the sample (of 25 to 100 instruments) is then decisive in convincing the managers of the need for a revision in the system of adherence to schedule. Under this assignment, thelaboratory organizes a plan of checking that will keep up with the scheduled load [see also Gebhardt (1982)].

In administering the checking plan in the time-interval system, the database is queried, using the calibration dates, to provide a list showing which standards and equipment are due to be checked in the forthcoming week.

Calibration Practice.   To ensure accuracy and to establish traceability, control laboratories have evolved some widely used procedures. Individual responsibility is established by requiring that all concerned sign for their actions. The equipment record, retained either in hardware or software, carries these signatures, as do the labels on the equipment. Dates are recorded for all actions in view of the role of elapsed time in the calibration procedures.

Manuals of practice are established, including tolerances for accuracy and methods to be used in calibration. In some types of test, these methods must be spelled out in detail, e.g., temperature or

humidity controls, time cycle, human technique, etc. (Witness the detail of some of the ASTM standards on test method.)

Training programs are established for personnel, including (in some cases) formal qualification certificates to attest to proficiency. Equipment is tamperproofed through sealing the adjusting screws. (The seals are then imprinted with the stamp of the laboratory.) In like manner, panels and drawers of test equipment are lock-wired, and the wires are lead-sealed together. (The laboratory takes no responsibility when seals are broken, and the company takes stern measures against tampering with the seals.) As a means of assisting enforcement, quality assurance audits are conducted to review the calibration control procedures.

Record and Analysis of Results.   It is most useful to keep a record of the results of checking calibration and of the extent of work done to restore accuracy. Typically, such a record lists

Observed deficiencies in the equipment

Causes of out-of-calibration conditions

Repair time and recalibration time

Periodic analysis of these data then becomes the basis for

1. Reducing checking for equipment shown to be stable
2. Redesigning equipment to eliminate causes of repetitive failure

Organization for Calibration Control.   Ensuring that measuring devices are calibrated correctly is critical to ensure that product is conforming to the customer's requirements. The best inspector is only as good as his or her gages. If the gage is in error, then we could reject good parts or accept bad parts. Both results are costly to the company; both send a message to the customer that the company does not have a basic control system.

A technician trained in metrology—the science of gaging—is the determining factor in the accuracy of the gage by calibrating to a recognized master, traceable in the United States to the National Institute of Standards and Technology or similar international organization. The calibration process is performed by following a set of test procedures developed for scientific instruments.

The quality system can elect to calibrate all measuring devices in house, send them to a commercial calibration service, return the device to the original manufacturer, or a combination of all of the above. The determining factor is usually based on master calibration up-front cost, frequency of needed calibration control, and turnaround time of outside source.

Regardless of how the actual calibration function is allocated, the frequency of calibration of each measurement device must be specified by a sytematic calibration frequency program. This program defines the categories of inspection, measuring, and test equipment to be covered and assigns responsibility for operating the program and maintaining records.

There are no standard rules and no body of knowledge that dictate how often measuring instruments should be inspected. The determining factors of calibration are use and mishandling (Palumbo 1997).

Physical design of the laboratory workplace has been greatly complicated by the proliferation of many varieties of specialized testing: ultrasonic, x-ray, vibration, shock, acceleration, heat, humidity, etc. The details of these designs are beyond the scope of this handbook. The practitioner must consult with the available experts: equipment manufacturers, researchers, metrologists, and still others. This must be a continuing process, since there is continuing progress in development of new tests and standards.

HUMAN FACTORS IN INSPECTION

A myriad of factors can influence inspector behavior; they are summarized by Baker (1975), as shown in Table 23.9. One factor, visual acuity or sight, is the dominant sense in human beings, and

great reliance is placed on it in inspection tasks. The effectiveness of the use of sight depends largely on eye movements that bring the images of significant features of the material being inspected to the most sensitive part of the retina. However, experience and studies have shown that the other factors in Table 23.9 have an interrelated effect on the effectiveness, productivity, reliability, and accuracy of the inspector. [See Megaw (1978) for related studies carried out in a textile factory.]

A detailed discussion of inspector errors below follows the discussion on human factors; however, it appears appropriate to first discuss the techniques and measurements developed to improve the reliability of the inspection function.

Machine Vision.   The term *machine vision,* or *noncontact inspection,* is applied to a wide range of electrooptical sensing techniques from relatively simple triangulation and profiling to three-dimensional object recognition and bin picking, techniques based on sophisticated computerized image-analysis routines. The applications are broad, ranging from relatively simple detection and measuring tasks to full-blown robot control. (See Table 23.10.)

The incentive to introduce machine-based systems, e.g., robots, is obvious—to eliminate human error. [See Spow (1984) for a discussion of robots in an automatic assembly application.] The key influences behind the growth of the machine-vision industry also include inspector capability, inspector productivity, and inspection costs. [See also Nelson (1984) for a review of machine-vision equipment, some designed to eliminate process contamination, in addition to human error.] Table 23.11 discusses these factors as they relate to inspecting printed circuit boards. [See Ken (1984) for a detailed discussion of automated optical inspection (AOI) of printed circuit boards (PCB); see also Denker (1984) for a detailed discussion on justifying investments in automatic visual PCB testing.]

Vision-based systems—human or machine—involve an inspection procedure: the examination of a scene. The examination, in turn, can lead to recognition of an object or feature, to a quality decision, or to the control of a complex mechanism (Schaffer 1984). When a human inspector is involved, human judgment and perception have an influence on the quality assessment process.

The most common application for vision systems involves measuring critical dimensions, detecting flaws, counting/sorting, assembly verification, position analysis, character or bar-code reading/verification, and determination of presence/absence of features on small parts.

TABLE 23.9   Variables Influencing Inspector Behavior

1. Individual abilities
   a. Visual activity
   b. General intelligence and comprehension
   c. Method of inspection
2. Task
   a. Defect probability
   b. Fault type
   c. Number of faults occurring simultaneously
   d. Time allowed for inspection
   e. Frequency of rest periods
   f. Illumination
   g. Time of day
   h. Objective of conformance standards
   i. Inspection station layout
3. Organizational and social
   a. Training
   b. Peer standards
   c. Management standards
   d. Knowledge of operator or group producing the item
   e. Proximity of inspectors
   f. Reinspection versus immediate shipping procedures

TABLE 23.10 Machine-Vision Applications

1. Inspection
   a. Dimensional accuracy
   b. Hole location and accuracy
   c. Component verification
   d. Component defects
   e. Surface flaws
   f. Surface-contour accuracy
2. Part identification
   a. Part sorting
   b. Palletizing
   c. Character recognition
   d. Inventory monitoring
   e. Conveyor picking (overlap, no overlap)
   f. Bin picking
3. Guidance and control
   a. Seam-weld tracking
   b. Part positioning
   c. Processing/machining
   d. Fastening/assembly
   e. Collision avoidance

TABLE 23.11 Selected Example of Factors and Effect of Automated Optical Inspection (AOI) on Printed Circuit Board

Manufacturing inspection costs	Inspection accounts for up to 30 percent of the manufacturing costs of complex double-sided and multilayer boards.
Inspection capability	Human inspection capability decreases well before 5 mil because of fatigue
Inspection productivity	AOI reduces the number of inspections from 30 to 7 per shift while obtaining a 1 percent yield improvement and fivefold increase in inspection speeds.

If parts are moving and not indexed, an electronic shutter camera may be needed. Many systems can handle randomly oriented parts, but throughput rates will be lower than for fixtured parts, and if the need is to inspect more than one side or area of the parts, separate cameras may be required.

Repetitive Function.   In highly repetitive subjective inspection (e.g., inspecting parts on an automated paint line), the process of perceiving can become numbed or hypnotized by the sheer monotony of repetition. In some way the scanning process and the model become disconnected, and the observer sees only what he or she expects to see but does not see anything not actively expected. The situation often can result in bad parts passing through the process and should be evaluated closely for effectiveness before being initiated. The known remedies are

- Break up the benumbing rhythm with pauses.
- Introduce greater variety into the job.
- Increase the noticeability of the faults through enhancing.
- Provide background and contrast cues.
- Arrange for frequent job rotation.

Vigilance becomes a big problem when faults are obvious and therefore serious but infrequent and unpredictable. What traveler has not wondered about the protection provided by 100 percent x-ray and metal-detection inspection of airline passenger carryon baggage and personal effects? In 1993, an audit by the U.S. General Accounting Office of airport security measures in the United States revealed the ease with which the "secure" areas of America's airports could be penetrated. Of the hundreds of attempts to breach security, 75 percent were successful; some of these successes were attributable to a failure of 100 percent inspection. The auditing agent who succeeded in passing a live hand grenade through the screening system provided an especially troublesome example (Gleick 1996).

INSPECTION ERRORS

The inspector, as the human element in the inspection process, contributes importantly to inspection errors. Inspection errors due to the inspector, called *inspector errors,* are discussed here. The reliability of the human inspector was discussed previously under human factors (as opposed to noncontract machine inspection or the machine-vision system). Other sources of inspection error, e.g., vague specifications, lack of standards, inaccurate instruments, etc., are discussed elsewhere in this handbook. (*Note:* The problem of human error is common to operators, inspectors, and anyone else. For an extensive discussion of problems of worker error, see Section 22, under Concept of Controllability: Self-Control.)

Inspector errors are of several categories:

Technique errors

Inadvertent errors

Conscious errors

Each of these categories has its own unique causes and remedies. Collectively, these inspector errors result in a performance of about 80 percent accuracy in finding defects; i.e., inspectors find about 80 percent of the defects actually present in the product and miss the remaining 20 percent. [*Note by the editor (Juran*): Numerous studies in various countries have yielded the 80 to 20 ratio as a broad measure of quantified inspector accuracy. For example, Konz and coworkers (1981) found that inspectors were only catching about 80 percent of the defects in glass subassemblies.] However, little is known about the relative importance of each category of inspector error (e.g., lack of technique, inadvertence, conscious). For further discussion, see Tawara (1980).

Technique Errors.   Into this category are grouped several subcategories: lack of capacity for the job, e.g., color blindness; lack of knowledge due to insufficient education or job training; and lack of "skill," whether due to lack of natural aptitude or to ignorance of the knack for doing the job. Technique errors can be identified in any of several ways:

Check Inspection.   A check inspector reexamines work performed by the inspector, both the accepted and rejected product. Figure 23.7 shows an example of the results of such check inspection of the work of several inspectors. It is evident that inspectors C and F operate to loose standards, whereas inspector B operates to tight standards. Inspector E shows poor discrimination in both directions.

Round-Robin Inspections.   In this analysis, the same product is inspected independently by multiple inspectors. The resulting data, when arrayed in a matrix (usually with defect type along one axis and the inspectors along the other axis), shows the defects found by each inspector in relation to the inspectors as a group.

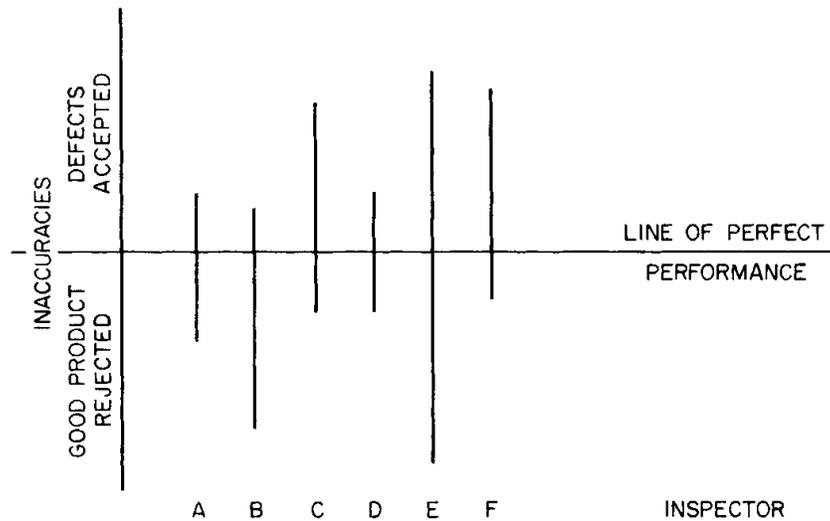
Repeat Inspections.   In this method, the inspector repeats his or her own inspection of the product without knowledge of his or her own prior results. The analysis of the resulting data discloses the extent of the consistency or lack of consistency of the inspector's judgments.


FIGURE 23.7   Analysis of inspection errors.

Standard Sample Array.   In this method, the inspector makes an "examination" by inspecting a prefabricated mixture of product consisting of good units plus various kinds of defects. The standard sample array is known by various names, including *job sample*. For added discussion, refer to Harris and Chaney (1969). All units were previously carefully graded by a team of experts and numbered for ready analysis of results. The inspector's score and his or her pattern of errors all point to the need, if any, for further training or other remedial steps. (In effect, the check inspection is conducted before the inspection.)

For example, in a company making glass bottles, an attempt was made to correlate process variables with the frequency and type of defects found by inspectors stationed at the cold end of the annealing lehr. The experiment failed because inspector variability from shift to shift exceeded product variability. This also threw suspicion on the accuracy of the inspection performed by the final product sorters at the end of the line. A standard sample array of 500 bottles was created and was used to examine the inspectors. (The examinations were conducted in the Training Department on a miniature lehr.) The suspicions turned out to be well founded (consulting experience of J. M. Juran).

Remedies for Technique Errors.
The need is to provide the missing skill or know-how and to answer the inspector's proper question, "What should I do differently from what I am doing now?" Unless the inspector is in a position to discover the answer for himself or herself, the answer must be provided by management. If no answer is provided, there will be no change in performance.

The various methods of analysis discussed earlier all can provide some clues that suggest the type of remedial action needed. In particular, use can be made of the concept of finding the knack. Under this concept, the data on inspector performance are analyzed to discover which inspectors give consistently superior performances and which are inferior. Next, a study is made of the work methods used by both types of inspectors to identify the differences in methods. Analysis of these differences often discovers what is the secret know-how (knack) being used to get the superior performance (or what is the secret ignorance that results in poor performance). Finally, the knack can be transferred to all inspectors through retraining (Czaja and Drury 1981 and Cooper 1980) or through being embodied in the technology (Kusch 1979).

Where the technique errors are the result of lack of job capacity, the foregoing may be of no avail, and the need may be to foolproof the operation (see below) or to reassign the inspector to a job for which he or she does have adequate job capacity.

Certification of Inspectors.   In critical inspections involving inspector judgment (e.g., interpreting x-rays of critical welds), it is increasingly the practice to require that the inspector be formally certified as qualified to do this job. [See Gibson (1983) for a further discussion of inspector qualifications in offshore industries.] The qualification process follows a well-standardized series of steps:

A formal training program on how to do the job

A formal examination, including a demonstration of successful performance of the job

A formal certificate attesting to the success in the examination

A license to do the job for some designated period of time

A program of audit to review performance and to serve as a basis for renewing the license

In some companies this concept of certification has been based on the "escape rate," i.e., the extent to which defects escape detection, as determined by subsequent check inspection. (See Measure of Inspector and Test Accuracy, below.) When this concept is used, a limited "license" (e.g., 2 months) is given to the inspector, subject to renewal if check inspection results continue to be favorable.

Inadvertent Inspector Errors.   These errors are characterized by the fact that at the time the error is made, the inspector is not even aware he or she is making an error. Also, the best intentions are present—the inspector wants not to make any errors. The term *inadvertent* or *unavoidable* is used to connote the fact that the human being is simply unable to achieve perfection, no matter how good his or her intentions. (This topic is closely related to inadvertent worker errors. For added discussion, see Section 5, under Inadvertent Errors.)

The theory of inadvertence has wavered up and down. For years it was the sincere belief of many inspection supervisors that when product was inspected 100 percent, the inspectors would find all the defects. Numerous unpublished and published studies have since demonstrated that human inspectors do not find all defects present. By and large, the human inspector finds about 80 percent of the defects present and misses the remaining 20 percent.

While the 80 to 20 ratio is widely accepted, there are numerous aspects that are not fully researched, i.e., how this ratio changes with percentage defective in the product, with types of inspection (e.g., visual, mechanical gaging, electrical testing), with product complexity, with amount of time allotted for inspection, etc. For a discussion from the viewpoint of human factors plus some supporting data (e.g., that increased product complexity results in increased inspector error), see Harris and Chaney (1969, pp. 77–85).

Inspection fallibility can be demonstrated easily in the industrial classroom. The following sentence has been used thousands of times:

FEDERAL FUSES ARE THE RESULTS OF YEARS OF SCIENTIFIC STUDY COMBINED WITH THE EXPERIENCE OF YEARS

The sentence is flashed before the audience for 30 s or for a full minute. Each member is asked to count and record the number of times the letter *F* appears. When the record slips are collected and tallied, the result is invariable. Of the *F*'s present, only about 80 percent have actually been found.

The existence of so extensive an error rate has stimulated action on several fronts:

1. *To discover why inspectors make these errors.*   To date, the research has not been adequate to provide conclusive answers, so industrial psychologists have not agreed on what the main causes are.

2. *To measure the extent of the errors.*   Techniques for this are now available. See Measure of Inspector and Test Accuracy, below.

3. *To reduce the extent of these errors.*   There is a wide assortment of remedies, as discussed below.

Remedies for Inadvertent Inspector Errors.   In the absence of convincing knowledge of the causes of these errors, managers have resorted to a variety of remedies, all involving job changes in some form. These remedies include the following:

Error-Proofing.   There are several forms of error-proofing that are widely applicable to inspection work: redundancy, countdown, and fail-safe methods. These are discussed in detail in Section 22, Operations, under Error-Proofing the Process. See also Inspection Planning, above.

Automation.   This is really a replacement of the repetitive inspection by an automation that makes no inadvertent (or other) errors once the setup is correct and stable. The economics of automation and the state of technology impose severe limits on the application of this remedy. See Automated Inspection, above.

Sense Multipliers.   Use can be made of optical magnifiers, sound amplifiers, and other devices to magnify the ability of the unaided human being to sense the defects. Development of a new instrument to do the sensing is the ultimate form of this multiplication. Evidently there is an optimum to the level of magnification, and this optimum can be discovered by experimentation. [For some industrial studies, see Harris and Chaney (1969, pp. 124–126, 137–142).]

Conversion to Comparison.   In many types of inspection, inspectors must judge products against their memories of the standard. When such inspectors are provided with a physical standard against which to make direct comparison, their accuracy improves noticeably. For example, in the optical industry, scratches are graded by width, and tolerances for scratches vary depending on the function of the product element (lens, prism, etc.) To aid the inspectors, plates are prepared exhibiting several scratches of different measured widths so that the inspectors can compare the product against a physical standard.

Standards for comparison are in wide use: colored plastic chips, textile swatches, forging specimens, units of product exemplifying pits and other visual blemishes, etc. Sometimes photographs are used in lieu of product. There are also special optical instruments that permit dividing the field of view to permit comparison of product with standard.

In some cases it is feasible to line up units of product in a way that makes any irregularities become highly conspicuous, e.g., lining up the holes in a row. (The childhood row of tin soldiers makes it obvious which one has the broken arm.) Some practitioners advocate inspecting units of product in pairs to utilize the comparison principle. See Shainin (1972) for further discussion.

Templates.   These are a combination gage, magnifier, and mask. An example is the cardboard template placed over terminal boards. Holes in the template mate with the projecting terminals and serve as a gage for size. Any extra or misplaced terminal will prevent the template from seating properly. Missing terminals become evident because the associated hole is empty.

Masks.   These are used to blot out the view of characteristics for which the inspector is not responsible and concentrate attention on the real responsibility. Some psychologists contend that when the number of characteristics to be inspected rises to large numbers, the inspector error rate also rises.

Overlays.   These are visual aids in the form of transparent sheets on which guidelines or tolerance lines are drawn. The inspector's task of judging the size or location of product elements is greatly simplified by such guidelines, since they present the inspector with an easy comparison for judging sizes and locations.

Checklists.   These may be as simple as a grocery shopping list used to verify that you purchased all the items you originally planned to buy. At the other extreme, a checklist may consist of the countdown for the lofting of a new space shuttle. [See Walsmann (1981) for a discussion of the purpose, advantages, and drawbacks as well as the development and implementation of various checklists.]

Reorganization of Work.   One of the theories of cause of inadvertent inspector errors is fatigue, due to inability to maintain concentration for long periods of time. Responses to this theory have been to break up these long periods in any of several ways: rest periods, rotation to other inspection operations several times a day, and job enlargement, e.g., a wider assortment of duties or greater responsibility. Some behavioral scientists urge reorganization of work on the broader ground of motivation theory, and they offer data to support this theory [see generally Harris and Chaney (1969, pp.

201–229)]. However, to date, there is no conclusive evidence that in Western culture reorganization of work (to provide greater participation, etc.) will give measurably superior results in work accomplishments. (See, in this connection, *Quality Control Handbook,* 4th ed., Section 10, under Processing System Design.)

Product Redesign.   In some instances the product design is such that inspection access is difficult or that needless burdens are placed on inspectors. In such cases, product redesign can help to reduce inspector errors as well as operator errors. For some examples, see Section 22, Operations, under Error-Proofing the Process. [See also Smith and Duvier (1984).]

Errorless Proofreading.   Beyond the techniques described in Section 22, Operations, under Error-Proofing the Process, there are special problems of error-proofing in inspection work. A major form of this is proofreading of text of a highly critical nature, i.e., critical to human safety and health. In such cases, the low tolerance for error has driven many companies to use redundant checking, despite which some errors still get through.

A closer look makes it clear that proofreading is of two very different kinds:

1. *Passive proofreading.*   Here, the proofreader takes no overt action. For example, he or she silently reads the copy while someone else reads the master aloud. Alternatively, the proofreader silently reads both documents and compares them. In such cases it is quite possible for extraneous matters to intrude and dominate his or her attention temporarily.

2. *Active proofreading.*   Here, the proofreader must take an overt action, e.g., he or she reads aloud, performs a calculation, etc. Such positive actions dominate the proofreader's attention and reduce the chance of error.

For a second example, in blood donor centers it was once usual to remove the whole blood from the donor, take it to a separate location, centrifuge it to remove a desired component, and then return the remaining fraction of the blood to the donor. This return demanded absolute assurance that the remaining fraction was being returned to that donor and to no one else. The system used involved piping both the donation and the return through tubing on which there were repeats of 10-digit numbers. The tubing was cut when the donation went to the centrifuge. Prior to return of the cells, two technicians checked to compare the two 10-digit numbers on the two ends of the cut tubing. One technician actively read the number on the tubing end attached to the donor. The other technician passively listened while comparing the number he or she heard with the number seen on the end of the tubing that was attached to the bag of blood cells.

It was sometimes feasible to use technology to make both technicians "active." For example, where the equipment was available, each was required to enter on a keyboard the number he or she saw. These signals went to a computer that compared the two numbers and signaled either a go-ahead or an alarm. This same principle of comparing two independent active sets of signals can be extended to any problem in proofreading.

Today another technology has eliminated altogether the need for this application of proofreading. The donor is now usually linked directly to the separating equipment. The blood is drawn from one arm, mixed with an anticoagulant, and passed through a separating machine that collects the specific component. The remaining blood components are returned to the donor in the opposite arm (Sataro 1997).

While the foregoing are listed as remedies for inadvertent inspector errors, most of them also can be used to reduce errors due to lack of skill or errors of a willful nature.

Procedural Errors.   Aside from inadvertent failures to find defects, there are inadvertent errors in shipment of uninspected product or even shipment of rejected product. These errors are usually the result of loose shipping procedures. For example, a container full of uninspected product may be moved inadvertently in with the inspected product; a container full of defectives may be moved inadvertently into the shipping area. Such errors can be reduced by error-proofing the identification and shipping routines:

1. The inspector must *mark the product* at the time of inspection. Sometimes the inspector places the good product in one box and the bad product in another or places the good product lengthwise and the bad product crosswise. Lacking the markings, there is always the risk that between shifts, during rest periods, etc., the unmarked product will go to the wrong destination.

2. The product markings should be so distinctive that the product "screams its identity" to packers and shippers. Bar codes should be used where appropriate.

3. The colors used for markers that identify good product should be used for no other purpose. These markers should be attached only when the inspector finds that there remains nothing to be done but ship the product.

4. Issuance of markers used to identify good product should be restricted to specially chosen personnel. (These markers are a form of company seal.) For products of substantial value, serial numbers may be used as a further control.

5. The markers should provide inspector identity. In some companies, the system of identification includes the operators and packers.

6. Shipping personnel should be held responsible for any shipment of goods failing to bear an inspector's approval.

Conscious Inspection and Test Errors

Management-Initiated. The distinguishing features of the willful inspector error are that the inspector knows that he or she is committing the error and intends to keep it up. These willful errors may be initiated by management, by the inspector, or by a combination of both. However, with few exceptions, the major notorious quality errors and blunders have been traceable to the decisions of managers and engineers rather than to those of the inspectors at the bottom of the hierarchy. Management-initiated errors take several forms, all resulting in willful inspector errors.

Conflicting Management Priorities. Management's priorities for its multiple standards (quality, cost, delivery, etc.) vary with the state of the economic cycle. When the state of management priorities is such that conformance to quality standards is subordinated to the need for meeting other standards, the inspectors' actions are inevitably affected, since they also are given multiple standards to meet.

Management Enforcement of Specifications. When management fails to act on evidence of nonconformance and on cause of defects, the inspectors properly judge management's real interest in quality from these deeds rather than from the propaganda. For example, if the supervision or the material review board consistently accepts a chronic nonconformance condition as fit for use, the inspectors tend to quit reporting these defects, since they will be accepted anyhow.

Management Apathy. When management makes no firm response to suggestions on quality or to inspector complaints about vague information, inadequate instruments, etc., the inspectors again conclude that management's real interests are elsewhere. Consequently, the inspectors do the best they can with information and facilities that they believe to be deficient.

Management Fraud. Periodically a company manager attempts to deceive customers (or the regulators, etc.) through fictitious or deceitful records on quality. Seldom can a manager acting alone perpetrate such a fraud. The manager requires confederates who submit themselves to orders, usually in a way that makes clear to them the real character of what is going on. An inspector who is a willing accomplice (e.g., for a bribe) shares in the legal responsibility. However, the inspector also may be a most reluctant accomplice, e.g., an immediate superior gives orders to prepare nonfactual reports or to take actions clearly contrary to regulations. In such cases the inspector cannot escape taking some kind of risk, i.e., participation in a conspiracy versus the threat of reprisal if he or she

fails to participate. These management-initiated errors parallel closely those associated with conscious worker errors. See Section 22, Operations, under Concept of Controllability: Self-Control.

Inspector-Initiated.   These errors likewise take multiple forms, and some take place for "good" reasons. It is important to understand the distinctions among these forms, since any misunderstandings are a breeding ground for poor industrial relations.

Inspector Fraud.   The inspector is subjected to a variety of pressures. The most rudimentary forms are those by production supervisors and operators pleading for a "break." Sometimes this extends to a collusion where piecework payments are involved, both for quality and for quantity certification. At higher levels are cases in which an inspector is exposed to suppliers who have a good deal at stake in the lot of product in question. Even a situation in which inspectors dealing directly with production supervisors who outrank them involves substantial pressures to which inspectors should not be subjected.

Another form of inspector fraud consists of reporting false results solely to improve the outward evidence of one's own efficiency or to make life more convenient. For example, Figure 23.8 shows the results reported by an inspector after taking a sample of n pieces from each of 49 lots. There is a large predominance of three defects per lot reported in the sample (exactly the maximum allowable number). The reason was found to be the inspector's reluctance to do the paperwork involved in a lot rejection.

In the example in Figure 23.9, the inspector was to take a sample of 100 pieces from each lot, with no defects allowable. If one or more pieces were defective, an added sample of 165 pieces was to be taken, with a total of 3 defects allowed in the combined sample of 265. It is seen that the inspector reported defects in virtually every first sample of 100 pieces.

However, no defects were reported in most of the second (larger) samples. It was found that the inspector could improve personal efficiency by taking second samples, since the time allowance for taking the second samples was liberal. Inspector fraud can be minimized by

FIGURE 23.8   Inspector error made for personal convenience.

1. Filling inspection jobs only with persons of proved integrity

2. Restricting the down-the-line inspector to the job of fact finding, and reserving to the inspection supervision the job of negotiating and bargaining with other supervisors or executives

3. Rotating inspectors and workers to have both employee categories evaluate first hand the consequences of actions and decisions

4. Including inspectors in customer presentations or visits

5. Conducting regular check inspections and periodic independent audits to detect fraud

6. Taking prompt action where fraud is discovered

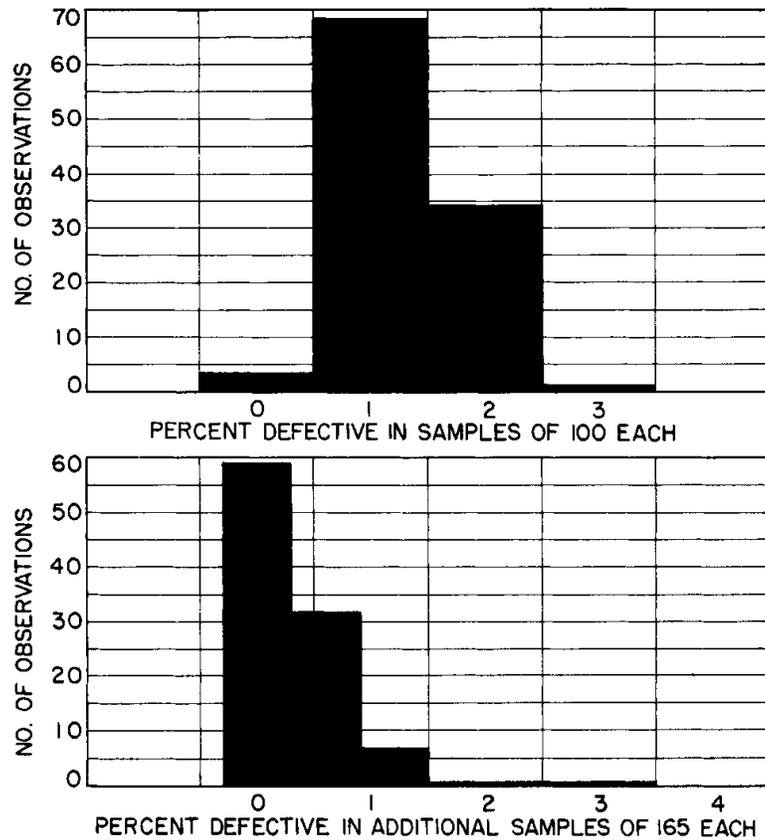
Inspector Shortcuts.   These may be unauthorized omissions of operations that the inspector has reason to believe are of dubious usefulness; e.g., accidental omissions had failed to give evidence of trouble. In some cases there is a shared blame; i.e., management has imposed a highly disagreeable task. For example, in a company making "tin cans," one inspection involved cutting up a can with hand-held tin shears, submerging the pieces in chloroform to remove the enamel, and measuring the thickness of the bare pieces with a micrometer. The cutting process was tedious and the chloroform


FIGURE 23.9   Inspector error made to improve personal efficiency.

was irritating to the skin, so the inspectors avoided the operation as much as possible. When better cutting tools and a different solvent were provided, the problem became minimal.

Flinching.   This is the tendency of inspectors to falsify the results of inspection of borderline product. Flinching is actually widespread among all persons who report on performance versus goals and especially when it is their own performance. Figure 23.10 shows a frequency distribution of measurement on volume efficiency of electronic receivers. There is an "excess" of readings at the specification maximum of 30, and there are no readings at all at 31, 32, or 33. Retest showed that the inspector recorded these "slightly over" units of product at 30. By this flinching, the inspector, in effect, changed the specification maximum from 30 to 33. This is a serious error (Juran 1935).

Flinching during variables measurements is easy to detect by check inspection, which is also conducted on a variables basis. Analysis of the inspector's variables data likewise will detect flinching (as in the preceding example).

The remedy for flinching is an atmosphere of respect for the facts as the ethical foundation of the Inspection Department. The main means for achieving this are examples set by the inspection supervisors.

One way *not* to deal with flinching is to criticize the inspector on the basis that the pattern of readings does not follow the laws of chance. Such criticism can be interpreted as being aimed at the symptom (the unnatural pattern of reading) rather than the disease (recording fictitious instead of factual readings). The risk is that inspectors will try to meet such criticisms by trying to make the false results look more natural, hence eliminating the symptom but not the disease.

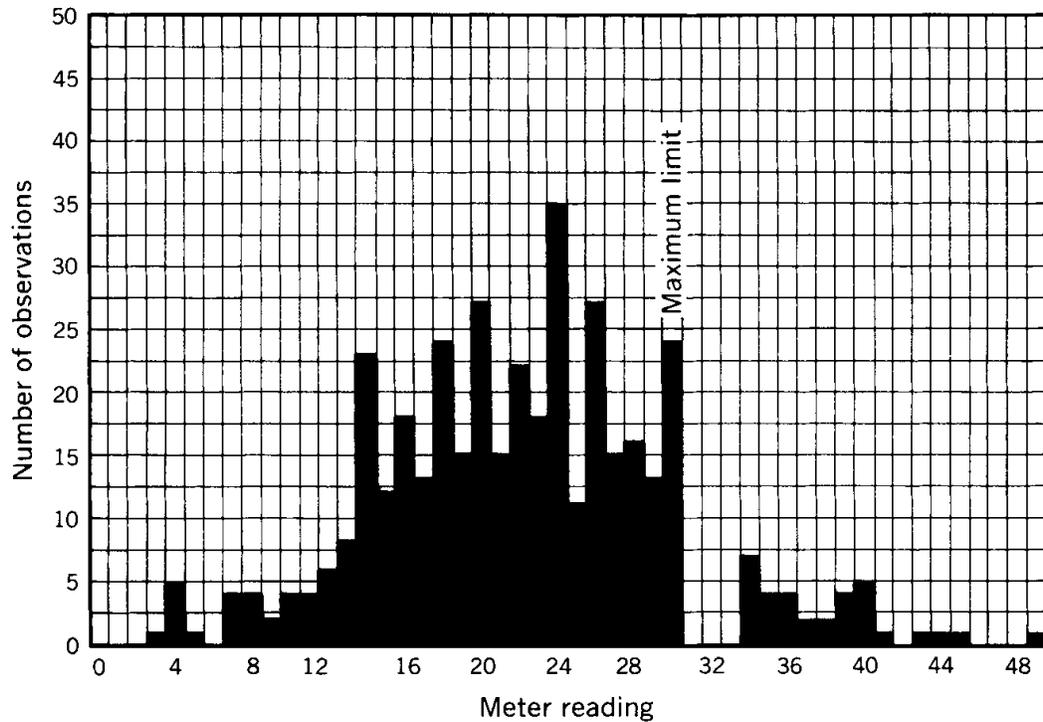
Flinching also takes place during attribute inspection. Numerous studies have shown that inspector errors in rejecting good product outnumber the errors of accepting bad product. In part, this arises because the good product outnumbers the bad and hence affords greater opportunity for error. However, it also arises in part from the fact that acceptance of defects often comes dramatically to the attention of higher management, whereas rejection of good product seldom does so. These same


FIGURE 23.10   How inspector flinches at design limit.

studies show that when check inspection is introduced and check is made both of product rejected and of product accepted, the rejection of good product is reduced without affecting the acceptance of bad product.

Another form of flinching is to modify the inspection results to conform to the results that the inspector expects. For example, a visual inspection was being performed following a specified lapping operation. An experiment to omit the lapping operations, conducted without inspector awareness of omission of the operation, resulted in rejection of less than a third of unlapped product.

In some cases, flinching by inspectors is actually management-initiated through manager pressures that seem to the inspectors to leave no alternative. In one company, the inspectors making hardness tests were discovered to be flinching to an astonishing degree. This practice had been going on for years. It developed that the manufacturing vice president had designed this hardening process himself when he was the process engineer. At the time, he had deluded himself as to its capabilities and thereby had been the author of this long-standing practice (Juran, early consulting experience).

Rounding Off.   The process of dispensing with unneeded accuracy is generally referred to as *rounding off.* Inspectors commonly round off their meter readings to the nearest scale division, as shown in Figure 23.11. The effect of rounding off is seen in the "picket fence" frequency distribution of Figure 23.10.

Rounding off is easy to detect from analysis of inspection data. A good analyst can, from the data alone, reconstruct the pattern of scale markings of an instrument without ever having seen the scale itself.

Rounding off is often a good thing, since it avoids undue attention to individual readings. Sometimes, however, the need for precision on individual readings is great enough that rounding off should not be practiced. The planner and inspection supervisor should be on the alert to identify situations in which rounding off is not tolerable, and they should provide accordingly.

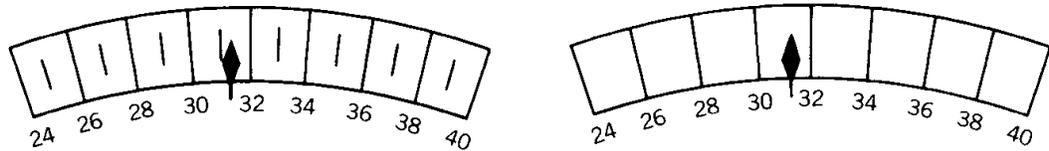
Instruments and gages should be selected properly for the application. [Churchill (1956) gives a quantitative discussion on scale interval length and pointer clearance.] One practice is to require "readings to be recorded to the nearest . . . . "


FIGURE 23.11   Rounding off.

Measure of Inspector and Test Accuracy.   The collective effect of inspector errors, from all causes, is so extensive that there is a need for measuring the extent of errors and for use of the data in controlling the effectiveness of inspectors. If this measurement is made only occasionally, use can be made of standard sample arrays (see above, under Technique Errors) and cross-check among inspectors, as well as check inspection. If the measurement is to be conducted regularly so as to discover trends in performance, then check inspection is necessary.

In conventional check inspection, a second inspector, i.e., a check inspector, reviews the decisions of the inspector by reexamining the product after it has been inspected. For an early example, refer to Taylor (1911). The best practice is to reexamine the rejected product as well as the accepted product.

Inspection errors may consist of accepting defective units of product or rejecting good units of product. If, in addition, the check inspection reviews the procedure followed by the inspector, other errors may be found, e.g., use of wrong issue of the specification, wrong instrument, improper filling out of documents, etc.

The convenient use of check inspection data to quantify inspector accuracy is to count the errors, to assign weights, and to use the composite of errors as an index of accuracy (of inaccuracy, usually). [See, for example, Gilman (1963).] In some schemes, the errors discovered in later operations or in customer complaints are included in the data. The composite of errors may be expressed in terms of percentage defective (found to exist in the inspected product) or in terms of demerits per unit. [Refer to Weaver (1975), which reports on a study of inspector accuracy during the production process, based on accept/reject decisions involving the product currently produced.] Either way, the scoring system is open to the objection that the inspector's accuracy depends, to an important degree, on the quality of the product submitted to him or her by the process; i.e., the more defects submitted, the greater is the chance of missing some.

A plan for measuring inspectors' accuracy in a way that is independent of incoming quality is that evolved in 1928 by J. M. Juran and C. A. Melsheimer. [See Juran (1935) for the original published description of this plan.] Under this plan, the check inspector, as usual, reexamines the inspected product, both the accepted and the rejected units.

In addition, the check inspector secures the inspector's own data on the original makeup of the lot, i.e., total units, total good, total defective. From these data, the following formulas emerge as applied to a single lot, which has been check inspected:

Accuracy of inspector = percent of defects correctly identified

$$= \frac{d - k}{d - k + b}$$

where d = defects reported by the inspector
     k = number of defects reported by the inspector but determined by the check inspector not to be defects
     $d - k$ = true defects found by the inspector
     b = defects missed by the inspector, as determined by check inspection
     $d - k + b$ = true defects originally in the product

Figure 23.12 illustrates how the percentage of accuracy is determined. The number of defects reported by the inspector, d, is 45. Of these, 5 were found by the check inspector to be good; that is,

$k = 5$. Hence $d - k$ is 40, the true number of defects found by the inspector. However, the inspector missed 10 defects; that is, $b = 10$. Hence the original number of defects, $d - k + b$, is 50, that is, the 40 found by the inspector plus the 10 missed. Hence

$$\text{Percentage of accuracy} = \frac{d - k}{d - k + b} = \frac{45 - 5}{45 - 5 + 10} = 80\%$$

In application of the plan, periodic check inspection is made of the inspector's work. Data on d, k, and b are accumulated over a period of months to summarize the inspector's accuracy, as for example:

Job no.	Total pieces	d,	b	k
3	1000	10	0	0
19	50	3	1	0
42	150	5	1	0
48	5000	10	4	0
Total		200	30	0

The totals give, for percentage accuracy:

$$\frac{d}{d + b} = \frac{200}{230} = 87\%$$

As is evident, the plan lends itself to simple cumulation of data. However, some compromise is made with theory to avoid undue emphasis on any one lot checked. Over a 6-month period, where the cumulative checks may reach 50 or more, the need for such compromise or weighting is diminished.

The check inspector also makes errors. However, these have only a secondary effect on the inspector's accuracy. In the preceding example, if the check inspector were only 90 percent accurate, only 27 of the 30 defects missed by the inspector would be found. The inspector's accuracy would become

$$\frac{200}{227} = 88.1\% \quad \text{instead of} \quad 87.0\%$$

In some situations, k is small and may be ignored. However, in other situations, notably for sensory qualities, the inspector may have a bias for rejecting borderline work. In such cases, it is feasible to use, as an added measure, the inspector's accuracy due to rejection of good pieces. This has been termed *waste*. Under the terminology used here:

$$\text{Waste} = \text{percentage of good pieces rejected} = \frac{k}{n - d - b + k}$$

where n is the total pieces inspected.

The *percent accuracy* is also equal to the percentage of material correctly inspected. This feature permits use of the plan in the pay formula of the inspector.

Some investigators have developed variations on the foregoing measures of inspector accuracy as applied to visual inspection. These include measures based on probability theory (Wang 1975) and on use of signal-detection theory in the analysis of industrial inspection (Ainsworth 1980).

The proportion of correct decisions made by the inspector is an intuitively good index of the inspector's efficiency when the costs of rejecting a good item and accepting a bad item are equal.

The two measures for evaluating inspector's efficiency, introduced by Wang (1975) are

$$N_\alpha = \frac{\text{number of true defects detected by the inspector}}{\text{number of true defects}}$$

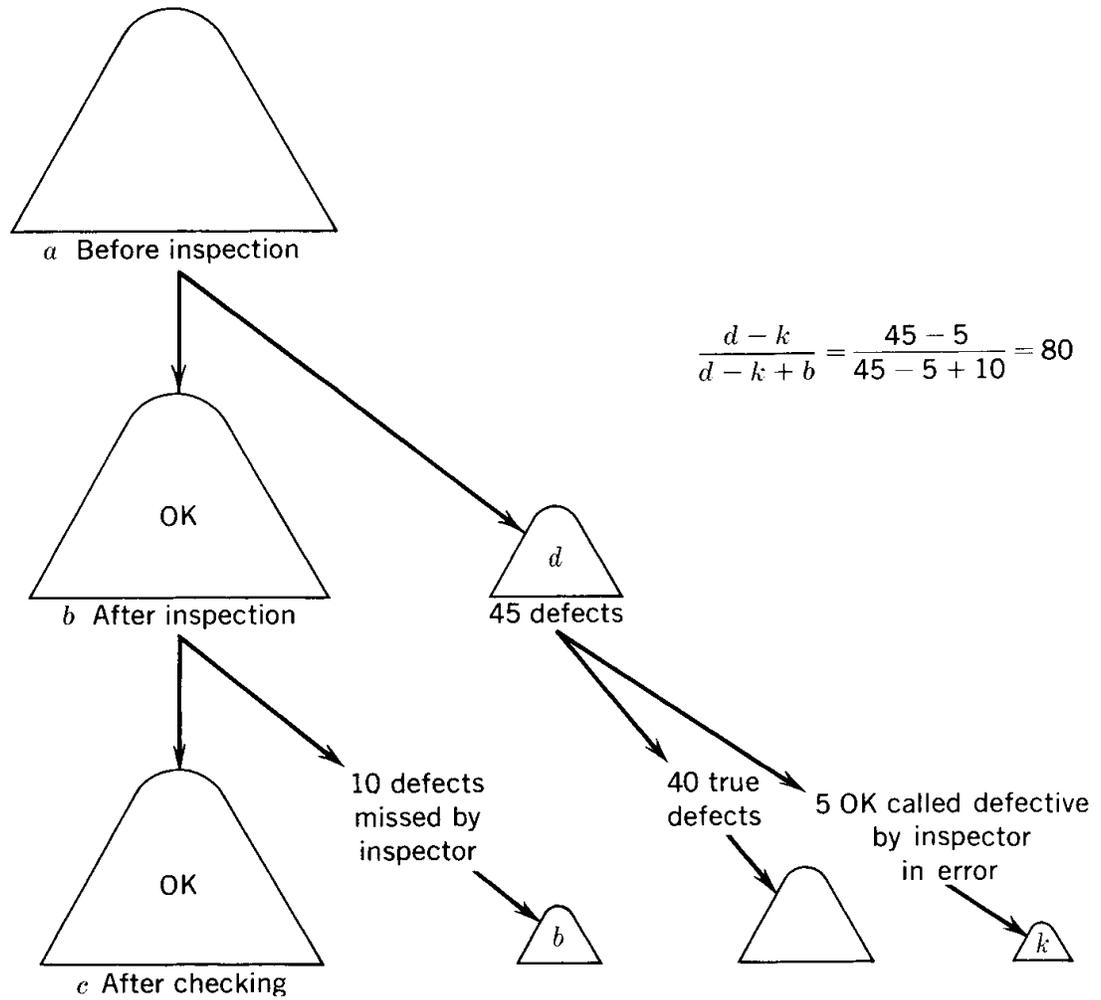
$$\frac{d - k}{d - k + b} = \frac{45 - 5}{45 - 5 + 10} = 80$$


FIGURE 23.12   Process for determining accuracy of inspectors.

$$N_\beta = \frac{\text{number of true defects detected by the inspector}}{\text{number of all defects detected by the inspector}}$$

If the two costs are not equal, the theory of signal detectability (TSD) provides a better measure for analyzing an inspector's performance. However, the use of TSD requires assumptions about normal and equal variant population distributions, and the probability density functions for the "good" and "defective" populations must be calculated. See Johnson and Funke (1980) for a discussion of the advantages and disadvantages of a number of human performance measures, including Wang's (1975) approach.

In the application of any plan to check the accuracy of inspectors, it is essential that the checks be at random. Neither the inspector nor the check inspector should know the schedule in advance. Random dice, cards from a pack, etc. should be used. It is also essential that the responsibility be clear. The inspector who has accepted defects under orders or through inaccurate instruments, etc. cannot be held responsible for the results.

INSPECTION AND TESTING SOFTWARE

Training.   As we move into the twenty-first century, we will be required to learn the concepts and application of computer-based technologies. Computer-based training has increasingly become a popular training tool for many organizations that do not require bilateral communications between

instructor and trainee and can provide alternate training schedules without having to rely on facility and instructor availability. Software for computer-based programs range from PC disks and interactive CD/ROMs to Internet links and cover topics for everything from gage calibration to 100 percent on-time delivery analysis (Kennedy 1996).

Statistical Process Control Interface.   Software organizes collected data and tracks them to measure performance and standards in manufacturing processes. Many manufacturers have integrated the measurement system directly onto the machine to provide for the operator an immediate analysis of the process variation through charts and graphic data.

Data Collection.   Software collects data from peripheral devices and retrieves data from the collection devices and downloads them onto a host computer. These data can then be analyzed for trends or problem solving.

Gage Calibration.   Software is used for monitoring and recording of measurement device hardware accuracy, reportability, and gage performance. Features include gage type, gage due date, next calibration date, location, assignee, gage inspector (metrologist), and calibration history.

Simulation.   Software is used for preproduction simulation to check for machine tool collisions, verify material removal of a machine tool, tool life analysis, inspection and test station layouts, and many other inspection and test interfaces into production processing. See "Software for Manufacturing" (1996).

SECTION 24
JOB SHOP INDUSTRIES

Leonard A. Seder

WHAT IS A JOB SHOP?

The terms "job shop" and "mass production shop," though widely used, are loosely defined. Managers who use these terms are well aware that industrial life as lived in the job shop differs considerably from that prevailing in the mass production shop. This difference extends to the problems of creating, controlling, and improving quality. This section undertakes to define the nature of the job shop and to explain the methods in use for dealing with job shop quality.

There is no single parameter which distinguishes the job shop from the mass production shop. Job shops vary in size from very small to very large. Some are captive; others are independent. Some serve sophisticated industrial customers; others serve relatively naive consumers. Their products range from one-of-a-kind nonrepeating items to large lots of frequently reordered stock items. Some make proprietary products of their own design. Others develop designs jointly with customers' designers. Many cannot even be classified neatly in the foregoing terms, since their product mix spreads across the whole spectrum of customer sophistication, design responsibility, lot sizes, repeat rate, etc.

Despite this difficulty of classification, it is possible to identify certain basic common types of job shops and to recognize among them differences and commonality that affect the fashioning of a quality control program to suit their individual needs. Table 24.1 identifies four common types of job shop, and shows some typical products or operations which exemplify each type.

Percent Repeat Jobs. The term "percent repeat jobs," which appears in the headings of Table 24.1, is one of the universal parameters of job shop operation. Percent repeat jobs is defined as the

TABLE 24.1   Types of Job Shops

Type	Description	Typical products—or operations	
		Percent repeat jobs low to moderate	Percent repeat jobs moderate to high
I	Large complex equipment	Locomotives Chemical plants Buildings Automated production equipment Radar sets	Farm equipment Aircraft Machine tools Printing presses
II	Small, simple end products and components	Fashion fabrics Industrial adhesives Circuit boards Fabricated metals Books	Tires Shoes Garments Wall covering Small appliances Metal shapes Automotive components Electronic components Private-label foods Furniture
III	Custom parts	Machined parts Forgings Weldments	Stampings Castings Molded plastics Screw-machine parts Molded rubber parts Extruded parts Containers
IV	Subcontracted services	Toolmaking Diemaking Moldmaking Printing Machining Testing	Heat treating Welding Plating Packaging Electropolishing

percentage of the total number of jobs in the factory in any one month that are identical repeats of job orders run previously.

The classification of low, moderate, and high percent repeat jobs have the following approximate values: "low" = under 35 percent; "moderate" = 35 to 80 percent; "high" = over 80 percent.

Large Complex Equipment.   Companies in Type I (Table 24.1) produce large complex units, each made up of thousands of different parts and components, each of these in turn being defined by its own "drawing number." These companies call themselves job shops because an individual job order or contract usually calls for a very small number of such large units, often only one. Only if the percent repeat jobs is moderate to high are they able to justify manufacturing these units as stock items and making (or buying) the input parts in economic quantities. Lacking a stock of finished units or components, it is necessary to produce from "scratch," and the time pressure becomes severe.

Small End Products and Components.   The Type II companies usually produce large quantities on any one order. However, they regard themselves as job shops because of the endless variations of size, shape, color, style, or configuration typically involved in their product lines. Even those with "standard"

product lines frequently show hundreds of different "model numbers" in their catalogs. Those who make "specials" for the various customers' unique requirements have thousands of drawing numbers in their engineering files.

Custom Parts.   These Type III companies are mainly in business as suppliers to Type I and II companies. They specialize in one or more of the processes listed and fill their shops with customer-designed parts of thousands of different configurations and compositions. Often they can satisfy a customer's annual requirements for a particular part number in just a few hours of production running time. The nature of the problems of such a job shop has been well portrayed by Furukawa, Kogure, and Ishizu (1981), as shown in Figure 24.1.

Subcontracted Services.   Type IV companies differ from Type III only in that they tend to be small, independent shops specializing in particular operations, often working on customer-furnished material. Captive shops of this type are often in-house departments within a large Type I, II, or III company. Variety of jobs is again the rule, each job usually requiring only a few hours of production time.

Jobs per Worker per Week.   All four types of job shops exhibit two recurring themes of commonality:

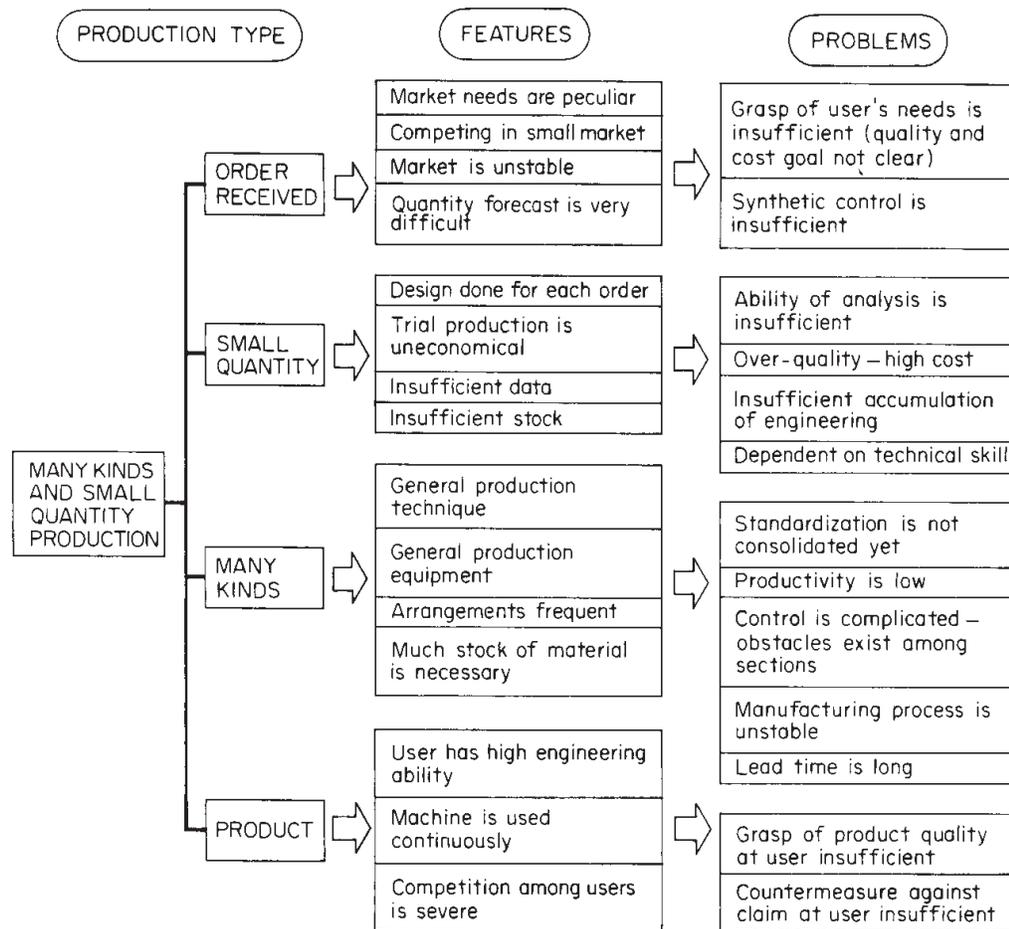
1. *Wide variety of designs* (due to a myriad of different configurations, options, colors, sizes, shapes, models)
2. *Short production time* for any individual production task on any one "job"


FIGURE 24.1   Problems of quality control at a plant producing to customer order.

These two factors may be conveniently combined into a single parameter of "jobs per worker per week," reflecting the average number of different orders, or different setups, or setup changes that will be handled by each worker over a week's time. (As more and more of the worker skills, memories, and decisions associated with setup changes are replaced by computers and automated setup changers, the name of this parameter will necessarily change to "jobs per machine per week.") Whatever the type of job shop, this number is generally much higher in the job shop than in the mass production shop. This fact has a direct bearing on the nature of the job shop quality program.

The percent repeat jobs (defined above) also varies in size among job shop types and within types. However, the percent repeat jobs is generally much lower for job shops as a class than for mass production shops. As implied in Table 24.1, the percent repeat jobs tends to be higher for some job shop types than others, e.g., Type II versus Type I. However, the rate varies over the whole range and for individual shops within one type.

Job Shop Grid.   When the two parameters of jobs per worker per week and percent repeat jobs are related to each other on the same diagram, there emerges a convenient way to quantify the distinction between the production shop and the job shop. The "job shop grid" in Figure 24.2 is designed to show this relationship.

The job shop grid opens the way to design and apply quality control methods which are keyed to the quantified parameters. At the outset it is evident that production shops are generally those with a small number of jobs per worker per week and a high percentage of repeat jobs. Above the level of 20 jobs per worker per week, we consider it a job shop regardless of the percentage of repeat jobs. Also, below a 50 percent repeat job rate, we consider it a job shop even though the number of jobs per worker per week is low.

THE JOB SHOP QUALITY PROGRAM

In a broad sense, the problems of job shop quality management are the same as for any other shop:

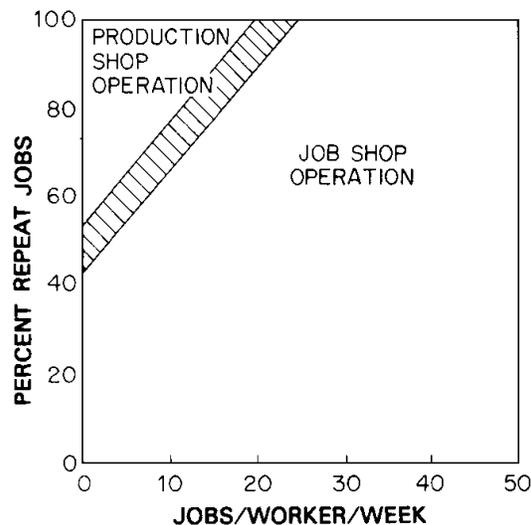
1. Planning of quality for new or modified products and processes
2. Controlling the quality during manufacture
3. Improving quality levels to reduce quality losses


FIGURE 24.2   The job shop grid.

Similarly, the concepts and principles of solution of quality problems are those presented in Sections 3, 4, and 5, and related application sections. However, the numerous job orders (which create a high number of jobs per worker per week and a low percentage of repeat jobs) greatly influence the details of the job shop approach to quality.

The impact of these numerous job orders is not on the materials, processes, or people; these generally remain common to all jobs. Neither is the impact on the systems, practices, and procedures; these likewise remain common to all jobs. (These common "ingredients" may, however, contain the root cause of chronic quality problems.) Rather, the impact is similar to that involved in launching many "new products" every week. For each of these "new products" there is need to discover (1) what is "new," (2) how this affects product design, plan of manufacture, special tools, quality requirements, etc., and (3) what needs to be done to assure that the "newness" is correctly identified and complied with by all departments.

Stated another way, the impact of the numerous job orders is primarily on preproduction planning, and especially on *manufacturing planning.* This planning creates a considerable problem of communicating to all concerned what is "different" about each order so that responsive action can be taken. The amount of such communication can rise to enormous proportions because of the multiplying effect of (1) the number of job orders, (2) the number of ways in which each order is different, and (3) the number of processes, tools, etc., affected by each of these differences. A consequence of this great volume of communication is that the problem of quality control is a problem in *quality of communication* as much as a problem in conventional process and product quality control. As a corollary, when product nonconformance is detected, the correction to be made is very frequently in some detail of the job plan rather than in the product or manufacturing process.

In the light of the foregoing, the quality program for the job shop must include special provisions for:

Planning to communicate essential quality information to all concerned

Controlling the errors and inadequacies in this communication

Improving not merely the processes and products but also the planning and communication

THE JOB NUMERICS

As noted, preproduction planning is a major job shop activity, and involves every job. Since each job differs from all others in *design,* each requires its own *product specifications,* spelling out in detail the materials, formulation, configuration, end-product physical properties, quality and reliability requirements, and the rest. (Simplification is often possible in instances in which a single specification can be used to specify a whole "family" of items largely resembling each other but differing only in specific detail of size or color, etc.)

Since jobs also differ in the exact manufacturing process to be followed, each requires its own *manufacturing plan,* to communicate to Production and Inspection the necessary details of input materials, operation sequence, inspection or laboratory release points, special or unique tooling, in-process properties required, mandatory processing restrictions, and the like.

There appears to be no accepted generic term to represent, for a specific job order, all the details of product and manufacturing process. "Job documentation" comes close, but it sometimes is used to include the recorded quality data, which are not part of our definition. Hence the author has coined the term "primary job numerics" to serve as such a generic term. Table 24.2 summarizes and gives typical examples of these primary job numerics. Obviously, mass production shops must also have these same numerics. However, in the mass production shops the numerics are few in number, tend to become stabilized, and are easily remembered by shop personnel. In the job shop they are many in number, are frequently changed, and require constant reference to the written documents.

Not all job shops have responsibility for preparing the numerics to define *both* product and manufacturing plan. Types III and IV (Table 24.1) ordinarily receive product specifications from their

TABLE 24.2 Primary Job Numerics

Aspect of definition	Typical examples
	To define the product
Materials	Material specification numbers for metals, chemicals, agricultural products, etc.
Formulation	Specific proportions of various materials to be used
Configuration	Drawing or sketch showing dimensions, component parts, assembly details, etc.
End-product acceptability	Dimensional, physical, chemical, optical, metallurgical, electrical, visual, etc., tolerances
	Functional test requirements
Reliability	Maximum failure rate, or degree of degradation in specified endurance test
	To define the manufacturing plan
Input materials	Sources, subcontractors
Operation sequence	Exact order of primary, secondary, finishing, packaging, etc., operations
	Specific machines, baths, ovens (when restricted)
Inspection points	Location of inspection stations or laboratory release points
Unique tooling	Design of specific form tools, molds, dies, assembly fixtures, artwork, etc.
In-process properties	Dimensions, thicknesses, densities, colors, electrical outputs, chemical values, strengths, etc., needed at specific operations
Mandatory processing restrictions	Temperatures and times for bakes, heat treatments, reactions, drying, curing, pasteurizing, etc.
	Hold times between operations

customers and hence prepare only the manufacturing plan. Types I and II prepare both sets of numerics for their own products, but only product specifications for those materials and components which they purchase.

The primary job numerics have long been recognized as essential and have found expression in various types of "legitimate" documentation in the shop. The product specification, manufacturing drawing, material specification, formulation or batching sheet, tool drawings, exploded assembly view, route card, operation sheet, inspection detail sheet, test procedure, and job order card are the more common names for the various means of communicating the needed numerics to shop personnel.

In the evolving techniques of computer-aided manufacturing (CAM), the problem of communicating and *updating* the primary job numerics to the production floor has been solved. The engineers or technical staff persons generally specify the primary numerics with inputs from manufacturing or process engineers. These are communicated via computer to the production personnel. The once-frustrating problem of time delay between the decision to make a change and the making of that decision officially known by advancement of the "change letter" is thus now avoidable.

The primary job numerics outlined in Table 24.2 are the minimum details necessary to define and make the product. However, they are seldom sufficient to assure the quality of the end product or to attain economic operation. There are additional numerics which provide the added information needed to minimize product deficiencies, rejections, repairs, yield losses, and customer complaints.

Some of these supplementary job numerics are shown in Table 24.3. For each aspect of product and process definition, there are special details, unique to the individual job, that are of value to the shop personnel. Communicating these details to the shop personnel provides the advance knowledge that can often spell the difference between success and failure to meet end-product requirements or between high and low quality costs.

It is probably no exaggeration to say that the key to preventing product deficiencies in the job shop lies in recognizing the importance of *specifying* the supplementary numerics. Once this is understood, the same computerized method used for the primary numerics is extended to the supplementary. This virtually eliminates the many "debates" and misunderstandings that formerly took place. Not all of these supplementary numerics are needed for all jobs. Indeed, one of the real dilemmas faced by job shop managers is the decision of how far to go in this direction (see below).

JOB PLANNING

To generate, communicate, and comply with all these job numerics requires that a major element of the job shop quality program must be concerned with individual job planning. This involves

TABLE 24.3 Supplementary Job Numerics to Prevent Product Deficiencies and Losses

Aspect of definition	Typical examples
Materials	Special supplier requirements for process control
	Special gages or test methods
	Packaging requirements
	Classification of characteristics
	Acceptable quality levels
	Certifications required
Operation sequence	Special work instructions
	Exact details of important hand operations
	Permissible deviations from sequence
Inspection points	Special gages or test methods
	Classification of characteristics
	Acceptable quality levels
Unique tooling	Identification numbers
	Tool inspection details
	Permissible tool deviations
In-process properties	Optimum settings of process variables
	Special gages or test methods
	Plans of control for operations with setup approval criteria, running approval criteria
	Statistical control plans to be used
Mandatory processing	Tolerances for times, temperatures, etc.
	Certifications required
End-product acceptability	Special gages or test methods
	Special customer "idiosyncrasies"
	Classification of characteristics
	Acceptable quality levels
	Customer data submittals or certifications
	Visible defect acceptability limits
	Customer sampling plan impositions
Reliability	Testing details

(1) organizing for job planning, (2) detecting and correcting job planning errors, (3) improving the job planning.

Organizing for Job Planning.   A major question is how far to go in completeness of planning. It is usual to carry out planning of the *primary* job numerics in total or to leave only minor details to be worked out during the production run. However, the *supplementary* job numerics present a problem in striking the proper balance between overplanning and underplanning. Establishment of the numerics beforehand will work to avoid errors and misjudgments during the production run. However, the volume of detail and the lack of adequate information of some aspects (e.g., the expected rate of occurrence of specific defects, sequence deviations, or tool deviations; knowledge of the optimum settings of process variables) make it uneconomic or impossible to fill in all the details.

A major consideration in this decision is the "percent repeat jobs." A shop with a low percent repeat jobs must necessarily devote a major effort to planning the supplementary job numerics, since there is no "second chance." A shop with a high percent repeat jobs can place its major effort in control, at the sacrifice of planning, since the control activities will, over a period of time, influence the evolution of the correct numerics. Figure 24.3 shows this contrast diagrammatically.

A further consideration in extent of planning is the time schedule. Planning can be less than complete when the manufacturing cycle permits a trial lot to be piloted through ahead of the job order to pin down many of the supplementary job numerics or when the job running time is long enough to use data feedback and corrective action for the same purpose. (See Job Shop Control, below.)

Responsibility for job planning varies widely among job shops. In all but the smallest shops, the primary numerics are commonly developed and issued by a staff group, separate from line production. This group is variously designated as Research and Development, Engineering or Technical (especially when definition of product is part of the work), or as Manufacturing Engineering, Process Engineering, Production Engineering, Estimating, Planning or Industrial Engineering (when the planning is mostly limited to definition of manufacturing plan). However, there is no universal pattern of responsibility for generating the supplementary numerics. In some instances, staff quality engineers or process engineers have this responsibility. In other shops, line supervisors, inspection supervisors, and even workers and inspectors have the assignment. In still other cases, the supplementary inspection numerics are prepared by staff specialists, while the supervisor is left to his or her own devices to develop and convey information on tools, setups, settings of process variables, etc.

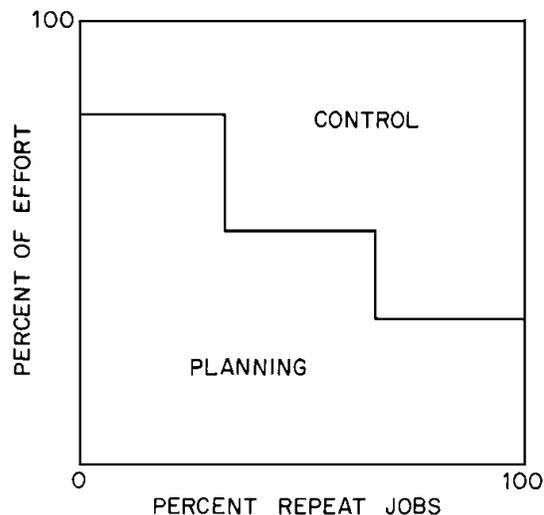
As is usual in matters of organizing, it is more important to be clear than to be logical or uniform. There is a need for providing the supplementary numerics, and the responsibility for doing


FIGURE 24.3   Effect of percent repeat jobs on allocation of planning effort.

so should be clear. The job shop which has left this question vague would do well to face it cleanly. As a general rule, if the generation and maintenance of any portion of the supplementary job numerics is to be delegated to Production, the responsibility and method must be made clear. Otherwise, in the author's experience, it tends to be neglected, poorly maintained, and ineffective.

Often the variety of work makes it necessary and possible to do the planning selectively on the basis of the size or complexity of the job. Jobs over a certain size, or involving new manufacturing techniques, or expected to become new standard products, are planned by the staff group, whereas small jobs, or those which involve only minor changes from "standard items" or previously run jobs, are planned by the line production people.

Detecting and Correcting Job Planning Errors. The sheer number of details involved in the primary and supplementary numerics makes it inevitable that errors will occur in job planning. Some will be the inadvertent errors of misplaced decimal points, transposed digits, incorrect arithmetic, and the like. Others will arise from lack of sufficient knowledge, by the planner, of processes, economics of manufacture, capabilities, and reliabilities.

To minimize planning errors, it is useful to review the planning in some appropriate way. For large jobs, this review tends to be elaborate and formal. The planning documents are circulated to the key departments, after which there is a formal review meeting. This meeting not only goes over errors and refinements; it also identifies possible problem areas. In addition, it may determine whether there is need to provide "sample" or "trial lot" evaluation before full production. The review meeting also may establish the guidelines for delegating development of the supplementary numerics to lower levels of organization.

For smaller, low repeat rate jobs, the planning documents are likewise circulated to the key departments. However, the review and sign-off usually take place without formal review meetings.

Enlisting the participation of workers in identification of errors has been a goal of many quality programs. Schafer (1978) describes a successful program for error identification in a machine shop. "Job check" cards (see Figure 24.4) were developed for machining, welding, assembly, electrical, paint, packaging, and crating to aid workers in performing a systematic review. When errors were found, workers filled out a problem report, which was circulated to the planners for corrective action.

MACHINING JOB CHECK

FIGURE 24.4 "Job check" card for operator detection of job planning errors.

For high percent repeat jobs, reliance is more heavily placed on the control system (see Job Shop Control, below).

Improving Job Planning. Improvement of this planning, as applied to manufacture, involves preparation and use of machine and process capability knowledge in establishing tolerances, choosing processes, classifying characteristics, etc. The approach, which is generally conventional, is discussed in Section 22.

A concept known as "group technology" involves planning of jobbing work by identifying "families" of parts based on commonality of operations. This commonality then is used as a basis for standardization of drawings, tooling, etc., with an obvious residual effect on quality planning. The group technology idea extends beyond planning to machine layout, product flow, and cellular and flexible manufacturing systems. See also Section 22 under Group Technology.

JOB SHOP CONTROL

The "jobbing" nature of the job shop is derived from the diversity of products. However, the manufacturing processes which turn out these diverse products exhibit a high degree of commonality in materials, machines, instruments, and people. As a result, the job shop systems for quality control of manufacture closely parallel the systems in use in the mass production shops, but scaled to the size and needs of the particular job shop. In addition, the large number of jobs per worker per week and the mass of detail contained in the job numerics make it important to have special approaches to data feedback and corrective action.

Overall Control System. Those minimal job shop systems that parallel the mass production systems are listed below, including references to the handbook sections that discuss conventional approaches:

Control system	Section reference
Supplier material	21
Identity and flow of "lots"	23
Process control decision making	45
Tool and equipment qualification and maintenance	23
Calibration and maintenance of measuring equipment	23
Disposition of rejected material	23
Analysis and followup of customer complaints	25

To formalize these systems, it is necessary to document them in a quality control manual which is then distributed to those concerned. Under ISO-9000 requirements, this is mandatory (see Section 11 under the Clauses of ISO 9001 and their Typical Structure for the ISO 9000 requirements of a quality manual).

In the job shop it is uncommonly important to provide a sound plan for making decisions on whether the process should run or stop, and to make clear delegation of responsibility for decision making on the factory floor. With limited workforce to spread over a multitude of jobs, it is also important that the job shop understand and make use of the concept of dominance (see Section 22 under Control Systems and the Concept of Dominance) in order to maximize the effectiveness of that laborpower. Setup dominance is the prevailing mode for most quality characteristics in the small-lot job shop, especially those of Types III and IV. The main reason is that the running time is usually so short that the "time-to-time" variation of the process is minimal. Hence "if the setup is right, the lot will be right." Accordingly, the job setup is a vital control station, and demands use of statistically valid plans for setup approval.

Earlier, simplified plans such as narrow-limit gaging and precontrol and control charts were used but were not widely understood. Computers have stepped into this breech. They have made statistical validity simple and automatic. There are numerous examples.

In the manufacture of expensive machined pieces, including multidimensional ones, special-purpose gages are used where needed to assure correctness of the *setup*. The data from these measurements are automatically fed into specially programmed computers to produce histograms, capabilities, control charts and other statistical evaluations to predict and thereby urge action, if needed, to assure lot conformance. (See Figure 24.5).

More generally, for any process, data from regular gages or visual inspection can be punched into hand-held computers by the person collecting the data. Instantly, the statistically valid "photograph" of the predicted lot quality from that setup flashes on the computer's miniscreen. The user doesn't have to understand the statistics; he or she sees the picture!

These developments have accelerated the trend toward establishment of a state of self-control by the operator, to whom the setup acceptance responsibility can now be delegated (See generally Section 22 under Self-Inspection).

Data Feedback and Corrective Action.   Many job shop managers have fallen into the trap of believing that once they have established an inspection system (even if, in a small shop, it means the hiring of the first inspector), they now have "quality control" and can relax. Now "quality control" will protect them against bad purchased materials, stop defects from being manufactured, and guard the outgoing product. It may well do these things, but an essential added need is to use the *information* gained from performing the inspection to *improve* quality. It can do this in several ways if appropriate feedback mechanisms are established:

1. For preventing defects in the unmanufactured portion of a job

2. For preventing defects in repeat orders of a job

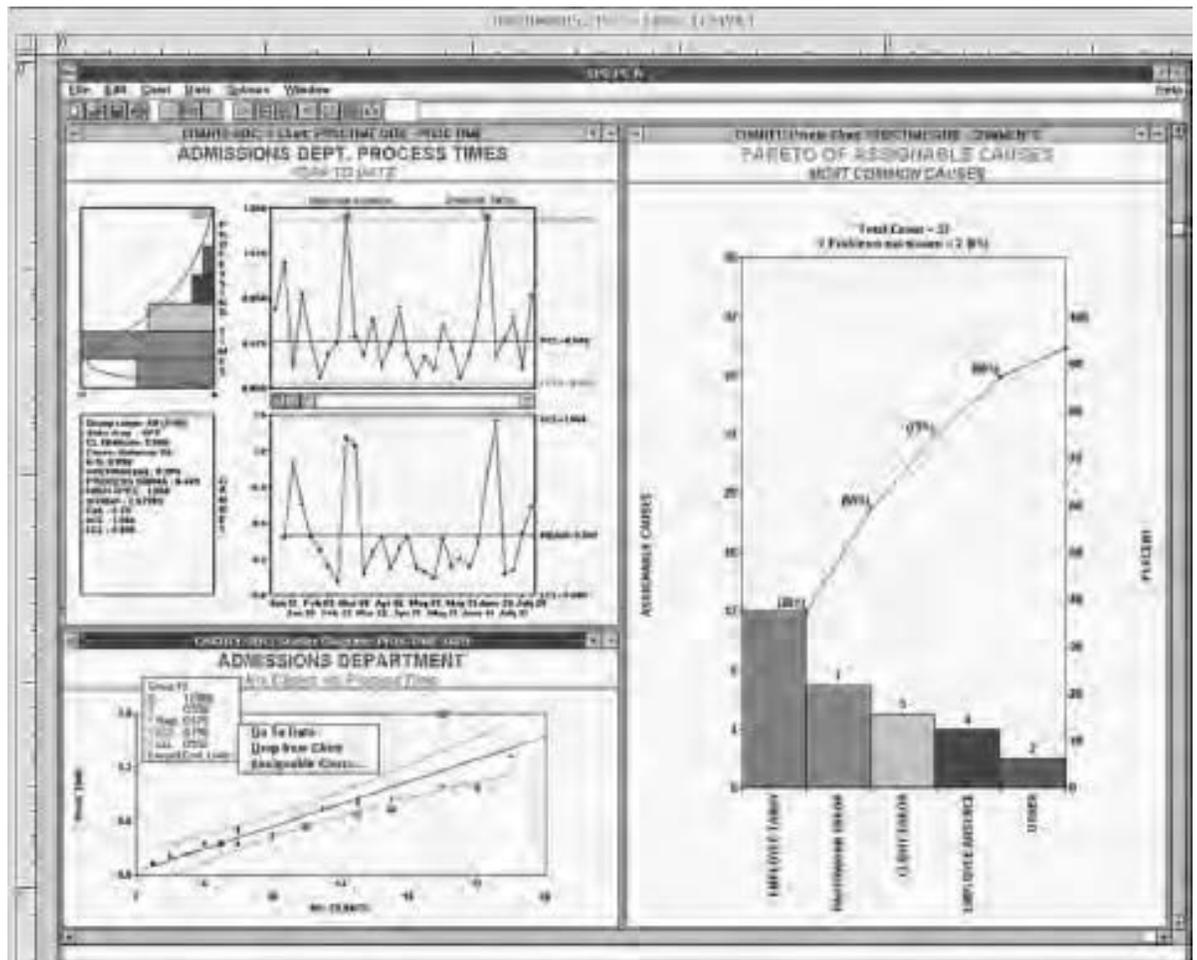
3. For preventing defects in future orders for other jobs in the same "family"

4. For correcting problems in the "ingredients" (i.e., policies, systems, procedures, practices) common to all jobs

The extent of these benefits available to a particular job shop depends on the "jobs per worker per week," the "percent repeat jobs," and other factors. Consideration of these factors leads to the "current job approach" and the "repeat job approach" as two basic ways of achieving feedback and corrective action.

The Current Job Approach.   This is a means of preventing defects in the unmanufactured portion of a job through feedback of information from the manufactured portion of the same job. It can be used whenever the running time of the job is longer than the time necessary to give the feedback signal, diagnose the cause, and determine and implement the corrective action. See, schematically, the top part of Figure 24.6. The value of such prevention is so obvious as to provide an incentive to prompt feedback of data on quality troubles, and prompt corrective action on the feedback.

Figure 24.7 shows the mechanism used in one electronics assembly plant to secure such prompt feedback and corrective action. The results of subunit, unit, and systems test are recorded by serial number as to the item and the nature of the discrepancy. Copies of the test records are reviewed daily by a quality control engineer who determines the nature of each deficiency and initiates a "corrective-action request" (Figure 24.7) to the design engineer, manufacturing engineer, components engineer, test supervisor, test-set maintenance person, supplier liaison person, or other individual who can take the necessary action. The quality engineer follows up each of the requests and the associated replies until the matter is disposed of by action, or by decision that no action is necessary.

Corrective action that will benefit the unmanufactured product may either involve a change in the *job numerics* or correction of an error in *complying* with the job numerics.


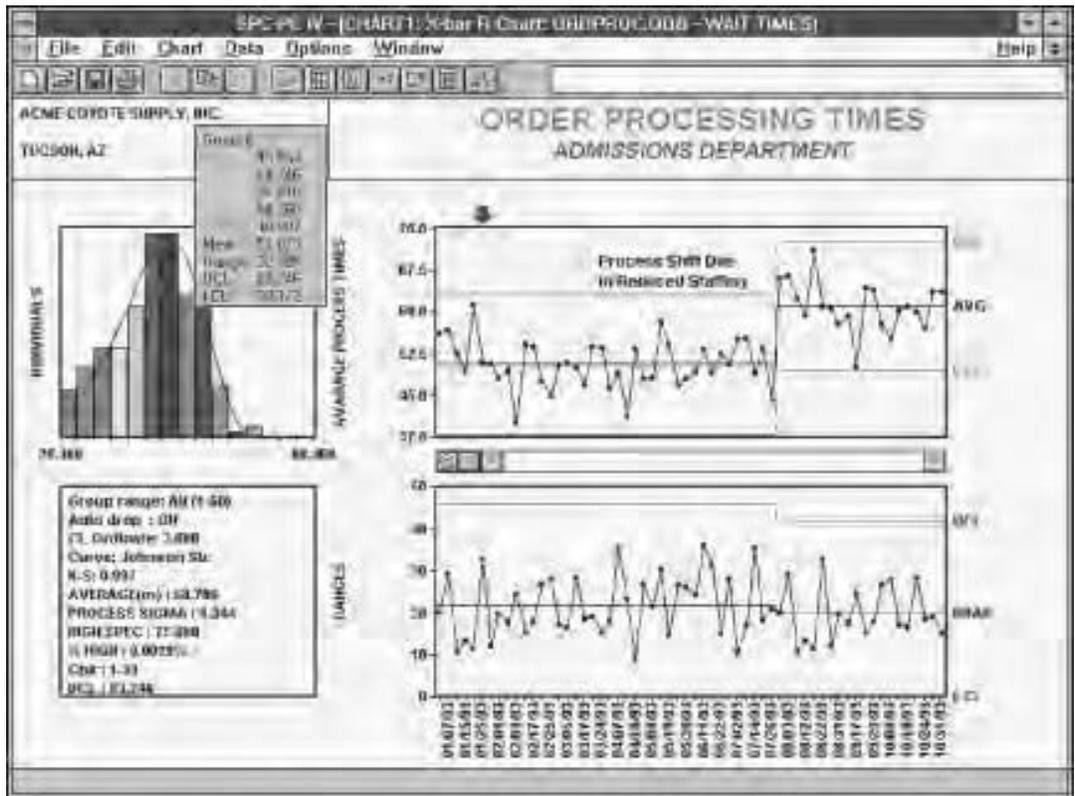


FIGURE 24.5 Computer software has enabled job shops to effectively utilize SQC tools. Shown are typical examples offered by Quality America, Inc.
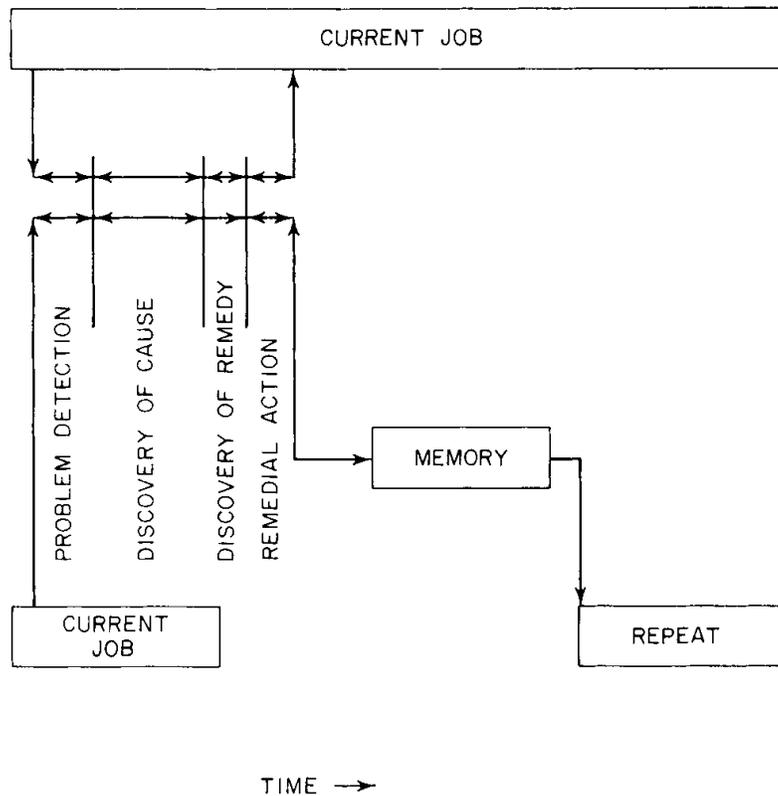

FIGURE 24.6 Current job versus repeat job corrections.

This current job approach is most applicable when the following combination of circumstances is present:

1. The economic gain through preventing defects in the unmanufactured units is obviously greater than the cost of the feedback and prevention machinery; i.e., large lots or expensive items are involved.

2. The causes of the defects are obvious enough to permit prompt diagnosis.

3. The organization for feedback and followup can be kept simple, e.g., one employee with a clear assignment.

In the job shop with a low percentage repeat job rate it is often desirable to create deliberately the opportunity to use the current job approach even when the normal running time would be too short to use it. Instead of processing the entire order as a lot, a small "pilot" lot or single item precedes the main lot, and time is allowed for the feedback and correction to take place.

The pilot lot idea has long been used in job shops. However, in its early form the pilot lot was processed like any other lot. Then the final results were scanned, and if no trouble was reported in production, everything was assumed to be satisfactory, i.e., the tentative job numerics could be made permanent. Often the pilot lot was considered to be solely the means of making samples for customer approval. Experience has shown that there is much value in expending extra effort in planning the trial lot, collecting special data, analyzing the data, and using the results to modify the job numerics.

For example, when a mechanical piece part moves through a series of operations, all of which can influence a critical dimension, the fact that 9 of the 10 pieces in the pilot lot conform to final specifications might seem to be adequate to firm up the numerics; yet the full job order could easily run 30 percent defective as a result of inadequate process capability or wrong process centering. By requiring measurements of the 10 pieces after each operation, and treating the means and ranges statistically, the alert analyst would easily discover the problem and, moreover, would be able to identify the operation responsible, thus preventing a large loss when the remainder of the order is run.

FIGURE 24.7 Typical rejection, disposition, and corrective action scheme.

The Repeat Job Approach.   For many jobs the running time is so short that the job is completed before the sequence of "analysis, feedback, and corrective action" can be completed. In such cases, the knowledge gained from the analysis cannot be put to use on the "current" job. However, this same knowledge can be put to use on a repeat order *provided there is a memory system* which can:

1. Store the knowledge
2. Provide ready recall when repeat orders are received

The lower half of Figure 24.6 shows diagrammatically the time relationship that permits this "repeat job approach" to give to future orders the benefit of the knowledge gained from previous orders. Since this approach involves the costs of maintaining a memory system, it is most applicable when the percent repeat jobs is relatively high, of the order of 75 percent or more. It probably cannot be justified economically if the percent is low, say 25 percent or lower. In between, the economics of the specific situation must be examined to determine whether it is less costly to provide protection for all potential repeat orders or suffer the losses of repeating the error for that smaller number of jobs that will be reordered. In addition, there are special situations that may warrant a memory system, as in the case of small first runs of development work on complex equipment, for it is generally important to "debug" the job numerics before production orders are received.

Memory System for Job Numerics.   Before the computer came on the scene, an astonishing variety of memory systems had been invented to serve this need. In designing the computer system, the designer would do well to become familiar with some of these to understand what is needed, i.e., not just the *specifications,* but the *experience* gained on past job orders. For example, in a plant manufacturing custom aircraft parts (Type III), a "job history file" was maintained by the manufacturing staff group. Into this file went the customer drawing and/or the specification, the job numerics, in-process and final inspection data on each run, nonconformance record, problems encountered, corrective actions taken, results of troubleshooters' investigations, recommendations, and formal change requests issued. When a repeat order was received, the planner would refer to this file and review the data and notes before issuing the new manufacturing order. Similar planning memories were in use in other shops covering items purchased from suppliers and/or items subcontracted to Type IV job shops. The purpose of all this information was that, on a repeat order, the designer could revise the specification, if needed, and the planner, in turn, could revise the other numerics.

Experience with such memory systems led to an important conclusion. They were most useful when the mix of data and notes were "digested" and the planned changes for future lots prepared during or immediately after the completion of the current job order. They were least successful when the data and notes were left undigested until the repeat order was received. By then, the undigested information would have deteriorated badly and the time pressure to produce the repeat order would often stymie the effort to take advantage of the system.

"Digestion" requires establishing the discipline of corrective action investigation and follow-up, *even though the current job may already be completed.* The organization for investigation may, as in the case of the current job approach, be limited to one analyst when simple technology is involved. However, where the causes of defects and the needed corrections are not obvious, more talents are needed. In any event, responsibility for the investigation and decision should be clearly allocated. It may be a material review board, corrective action board, factory service group, quality engineering, or other specially designated team. The agreed-on corrective actions are ordinarily recorded, and the responsible department designated, together with the expected date of accomplishment (see Figure 24.7). Diligent follow-up by a systematic routine is then needed to assure that these intentions are executed during the interval between orders. Someone must therefore be given the job of "keeping a book" on pending corrective actions until completion.

Memory Systems for Manufacture.   These systems were created, usually by production departments, to alert personnel to the hazards of known prior errors of execution, and to evolve more optimum supplementary numerics. For worker-controllable defects, for example, special "warning" or "caution" slips are often attached to the blueprints or instructions in the job file maintained in the factory. The worker assigned to the repeat order is thereby "flagged" to exercise special care of a particular job. An example is seen in the "pitfall sheet" shown in Figure 24.8, which was used in a large job shop described by Fletcher and Novy (1972).

A further example is the job "setup card" file maintained for some processes. Each card is a record for a single job order. On the card are posted the conditions which prevailed in the process while that job was being run, as well as the results of inspection and test. For example, in calendering plastic film, the setup involves such numerics as roll speeds, roll temperatures, roll spacing, material feed rate, and many others. Often some of these are altered (and duly recorded) during the

run to improve the quality of film being produced, based on the judgment of the supervisor. The subsequent inspection or lab test results are likewise posted to the card.

When this same plastic film is reordered, the setup person consults the card file to identify the lots which showed the best test results. He or she then tries to reproduce the process conditions which prevailed during the manufacture of this best product. As the card file builds up, a further step can be taken by analyzing the data through more sophisticated statistical methods, e.g., regression analysis (see Section 44). Computer programs offer an excellent opportunity to carry out such work "just in time" for the next order.

Memory Systems for Inspection. Such memory systems have usually consisted of job history cards to which inspection results were posted. The resulting knowledge of job quality levels and frequencies of specific defects can be used for a variety of improvement purposes. It can warn of inspection errors, lead to revision of defect classifications and acceptable quality levels (AQLs), promote changes in

inspection or test methods or gages, provide additional supplier instructions or notifications, furnish Pareto summaries of the vital few defects of each job, identify jobs where inspection or testing can be reduced, etc.

In addition, the memory system concept offers the job shop a way to diagnose the causes of "mysterious" defects, to determine process capabilities, to discover dominance, and to perform other statistical analyses. For example, in mass production, a few days or even hours may produce enough defects to provide the data needed for conclusive analysis. Job shop managers ordinarily are envious at these opportunities to collect and analyze data in such short order, and they often give up trying to apply such techniques to jobbing work. However, repeated small lots, plus a memory system, plus patience, will likewise furnish the data, analyses, and solutions. When the data are organized by machine center rather than by defect type, the economics of analysis may be more favorable.

Computer Memory Systems.   Computerization of such memory systems has provided much more effective and efficient accumulation of, and real-time access by production personnel to, the needed job numerics and useful information. At the same time, the stored data can be readily manipulated to prepare Pareto analyses and to perform the more sophisticated analyses referred to above. Rapid analyses made possible by the computer can go a long way in diagnosing job shop quality improvement problems, hitherto felt to be too complicated and time-consuming to pursue.

However, it is not obvious that computer programs will be dedicated to these memory systems unless the significance of the foregoing descriptions of the spontaneous and "unofficial" memory systems is recognized. They were the primitive responses to a real need; that need must now be satisfied by a well-planned computerized system.

SERVICE INDUSTRY JOB SHOPS

The thrust of this section is aimed at manufacturing industries where the term "job shop" originated and where the unique problems of such a shop tended to slow progress in applying quality control methods. However, many service industries, it turns out, are job shops. In hotels, hospitals, insurance agencies, and many others, everyday life is a variety of different events, patients, policies, or customers. The applicability of the methods of job planning and control discussed in this handbook section has been convincingly demonstrated by Patrick Mene, vice president of the Ritz-Carlton Hotel chain. He applied them to the planning and control of "events" (i.e., meetings and conferences). He defines the "primary event numerics" (his words) as "the minimum information to define event *products* and *work*." His numerics to define *products* include such items as

1. Types of guest rooms to be required
2. Configuration and seating capacities of function rooms
3. Particular audiovisual requirements
4. Food menus and specifications
5. Beverage brands and container sizes

The primary numerics for *work plans* include:

1. Required supplier input materials
2. Recipes and order of service for meals
3. Inspection points, rehearsals, food tasting
4. Exhibits, decorations, etc.

But, as in manufacturing, "the primary event numerics are seldom sufficient to assure the quality of the event…additional numerics are needed to minimize mistakes, rework, breakdowns, delays,

inefficiencies, variation, customer complaints and rebates." The secondary event numerics to prevent defects and losses include:

1. Special supplier brand names, material requirements, test methods, AQLs
2. Sequence and exact details of important operations, special work instructions
3. Special test methods, control plans, AQLs, times, temperatures, staffing requirements, etc.
4. Special customer likes or dislikes

The Ritz-Carlton quality program includes the procedure for event *planning* to minimize errors. For large events, this includes formal review meetings and sign-off on the written plans. For smaller, simple, or repeat events, the written plan is developed without formal meetings. *Control* procedures involve ways of detection of errors in the event numerics or correction of errors in complying with the numerics. Efforts are concentrated on diagnosing the cause of an error "while the bits and pieces are fresh in mind" and, though the knowledge is too late to be used on the current event, it is put to use on a repeat order of the event or a future event in the same family. See also Sections 30 through 34 for quality in various service industries.

IMPACT OF ADVANCES IN METALWORKING TECHNOLOGY AND COMPUTERIZATION

Advances in metalworking production technology and computerization of process decision making have had a major impact on job shops engaged in the fabrication of metal parts. While most of these developments have been aimed at increasing productivity, they have dramatically altered the basic worker-machine relationships that previously characterized small batch production of metal parts.

New Developments.   The thrust of the new developments, from the quality standpoint, has been to improve process capability in a number of ways and reduce the dependence on worker judgment for process control decisions. Among the developments have been:

- Improved tooling, fixturing, and work movement methods, such as pneumatic and hydrostatic holding devices.
- Numerically controlled machine tools, in which punched tapes or computers establish and set machine operating speeds, feeds, and other cutting conditions.
- Automatic selection of proper tools, from a carousel holding as many as 60, and their insertion into the machine chucks, which sharply reduces job setup time and makes small lot production even smaller.
- Computer control of the motions of the machine to execute the desired functions from simple hole drilling to very complex contouring.
- Production of a variety of goods from a single set of tools and equipment by means of programmable automation (see Blumenthal and Dray 1985).
- Use of sophisticated robots for assembly operations and inspection of dimensions of parts (see Blumenthal and Dray 1985).
- Design of high speed, multidimensional gages which not only speed up difficult measurements, but do so simultaneously at a new level of accuracy and precision.
- Direct input of the results of such measurements into computers.
- Mind-boggling ability of the computer programs to instantly turn out all manner of data summaries, including process centering and capability, control charts, positional diagrams, multivariate charts, gage repeatability and reproducibility, and other useful information.

Effect of Developments.   The main effect of the metalworker developments has been to increase radically the amount of job planning and reduce, though by no means eliminate, the amount of job controlling in the traditional sense. In terms of the earlier discussion in this section, many of the supplementary numerics have had to be thought out and incorporated into the computer program. While such a move is to be applauded, it can bring on new needs for controlling:

> The programmer typically works in an office away from the factory floor. Only a few are experienced machinists.…Programs often have mistakes.…A misoriented tool can drill a hole in the wrong place or become chipped…and debugging takes anywhere from two hours to two weeks (Blumenthal and Dray 1985, p. 34).

> The machinist must still set up the workpiece to be cut, make adjustments to correct for tool wear and stop the machine if anything goes wrong (Shaiken 1985, p. 18).

> An operator may find that the rough casting to be machined is larger than the programmer expected and thus requires more cutting. An alloy may turn out to be harder than expected, in which case the part must be fed more slowly into the cutting tool (Shaiken 1985, p. 19).

Job Planning and Controlling.   Most of these developments make the need for detecting and correcting job planning errors even more of a necessity than before. Software development and quality assurance, discussed in Section 20, becomes a new routine operation in shops that adopt the new technology.

A second necessity is validation of the correctness of all the planning details, including the software, by thorough setup acceptance of the very first pieces from the automated process. Process centering and capability are determined using any one of a number of available software packages. In addition to providing a validation of the setup, this establishes a benchmark against which to judge later repeat runs.

Regular setup acceptance at the time of each subsequent job order can thus be reduced to a simple determination that no change has taken place since the validation, i.e., tool sharpness has been maintained, work placement is correct, feeds and speeds are optimum for *this* lot of material, etc.

QUALITY IMPROVEMENT

To remain competitive the job shop must constantly engage in improvement or "breakthrough," quite aside from its day-to-day problems of enforcing quality compliance. The mass production shop must likewise engage in breakthrough, and the conceptual approach to breakthrough is identical for these two forms of industrial organization. Where they differ is mainly in the nature of the improvement "project." Because of sheer volume, the mass production shop quality improvement project usually involves a specific defect on a specific product, e.g., the 3KL cylinders are out of round on the 2.500-in (63.5-mm) dimension. In contrast, the job shop quality improvement project is usually concerned with remedy of some common cause which cuts across a variety of jobs.

The preoccupation with individual jobs is often a detriment to organizing for job shop improvement. A given common cause may adversely affect, say 25 percent of the jobs (see, for example, the case of "inductance out of specification" below). Preoccupation with looking for "blame" or for the "corrective action" in each of the jobs affected may blind the managers to the existence of a common cause, and thereby to the opportunity for leveraged improvement.

Identification of logical job shop improvement projects is largely a matter of ingenious use of the Pareto principle (see Section 5 under Pareto Principle). The need is to identify those common causes which are at the root of the greatest amount of job shop trouble, and thereby will result in the greatest value of improvement for the least cost of analysis. Once a project has been chosen, the usual limitation to solution is more a matter of management than technology; someone must be liberated from the daily, job-to-job problems and given a license to diagnose the improvement projects.

Three approaches for project identification in job shops are presented below:

The chronic offenders approach

The product family approach

The non-job approach

The Chronic Offenders Approach.

In this approach, the use of the Pareto analysis is first one of identifying the few jobs that result in the bulk of the quality losses. The term "chronic offenders" refers to these few jobs.

For example, a manufacturer of a line of floor polishers found that punch-press scrap was an important quality cost. A Pareto analysis of this scrap by part number (Figure 24.9) established that six of the parts accounted for half of the value of the punch-press scrap. It became a logical project to reduce scrap on these chronic offenders, since the "percent repeat jobs" was high. (The detailed approach to analysis of causes and discovery of remedy is discussed in Section 5, The Quality Improvement Process.)

In the complex assembly job shop, interest centers on individual assembly defects rather than on jobs per se. Defects may be so numerous and varied on each job that corrective action must be concentrated on those recurring defects which account for the greatest dollar loss, or are the most serious to the customer, or both. A "chronic offender" chart is then made for each major job, indicating the predominant defects. When high losses and seriousness are both involved, the list can be a composite of "five top dollar-loss defects," plus all the serious ones.

Corrective action for chronic offenders follows the general methods discussed under the Repeat Job Approach, above. In addition, the list of chronic offenders is publicized for the attention and priority of all—managers, supervisors, analysts, production workers, inspectors, etc. (In one plant in which the defects were mainly worker-controllable, good results were achieved by posting the chronic offenders list in each production department.) Along with this, the plant manager received a weekly bulletin of progress in tackling these high dollar-loss items.

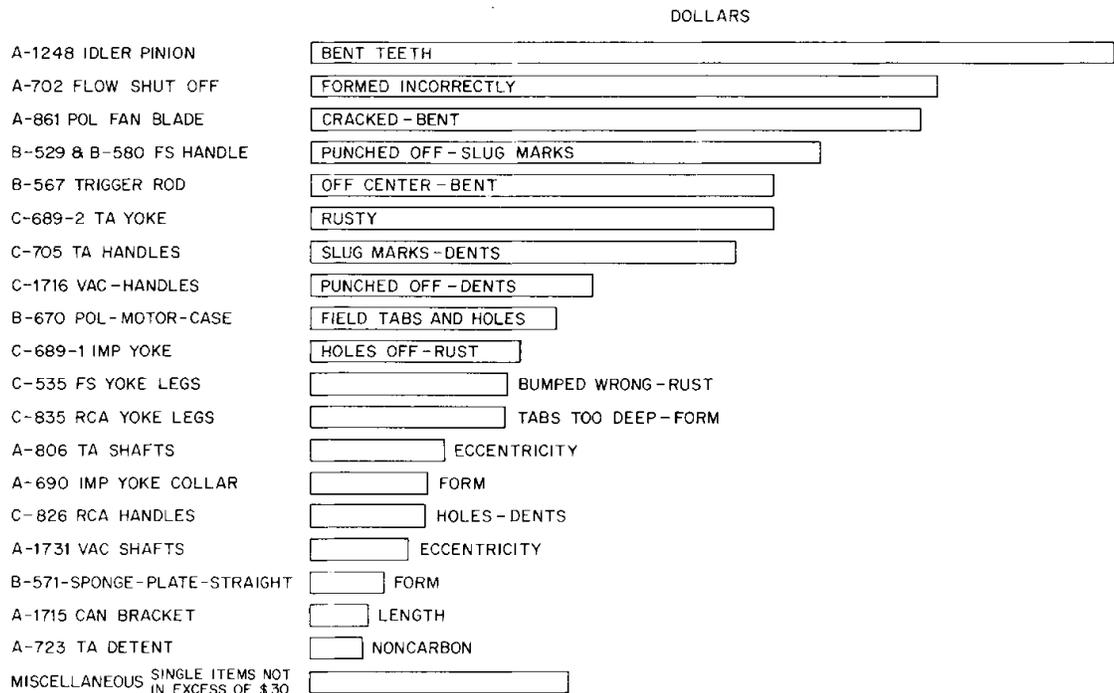
The chronic offenders list is never static. Some projects are removed from the list because they have been solved. New projects are added to the list as the result of new customer demands or com-


FIGURE 24.9   Pareto analysis by part number.

petitor practice. Accordingly, it is necessary to revise the list of the "worst" offenders periodically (in the same manner that law enforcement officers revise the list of the ten most wanted criminals).

The Product Family Approach.   This approach utilizes the fact that all jobs in a product family have similar customer requirements, design specifications, sequence of operations, process variables, inspection instructions, or other job numerics. Under such conditions, any job is a repeat for any other job in the same product family. Through this relationship, the percent repeat jobs is greatly increased. In consequence, the effort of diagnosis and remedy is amortized over a greater number of jobs. This amortization tends to make this approach economic for moderate and even low percent repeat job rates.

The instances of "families" are legion. Tire manufacturers have hundreds of job specifications to cover all permutations of brand, size, fabric, construction, grade, wall color, tread design, etc. Yet, most of the numerics for, say, a four-ply nylon tire are alike (allowing for size scaling) for all members of that family. In the calendered vinyl plastics business, myriads of artistic printing and embossing patterns are applied to only a dozen or so basic families of laminated, unsupported, or coated films. Again, the job numerics for each of these families prior to printing and embossing are largely alike. In machine shops, the family concept has led to the group technology approach of identifying operations, sizes, materials, etc. that are common to a whole group of parts and restructuring the plan of manufacture.

The product family approach directs its efforts toward improving the job numerics for the entire family. This may come about in several ways:

1. By extending to all members of the family the knowledge gained when using the "current job" control plan. Once corrective action has become known for one job, such knowledge can be used to benefit other members of the family.

2. By utilizing the product family concept in setting up the memory system for the "repeat job" approach. Such usage supplies more data in a shorter time, and facilitates the identification of chronic offenders or defect concentrations. In turn, diagnosis of these "vital few" family problems leads to remedies which can be extended to the whole family.

3. By setting up a special project, in the absence of a memory system, to furnish the information in item 2 above and tackle the "vital few."

The Non-Job Approach.   "Non-job" is used here in the sense of an approach to chronic defect reduction through discovery and elimination of common causes that are not job-related, i.e., the causes that cut across many jobs. Because the causes common to many jobs are quite numerous, the first step in the non-job approach is to use the Pareto analysis to identify those common causes that might warrant further analysis. The Pareto study is conducted in various ways—by defect type, failure mode, process, department, discrepancy, "basic cause," etc. Out of these studies emerges the most promising avenue for further study, usually that Pareto distribution in which the fewest number of defect types (or whatever) account for the greatest proportion of the trouble.

The usual starting point is to study the distribution of rejects or losses by *common symptoms,* on the normally valid premise that common symptoms will be found to have common causes when further analyzed. For example, an electronics assembly shop found (at subassembly) that a Pareto distribution by defect provided a good basis for further study, since one defect (solder) accounted for about 37 percent of all defects (Figure 24.10). Studies by failure mode, error type, discrepancy, etc., are similar in nature.

For many products, the study can usefully go one step further, even at the exploratory stage. Whenever the causes for the principal symptoms categories are "obvious" (i.e., all knowledgeable hands agree) from the nature of the symptoms, then an analysis can be made by *basic cause categories.* (Such obvious causes are so well recognized that they often find their way into the very name of the defect, such as "toolmarks," "incompletely lapped," "undercured," or "double-knurled.")

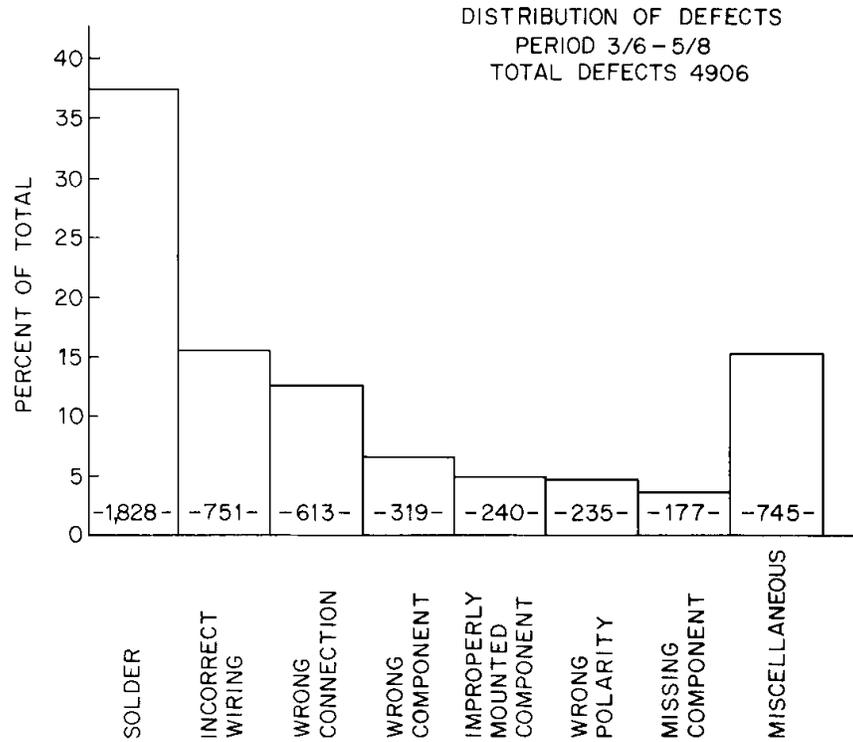
In an automobile tire plant, a Pareto distribution by defects was of no avail, since there was not sufficient concentration among the 85 identifiable defect types to justify study projects for each of


FIGURE 24.10 Pareto analysis by common symptoms.

about 20 principal defects. However, by regrouping the 85 defect types into 7 basic cause categories (Figure 24.11), it became evident that one operation (curing) required better control systems, while another operation (finishing) needed improved attention to setups. It also became evident that the relationship of ply angle to width required a more complete planning of the supplementary job numerics by Engineering.

In still other cases in which causes are not obvious and defects might be the result of any of several possible causes, it is nevertheless instructive to attempt to classify by basic cause categories in the job shop. This can be done by setting up a special study for a limited period (e.g., a week or a month), during which time each rejection or error is carefully traced to its origin by a task force representing Engineering, Production, and Inspection. Based on the facts unearthed, they try to agree on the cause classification.

For example, a sheet metal fabricating shop studied its rejections in this way and obtained the Pareto distributions shown in Figure 24.12. The most promising direction for study was the basic cause category "operator error," since operator errors (acknowledged as such by the operator in each case) were by a wide margin the biggest single class.

One machine tool builder prepared a check sheet to assist supervisors in analysis of causes of defects. The check sheet required each foreman to:

Describe the defect in terms of the specification, and of the effect on assembly or customer

Identify the source of process dominance (see Section 22 under Planning Process Controls)

Identify the plan in use for detecting nonconformance

Identify where the defect occurred and where it was found

Determine the extent to which worker self-control was present (see Section 22 under Concept of Controllability)

Determine basic cause for the defect (Figure 24.13) (see Section 5 under Diagnostic Journey)

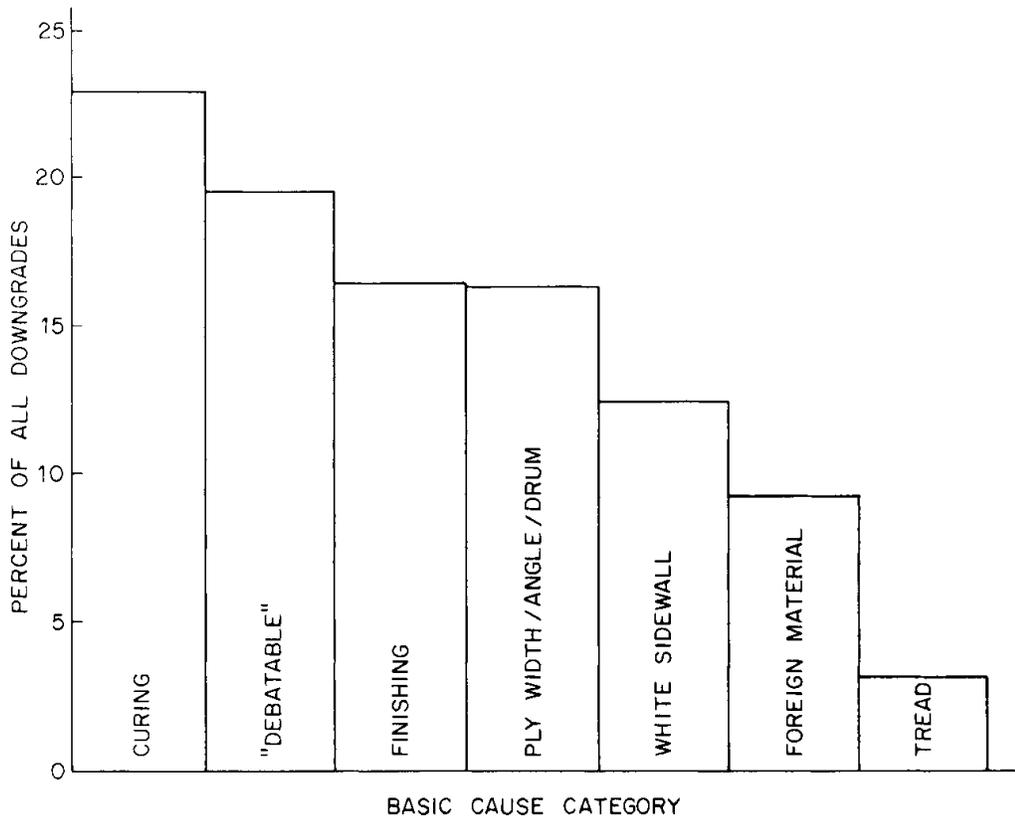
The resulting data offered many possible useful Pareto analyses.


FIGURE 24.11   Pareto analysis of auto tire downgrades by basic causes.
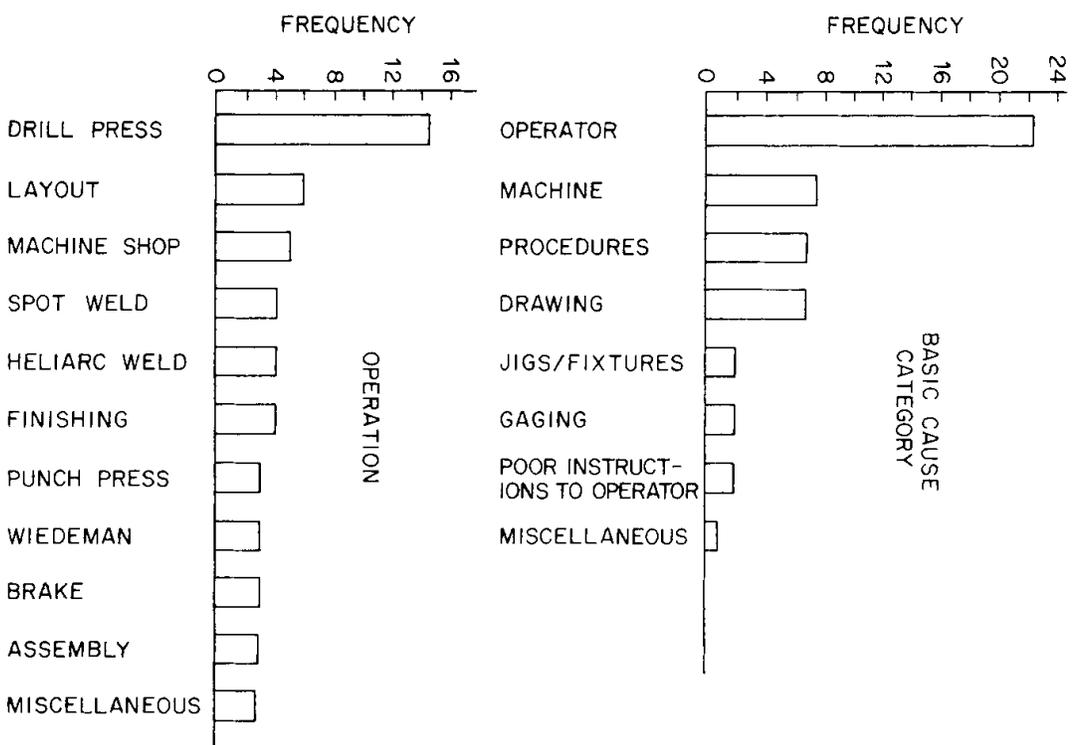

FIGURE 24.12   Two-way Pareto analysis by operation and basic cause category.

WHAT WAS THE BASIC CAUSE FOR THE DEFECT?	
____Specification not clear	____Tool wear
____Spec misinterpreted by operator	____Operator loading wrong
____Routing error	____Operator repeatability
____Machining sketch error	____Machine repeatability
____Tape error	____Measurement method
____Tooling error	____Measurement error
____Fixture wrong	____Deviation from routing sequence
____Operator setup error	____Supplier material defective
____Layout error	____Machine malfunction
____Prior operation wrong	____Wrong feeds and speeds
____Other (describe below)	____Operator inattention

FIGURE 24.13   Check sheet for basic cause analysis in a machine shop.

In a company making electrical inductors, "inductance out of specification" was by far the most frequent defect. Frequency distributions of a dozen high-reject lots showed two different symptoms patterns:

1. Some lots had adequate within-lot variability, but had poor centering of the mean of the distribution, resulting in rejects all beyond one of the limits.

2. Other lots had excessive within-lot variability, resulting in defects outside of both limits.

The common cause in this case was in the Engineering department "sample shop," which established product tolerances (e.g., inductance, resistance) as well as manufacturing instructions for wire size and number of turns. The practice of the sample shop was to make a single trial coil to meet the customer's electrical requirements. Then, the wire size and number of turns that had been used to make this trial coil were incorporated in the manufacturing instructions. The system was defective because it failed to consider the effect of production variability from coil to coil. The results of one trial coil provided no information on natural coil-to-coil variability from which to establish the tolerance width, nor was the sample coil necessarily at the center of the tolerance range, as assumed by the Engineering department—hence the observed symptoms when the Production department followed the manufacturing instructions for wire size and number of turns. When the sample shop procedure was changed to making three coils, with calculated consideration for expected variability, there soon was a substantial reduction in the rejections.

It is evident from such cases, especially the last one, that job shop quality improvement is not confined to changing the job numerics or to providing a warning to Production the next time the job is run. The "common cause" often interacts randomly with jobs; it can affect any job at any time. Once tracking of such a common cause gets under way, the diagnostic trail frequently leads back to the fundamentals of the very system of preparing specifications, of assigning tolerances, of bidding or estimating, of controlling processes, etc.

Diagnostic Techniques.   The techniques for diagnosis and remedy of the chronic problems in the job shop are similar to those in any shop; they are covered in detail in Section 5. However, the job shop diagnostician is seldom able to collect large quantities of data at will; lot sizes are too small. This calls for ingenuity by the diagnostician in collecting the needed data from repeat orders of a job or from several members of a family. Often a variant of the "memory system" (see under The Repeat Job Approach, above) provides the answer by accumulaing the data gradually over a period of time.

For example, machine capabilities in a job shop can be determined from an accumulation of measurements of 5 to 10 pieces per job over a series of jobs. As the data accumulate, a statistically ade-

quate basis for estimating machine capability emerges from the "within-job" range. (See Section 22, under Process Capability.)

Similarly, dominance can be identified by recording 5 or 10 "first piece" and "last piece" measurements on a series of jobs in the memory system. If, for a given machine or process, the series of jobs shows no significant change between the two sets of measurements, setup dominance is indicated; otherwise, time dominance. In the latter event, the accumulated data give important quantified information on whether the time-to-time variation is steady or erratic from run to run. Recording of worker identity is the key to identifying worker dominance.

Even "within-piece" or positional concentration of defects can be discovered by accumulation of data from small lots. In a plant making large castings for pumps and air compressors, a condition of leaks in castings was remedied only after patient recording of the location of the leaks, month by month. In this case the castings were made a few at a time, repaired, and shipped out. The memory device was a drawing copy on which the diagnostician accumulated all leak locations.

REMEDIES FOR JOB SHOP PROBLEMS

When the identified problems are job-related, so are the remedies. In the chronic offenders and product family approaches, the remedies indicated by the diagnoses are usually changes in the job numerics. When the identified problems are not job- related, as in the non-job approach, the remedies must go deeper, e.g., modification of the overall system of specification, planning, or control.

Challenging the Basic Premises.   The most difficult remedies are those for which it is necessary to question the basic premises or axioms underlying management thinking. These premises are often of such long standing that little effort is being devoted toward changing them or even questioning them. These premises are further entrenched because their effect is interdepartmental, i.e., several major company departments are involved. In consequence, a change requires acquiescence or formal approval from the upper management of the company.

Some widespread examples of the need for challenging basic premises are listed below. In studying these examples, it is well to keep in mind that these premises were very likely well founded in years gone by but have meanwhile become obsolete by the slow, undetected movement of events.

Unrealistic Specifications.   The large number of jobs per worker per week (so usual in the job shop) exposes the production and inspection personnel to a very large number of quality characteristics. Under such conditions, systems of "unrealistic specifications loosely enforced" become unmanageable because the shop people must carry in their heads so much detail of how loosely to enforce the specifications.

For job shops engaged in custom work, the way to avoid recurring violation of specifications (by workers who conclude that the tolerance is unrealistic or unimportant) seems, on the face of it, to give binding force to the specifications. However, no amount of criticizing, threatening, or pleading will assure compliance if the process capability is inadequate. The trouble is that the system is founded on a defective premise. The remedy lies not in more intense use of the present system; the remedy lies in change of the basic system.

This is not as easy as it sounds, since the system is logical once the basic premise is accepted. It is common to discuss enforcement of tolerances without questioning the basic premise itself. Such discussions may settle the specific instance without settling the broad question. It is only when the question "tight tolerances loosely enforced versus realistic tolerances rigidly enforced" appears on some important agenda as a topic in its own right that the question has been brought out in the open.

Informal Communication.   In very small model shops and specialty shops the communication from designer and planner to mechanic is highly informal and includes much oral communication. As the shop grows, this close relationship is gradually eroded by sheer size and complexity, and the

need is for greater formality and greater reliance on written communication. However, in some job shops this communication retains many aspects of the informality of the model shop or speciality shop despite the fact that these have long since been outgrown. As discussed under The Job Numerics, above, the communication of the supplementary job numerics is a necessary response in the modern industrial world of multiplicity of requirements.

Quotation Review.   The prevailing practice in quoting prices to customers is to base them on cost estimates prepared by an estimator who makes use of cost standards based on historical data.

In some types of product, the precision demanded has become such that the decisive factor in meeting cost and delivery standards is the ability to hold tolerances. Yet seldom is the estimator provided with adequate standard data (on the cost of precision) to come up with quotations which reflect the realities of holding the precision demanded.

Of course, adequate standard data should be prepared and made available to the estimators, who in turn should be trained in how to use them. Until this is done, the job shop is well advised to bring the Quality department into the quotation procedure so that available quality capability knowledge is utilized. Use of this knowledge can aid in identifying unrealistic tolerances, predicting costs, anticipating gaging problems, defining vague characteristics, and improving inspection planning.

The basic premise here is that the estimator should be able to prepare the quotation. The premise is sound only if the estimator is equipped with the data on which a sound quotation can be built up.

Quality Planning.   The "basic premise" question here is primarily one of separation of planning from execution. However, the question extends to numerous facets—choice of methods, tool control, gage control, definition of responsibilities, feedback systems, etc. The really decisive question is whether to formalize or not. Once there is a decision to formalize, the people involved can usually find ways appropriate to their needs.

An example of combined quality planning and execution is the Engineering department model shop. These shops are staffed by skilled model makers working directly with the engineering designers. The atmosphere is highly informal, with little reliance on drawings, tolerances, methods sheets, or other written communication. The model maker is expected to make the model by utilizing general-use machinery, to create ingenious setups so as to avoid expenditure for tools, to consult freely with the designer on open questions, and even to contribute ideas to the design itself. In such an organization form, reliance for quality is on the model maker rather than on some formal system.

As the job shop grows, the need arises for a greater degree of separation of planning from execution. This need is met by the creation of separate planners and a Planning department. (The quality counterpart of this is separate quality engineers and a Quality Engineering department.) The planners soon find (as did the model makers before them) that the planning should not be uniformly applied to all jobs or functions. Some jobs are more defect-prone, more expensive, more unstable than others. Hence there arises the need for a rationale or logic to determine which part of the planning is to be done by the planners and which is to remain with the shop personnel.

Outdated Factory Organization.   Many job shops organize their machinery on the colony plan, e.g., all lathes are in one room, all presses in another, etc. The intention is to reduce investment in machinery and to develop skills in the respective processes. This colony form of machine organization multiplies greatly the problem of preparing the job numerics and increases the opportunities for error. (It also increases process inventories, overall manufacturing intervals, and the complexities of process control.)

Here the basic premise is that as the job shop grows, the colony organization must be retained. This premise has been questioned on the grounds that growth should be through creation of "cellular" groupings, which use special machine designs to minimize the preparation of extensive job numerics, increase machine utilization, improve coordination, etc. Highly automated forms of such cellular groupings, known as "flexible manufacturing systems," are in use, which can significantly lower production and quality costs. A good description has been given by Black (1983).

For example, a manufacturer of cigarette making machinery embarked on a program of:

1. Use of light alloys to increase speed of metal cutting
2. Design of special machines on the Numerical Control principle to perform multiple operations during a single setup
3. Design of special inspection machines to verify the setups
4. Organization of the shop into small, compact crews (see the discussion of "Group Technology" under Improving Job Planning, above)

Multiple Suppliers.   For the small job shop, material usage is so modest that when an adequate source of supply has been established for any specific material, there is little point looking for a second source. As the shop grows, material usage grows with it, and there may be a need to shift from single to multiple suppliers for some materials. However, the basic premise of single suppliers may meanwhile have become so rooted that it blocks consideration of multiple suppliers.

Worker Motivation.   The economics of job shop planning favor a higher degree of delegation to the work force than is readily feasible in the mass production shop. This delegation reduces the prevalence of worker monotony and boredom, but also increases the extent of worker controllability of defects. (See generally Section 15 and especially under Open Communications. See also Section 22 under Concept of Controllability.) As these defects are brought to light, the managers conclude that since worker inattention, blunder, etc., created these defects (which is often true), it follows that better worker attention, etc., will eliminate all defects. An extension of this logic is that the way to improve quality is to penalize workers for defects. However, the logic is based on a defective premise, since even if worker errors can be eliminated, there still remain the management-controllable defects (which usually are about 80 percent of all defects).

Actually, the wide delegation of duties to shop personnel, so prevalent in job shops, creates a favorable climate for new approaches to increasing job interest and improving worker motivation. The job shop is thereby a good laboratory for testing out some of the modern ways being evolved to improve motivation (see Section 15 under Design Principles of Work and Organization).

THE SMALL JOB SHOP

The approaches discussed in this section for planning, controlling, and improving quality require much technique and effort beyond that needed for the basic "line" activities of designing and producing the product. In the large job shop this additional work is mostly performed by staff specialists in a "Quality Engineering" department. However, the small job shop seldom can justify use of such full-time specialists. Neither can this small shop endure high quality losses. The answer to this dilemma is universal for all small enterprises: everyone wears several hats. The necessary quality "staff" activities do get carried out, but as part-time tasks for someone who is busy with many other part-time tasks.

For example, in one small job shop a wide array of quality tasks was assigned as shown in Table 24.4.

SECTION 25
CUSTOMER SERVICE[1]

Edward Fuchs

INTRODUCTION

During the 1980s, customer service emerged as a critical success driver in many companies that pursue the management approaches of leading-edge enterprise. The compelling logic behind the importance of customer service is simple (Grant and Schlesinger 1995). As rapid cycle times diminish the ability of providers to differentiate their products, customer service is one of only very few ways to motivate customers to enhance behaviors that affect the enterprise's sales and profitability. Customer service includes transactions with customers and relationships with customers that occur before and after purchase of product or service. These transactions and relationships differ for different types of products and services. It is convenient to view possible customer service elements as innovative or traditional, as is illustrated in Table 25.1.

It should be understood that the list in Table 25.1 is not a complete listing of possible customer service elements. In fact, leading-edge companies always strive to find new elements that will provide a competitive edge. I call these elements *key customer satisfiers* (KCSs). In some cases, KCSs involve the transfer of value to customers. In other cases, they involve relationships with customers. Assignments to the traditional and innovative categories are not always the same for different markets. What may be innovative in one market may be traditional in another.

The *value proposition* of a product is the totality of the service and tangible product elements that are perceived by customers as valuable, leading to decisions to purchase the products offered for sale in preference to competitors' products. The weight of evidence (e.g., see Grant and Schlesinger 1995) is that the marketing trend for many products and services continues to be the extension of the value proposition to include more transactional (value-transfer) items and more and more relational

---

services. This is so because the trend is continuing for the products in many industries to become undifferentiated and commoditized. This trend is especially true in mature industries but is increasingly the case in industries such as consumer electronics and personal computers. Consequently, the traditional criteria used to distinguish between the product (manufacturing) and service sectors are breaking down. Products often include tangible goods bundled together with associated real-time services and ongoing information exchange. Anyone who has purchased and installed a personal computer software package will recognize this extended value proposition.

This section describes the quality considerations of customer service, the use of customer service as a strategic differentiator, and the design, structural, and operational considerations of high-quality customer service performance. Elements of behavioral science, organizational design, and systems engineering all are brought to bear on these topics (Pyzdek 1994). Reference to other sections of this handbook is made where appropriate.

CONSIDERATIONS OF QUALITY IN CUSTOMER SERVICE

There are four important areas where quality must be considered in customer service: strategic intent, design, organizational structure, and operations. The first is *strategic intent.* As part of a strategy formulation, the overall approach to quality is determined for the product or service. A subset of the overall approach is the use of customer service elements as strategic differentiators. Examples of marketplace advantages that may be achieved by providing value-added customer service are reduced customer turnover, increased repurchasing performance, increased product or service use, and customer referrals. Value-adding customer service also may yield higher profit margins and growth in market share. The customer service strategy is determined as part of the annual business planning cycle or as part of the product planning cycle. Customer service elements are hypothesized based on insights from the available body of knowledge about the industry and its marketplace. The insights are then verified using systematic methods. The results of the verification step may be confirmation that the proposed approaches to customer service indeed are opportunities to achieve marketplace advantages or that modified or alternative approaches yield more value-adding capability. Iteration may be required until there is closure and consensus on the strategy to be undertaken.

The second important area where quality must be considered is the *design area.* Companies that emphasize customer service design customer service capabilities as part of the product/service life cycle. Structures and processes are devised during the design phase to implement the strategy for customer service that was determined in the strategy formulation. The approach to design that is presented here is patterned after the service systems engineering framework of Pyzdek (1994). Pyzdek's framework combines concepts and methods from the systems engineering, organizational design, and behavioral science fields. All these components are important to achieve an effective design of customer service delivery capabilities.

The third area where quality must be considered is *organizational structure.* This is where quality is built into the organization's customer service delivery structure according to the requirements

of the product or service life-cycle design. Important considerations are enabling technologies and training, process engineering and reengineering, legacy migration, and outsourcing. It is common to find that process models for customer service capabilities involve almost every business function and, therefore, almost every part of the organization. This creates an opportunity to use customer service as an integrating force that knits together a company's quality thrust. However, in many firms this pervasive characteristic also creates a problem of distributed responsibility and accountability for effective customer service.

The last important area where quality must be considered is the *operational area.* This is where results are achieved, measured, and improved. The ongoing performance of operating customer service processes is important here and includes such considerations as human performance, process control, process capability, process improvement, and performance metrics. Three areas of consideration dominate an effective end-to-end life-cycle design. The first includes continuous communication, reward, recognition, and development of customer-facing associates; second is continuous oversight of processes in search of stress cracks that may be caused by saturated processes, by changes in customer needs, or by other considerations not congruent with the design intent and implementation criteria; and the third is continual environmental scans in search of early warning signs of changing markets, of new opportunities, and of new competitive threats. Common to all these considerations is the need for instrumentation for collection and analysis of information.

Here I present a model that features customer service as a strategic differentiator. To illustrate the use of the model, data and examples are provided, taken from the literature, from published benchmarks, and from Baldrige Award–winning companies. The reader may wish to review the contents of Sections 3, 13, and 18 as preparation for this topic.

The model presented in Figure 25.1 helps us visualize customer service as a vehicle to achieve strategic goals and objectives for a product or a service or for a family of products or services (Innis 1994). During the planning period for a specific product, or during the annual business planning interval for the forthcoming year, customer service is proposed as a competitive differentiator. The elements of customer service that may be appropriate for the particular type of product or service are selected. These elements are a subset of the assumed KCSs for the product or service. Insight for this inductive step may come from experience with previous products, from customer feedback such as complaint or suggestion data, from competitive analyses and environmental scans, or from new technology or business capabilities. A structured approach for this step, called *service blueprinting,* is described below, under Strategic Intent, AT&T Universal Card Services.

At this point in the strategy development, these insights should be verified. This verification step often is omitted, leaving the ultimate verification to the marketplace. This sometimes turns out to be an expensive shortcut. Therefore, every effort should be made to obtain verification. KCS data for the industry or for the specific product or service must be acquired. Identifying and addressing the key customer satisfiers constitute an essential step toward achieving customer satisfaction. KCS data are acquired from market research studies conducted in appropriately defined market segments. The KCS data provide insight into the specific product and service attributes that are important to customers in each market segment and the degree of importance the customers attach to each attribute. Depending on the industry, on its marketplace characteristics, and on the particular type of the product or service, one or both of two types of market research are commonly used for this purpose (see Section 18).

In many cases, it is possible to verify the proposed KCSs by using such preimplementation techniques as focus groups or market research surveys or by limited prototyping experiences. In other cases, it may be necessary to use a rapid cycle-time implementation of initial production to get feedback. This is called a *beta test* in some industries. A more traditional term is *field trial.* These alternatives are illustrated in an expansion of the Lisrel model as shown in Figure 25.2.

The well-known quality function deployment technique often is used as the vehicle to integrate two important steps, the understanding of what is important to customers in market segments (e.g., KCS data) and the correlation of the important attributes, stated in terms meaningful to the customer, with specific product and service attributes, stated in terms that are meaningful to the designer (see Section 3).

When the strategic approach to customer service is verified, improved and updated, and documented, it is usually included in a preliminary business case.

STRATEGIC INTENT

AT&T Universal Card Services.   The Universal Card Services business unit of AT&T provides an impressive example. From the time the business was first created in March 1990, it took only 30 months to become the second largest credit card issuer in the United States. How did AT&T differentiate what had been a commodity product and service? What prompted AT&T at the outset to rush in and try to establish a winning credit card business? AT&T was looking for ways to reinforce brand loyalty for long-distance calling services. A credit card that is also a calling card seemed like a natural marriage. However, there were hurdles to overcome. Customers were not satisfied with the credit cards that they had. Card users did not like the high fees, and they did not generally like the service that they received. They complained angrily about surly service representatives who took weeks to process changes and who embroiled anxious customers who had lost their cards in tangles of paperwork and phone calls. AT&T asserted that it could do better. Using the service blueprinting process, described below, AT&T chose a differentiating capability that had never been provided to credit card owners in the past: world-class customer service. To differentiate the customer service significantly, several important moments of truth in the customer service blueprints were selected. Market research studies showed clearly that one moment of truth would not have been enough.

The blueprinting process is illustrated and summarized in Figure 25.3. The blueprint is usually recorded as a flowchart of the particular process under study. The flowchart is segmented to clearly illustrate the lines of interaction between the service and the customer and the so-called line of invisibility. The line of invisibility is the boundary between the directly customer-facing subprocesses and the "back-office" subprocesses that support the customer-facing elements. Using the blueprint diagram, it becomes possible to answer the questions summarized in the bullet list in Figure 25.3. These answers provide the basis for selecting key moments of truth and for making other implementation decisions.

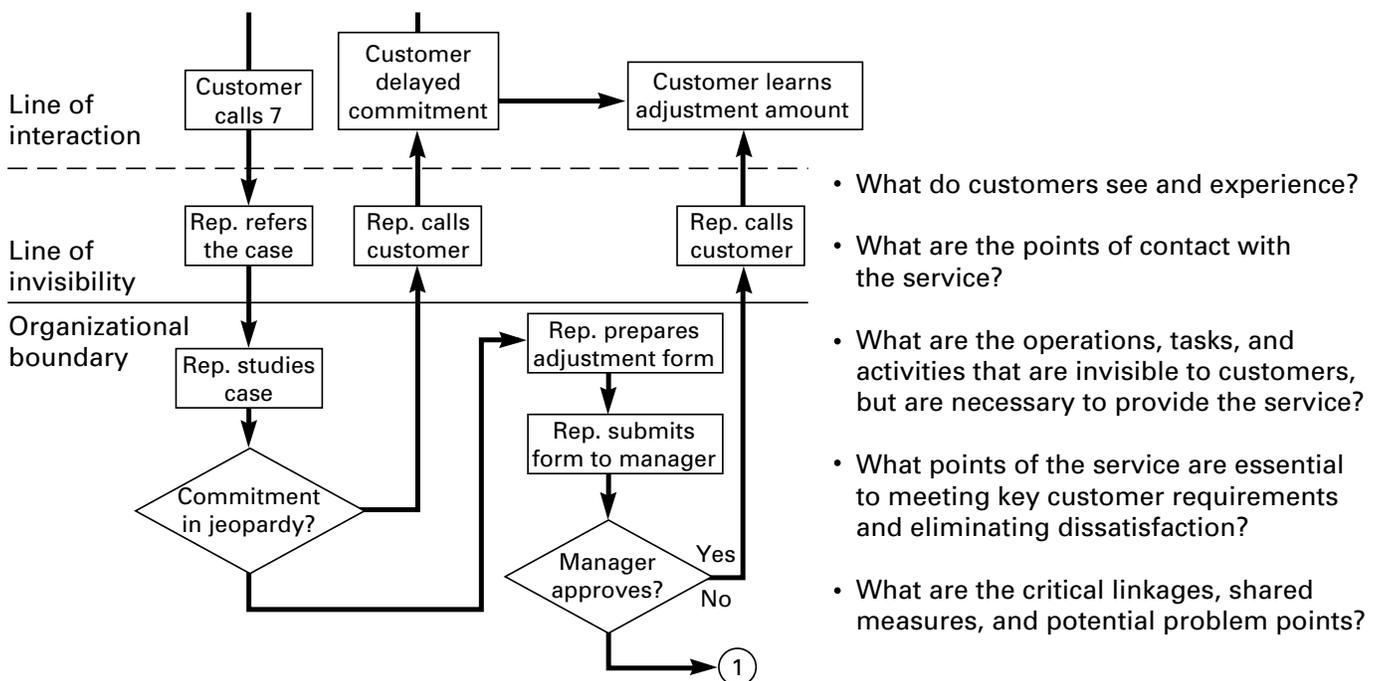
The service blueprint, which was implemented as a process, included fast, accurate, supportive, and helpful customer service representatives. The service representatives are empowered and rewarded for helping customers. First, a rigorous *daily* customer satisfaction measurement process was put in


FIGURE 25.3   Example of the customer service blueprint (see Section 3).

	Quarter or Period	Number of quality days as percent of total	Bonus as percent of salary
Associate Quality Days and Bonus	1990-4th quarter	76.1%	6.4%
	1991-1st quarter	87.8%	11.4%
	1991-2nd quarter	92.3%	9.9%
	1991-3rd quarter	96.7%	12.0%
	1991-4th quarter	95.7%	11.6%
	1992-1st quarter	60.0%	10.6%
	1992-2nd quarter	75.8%	7.5%
	1992-3rd quarter	76.1%	7.9%
	1992-4th quarter	95.7%	10.8%
	1993-1st quarter	84.4%	9.4%
Management Quality Days and Bonus	1991	87.9%	5.6%
	1992	66.1%	4.7%
	1993-1st quarter	76.6%	5.6%

FIGURE 25.4   UCS quality days: performance and bonuses. [*From AT&T Operations (1998).*]

place, coupled with a *daily* bonus plan. Figure 25.4 offers an example of bonuses actually received during a period of time. On those days when the service representatives do not receive their bonus, no manager receives a bonus. Second, the customer service processes are supported by leading-edge technology. This gives the service representatives easy and rapid access to all the information that could possibly be needed in support of the customer. Third, the customers are given differentiating value in the form of lower interest rates than are provided by any other vendor. And fourth, the company undertook the role of the agent of the customer in relationships with credit bureaus and other users of credit information.

In recent years, AT&T Universal Card Services has initiated more than 300,000 new accounts per month. This growth stems in part from the sales story that is part of the front-end, customer relationship-building process. It also comes from finely tuned customer service operations that also were part of the strategic design of the business and which have been improved and enhanced over time. This customer service strategy was part of AT&T's Baldrige Award–winning approach.

New England Telephone.   The Interexchange Customer Service Center (ICSC) of New England Telephone Company knew in 1988 that it had to make changes. ICSC is the interface between the local telephone company and the interexchange carriers. Its customers are AT&T, MCI, Sprint, mobile, radio, and television common carriers. The customers did not like the job that the center was doing, nor did management or the employees (Clarke 1992). Morale was low. The organization conducted a customer assessment and created a service blueprint. It was discovered that customers thought that New England Telephone was reactive rather than proactive. It found the company unable to relate individual jobs to customer needs. The service blueprint revealed that the organization design was that of a job shop. Employees each took a piece of paper in a hand-off and processed it. Everyone did the job according to the job description, but accountability for the results occurred only at executive levels. It was not possible to relate individual tasks to customer needs, nor to coordinate and track customer service requests and results. ICSC developed a strategic vision, which was to "…outperform competitors by providing our customers the highest level of service quality. We will be the 'best of the best' within our industry…." The solution was to reengineer the operation, establishing a customer-focused team structure responsible for all processing and service support for a customer segment. The changes affected not only ICSC but also all the company organizations that provide technical and operational services, such as network and accounting.

Hewlett-Packard Company.   Hewlett-Packard summarizes its overall strategy for quality with two acronyms (Spechler 1988). The first acronym is *FURPS*. The letters in the acronym have the following definitions:

- F = functionality. The feature set, capabilities, comparability, and security.
- U = usability. The human factors, consistency and documentation of the product.
- R = reliability. The frequency and severity of failures. The predictability and accuracy of the product.
- P = performance. The speed and efficiency of the product, as well as resource consumption.
- S = supportability. Maintainability and servicability of the product, along with its ability to be installed.

The second category of quality attributes uses the acronym *AART*. AART refers to the relationship with customers. The letters in the acronym have the following meanings:

- A = anticipation. The ability to identify, understand, and help solve customer needs before they become problems.
- A = availability. The degree to which products and services provide for uninterrupted use at full functionality.
- R = responsiveness. The ability to provide timely, accurate, and complete information and/or solutions to customer-initiated requests for help.
- T = transitions. The ease of initial startup and ongoing changes as individual products and services evolve and conform to new needs and technologies.

Many of these attributes are strongly related to customer service. Two areas of implementation where Hewlett-Packard sought to differentiate itself with exceptional customer service are the field customer engineers (CEs) and the response center engineers. The field customer engineers, who provide on-site hardware maintenance, have been equipped with hand-held portable terminals. Through these terminals, they receive notification of service calls they need to fulfill. They use the terminals to upload symptoms and to download diagnoses. At the completion of the call, the CE enters repair details, such as revised failure symptoms, parts used, and labor effort. This information enters a relational database, where it is used for parts inventory management, staff capacity management, determining training needs, and to produce the quality metrics that are part of the strategic goals and objectives.

The methodology used by Hewlett-Packard to develop, deploy, and track strategic plans, goals, and objectives for these attributes is called the *hoshin kanri planning process. Hoshin kanri* was introduced within Hewlett-Packard in the Yokogawa Hewlett-Packard subsidiary in Japan. *Hoshin* has been loosely translated into English and is generally referred to in Western countries as *policy deployment* (see Sections 3 and 13).

Motorola. Motorola's strategic customer service thrust was prompted by findings from the CEO's personal visits with key customers (Motorola 1989). The CEO visited the top 10 corporate customers during a 5-month interval in 1988 and then presented the findings to the Motorola Corporate Quality Council. Quality was the battleground of the 1980s, but the council concluded that service was evolving as the next competitive challenge. In response, one business sector established a service strategy task force to focus on the issues of customer service and to develop recommendations. The task force comprised eight senior managers, including seven officers. The eighth member was the chairperson, who was appointed to facilitate and coordinate the task. They left their current job responsibilities and moved to an off-site location for 3 months. The task force began its work with customer and associate assessments using formal survey instruments. They surveyed 54 customers worldwide and 220 Motorola business-sector employees. The highlight of the customer survey was that responsiveness emerged as the competitive issue; customers took for granted perfect quality and on-time delivery. By contrast, the employee assessment revealed that employees believed on-time delivery to be the most important issue (and, at that time, the area in which their performance was weakest). Further, the employees believed that service and responsiveness were areas of company strength and needed only improvements in teamwork, communications, and consistent goals to support them.

The task force grouped the issues revealed by the data into six categories. Then, using Pareto analysis, the task force identified issues that warranted action. (See Section 5, The Quality Improvement Process, under Quality Improvement Goals in the Business Plan.) The task force came up with 52 action items, of which the top 10 were considered urgent. One of the six categories was on-time delivery. Examples of key action items in this area included the following three statements (Motorola 1989):

1. One hundred percent on-time delivery will be the acceptable level of performance on which compensation will be based. (This replaced an incremental improvement goal.)
2. There will be disciplined use of the on-time delivery index. This means no recutting of orders, no early shipments unless approved by the customer, and no partial shipments unless approved by the customer.
3. Training in and application of the methods of short-cycle-time production and order realization will be required for all organizations, with applied measurements and goals.

Another catagory of issue from among the top six was responsiveness. Here the task force decided on the following key action items (Motorola 1989):

1. A schedule of formal visits with all key customers
2. A no-questions-asked return policy
3. Development of systems and procedures to take an order anywhere in the world and ship it anywhere in the world
4. Elimination of the "will advise," "will schedule," and "Motorola to advise" from the backlog lexicon

The consequences of these actions and comparable action on the other issues were reflected by a number of Motorola quality awards and in independent third-party customer satisfaction assessments that revealed improved perceived performance.

DESIGN

Many of the design approaches that apply to customer service processes apply to the design of any business process and are well covered in Section 6, Process Quality Management, and in the reengineering literature, the human factors literature, the organization design literature, and elsewhere. Pyzdek integrates the systems engineering considerations, the organization, and the human factors considerations into an integrated design paradigm that he calls *service systems engineering.* The term *service systems engineering* actually has been used for decades in industries such as the transportation industry and the telecommunications industry to size traffic-carrying systems and facilities. Techniques employing approaches from the fields of applied probability and statistics are found in the systems engineering and operations research literature. What distinguishes Pyzdek's approach is the integration of these approaches with the very important behavioral and organization considerations (Pyzdek 1994).

Pyzdek defines a *service delivery system* as a systematic arrangement of human resources and technology designed to create successful service encounters. A *service encounter* is the direct interaction between a retail or service firm and a client. As described in the preceding section, success is measured in terms of a set of business performance criteria.

Systems Engineering.   Table 25.2 identifies the major inputs, activities, and outputs of the service delivery systems engineering process. Managing these steps for quality involves knowing how the precise and measurable quality objectives for the final customer service translates into specific, measurable performance standards for the inputs, outputs, and activities.

TABLE 25.2   Major Inputs, Activities, and Outputs of Service Delivery Systems

Inputs	Activities	Outputs
Information from business case, including • Market segments • General service definition • Demand or volume forecast • Quality, reliability, other performance goals	Analyze/clarify user needs and service objectives	Create service requirements document, including • Functions • Performance • Quality and reliability standards
Service objectives and customer needs	Create a functional framework	High-level service architecture
Service constraints	Create functional and cost boundaries	High-level cost objectives
Technology roadmap	Analyze available technologies	High-level technology architecture
Feasibility analyses and exploratory service development results	Plan service development	Service design and implementation documentation

Organizational Structure.   The planning and management controls associated with the specific customer services are intended to guide and support managers and associates in all parts of the organization in their definition of meaningful tasks and in the specification of procedures to monitor their effective completion. From this perspective, it is easy to recognize the central importance of organizational structure. Responsibility has to do with the nature of the tasks entrusted to each individual. The design process is a primary vehicle to identify, in a coordinated manner, the major tasks faced by the enterprise and to organize those tasks in the most effective way (Hax and Maluf 1984).

The organizational structure to perform the customer service functions may be defined as "the relatively enduring allocation of work roles and administrative mechanisms that create a pattern of interrelated work activities and allows the organization to conduct, coordinate and control its work activities" (Jackson and Morgan 1978). There are three accepted basic types of organization for managing customer service work and two newer, emerging approaches. The accepted organizational types are functional, divisional, and matrix. They are important design baselines because these organizational structures have been tested and studied extensively, and their advantages and disadvantages are well known. The matrix structure is a hybrid combination of the functional and divisional archetypes. The newer, emerging organizational designs are process and network organizations.

The design attributes associated with division managers, functional managers, process managers, and network managers of customer services are summarized in Table 25.3. There is emerging evidence that divisional and functional organizations may not have the flexibility to adapt to rapidly changing marketplace or technological changes. This is especially true of larger customer service organizations associated with large companies. For this reason, there is a trend in large companies to outsource the customer service function, a topic that is addressed below.

Human Resources.   Behavioral science helps us to understand human capabilities, capacities, and needs for the design of customer service systems. This understanding is becoming increasingly important for several reasons. First, modern technology, especially information technology, is providing the foundation for customer service systems. For these systems to be successful, it is essential to design effective human-machine coupling. Second, modern technology is increasingly embodied in products and services, making new and unusual demands on customers. For these products and services to be successful, user-friendly human-machine interfaces again are essential. Third, to the extent that the user-friendliness of products and services is less than perfect, customers will make use of customer services to help them through the rough spots.

TABLE 25.3   Design Attributes of Various Roles in a Customer Service Organization

	Division manager	Function manager	Process manager	Network leader
Strategic orientation	Entrepreneurial	Professional	Cross-functional	Dynamic
Focus	Customer	Internal	Customer	Variable
Objectives	Adaptability	Efficiency	Effectiveness	Adaptability, speed
Operational responsibility	Cross-functional	Narrow, parochial	Broad, pan-organizational	Flexible
Authority	Less than responsibility	Equal to responsibility	Equal to responsibility	Ad hoc, based on leadership
Interdependence	May be high	Usually high	High	Very high
Personal style	Initiator	Reactor	Active	Proactive
Ambiguity of task	Moderate	Low	Variable	Can be high

Sources: The first two columns are adapted from the work of Financial Executive Research Foundation, Morristown, N.J. The last two columns represent the work of the author.

Because new customer service systems involve more interactions between users and supporting systems than ever before, making these systems easy to use and error-free is a major goal of their design. Properly designed information input arrangements, easy-to-read screens, announcements, timings, and instructions increase user acceptance, minimize errors, and promote effective use. Training programs for customer service representatives and easy-to-understand and easy-to-use instructions for customers are very important.

The design of new customer service systems can be evaluated for user-friendliness by coordinated studies that include (Bell 1983)

- Analysis of present customer service systems
- Benchmarking of best-in-class customer service systems
- User interviews
- Laboratory studies of protocols for user-system interactions
- Field tests of customer services
- In-service follow-up studies for continuous improvement

Investigation of best-in-class systems is particularly useful. In the area of customer service, certain companies are well known for the efficacy of the approaches, e.g., L.L. Bean for order entry, Fidelity Investments for account inquiries, and GE for broad customer support.

It is clear that the customer service representatives as well as all other employees whose work affects the customers' perception of service are critical elements of the customer service design. The design of the roles of individuals in the enterprise, including those whose jobs involve customer service, must be within the frame of a human resource architecture for the enterprise. An example of such an architecture is that in Figure 25.5. In order for the customer service design to be successful, the design must address more than the functional processes and systems associated with the service. Each of the people considerations identified in Figure 25.5 also must be included, either directly or by reference to the overall human resource architecture design documents.

Electronic Data Systems (EDS).   In 1992, EDS put in place a matrix organizational structure radically different from those in most successful U.S. companies (EDS Homepage Internet www). The matrix structure is a hybrid that has elements of the divisional and network designs. The structure involves 35 to 40 strategic business units (SBUs). The number changes frequently, as it would in a network design, due to business demands. There are approximately the same number of strategic support centers (SSCs), which support SBU requirements. The organizational relationships

between the SBUs and the SSCs form a matrix. Think of the various SSCs as the entries in the columns of the matrix and the SBUs as the entries in the rows of the matrix. Stanford University's business school has included in its core curriculum a case study of this organization design. In this design, key customer service teams reside organizationally in the SBU, which is the profit center, while commodity production services (e.g., EDS information-processing centers) are outside the profit centers, in the support organizations. The SSCs have the people with the subject matter expertise to perform key functions for the SBUs, and the SBU managers have the budget to pay them for their support services. EDS's approach to human resources is based on customer focus and rewards. These are the key elements of the HR architecture.

- *Customer focus:*   The company keeps its people focused on what is important: quality delivery. The company practices a severe approach to employee alignment—"If you can't change the people, change the people!"
- *Reward system:*   Since 1993, EDS has changed its reward system to emphasize team awards. This appears to be comparable to the approach practiced by AT&T's Universal Card Services, described earlier.

STRUCTURE

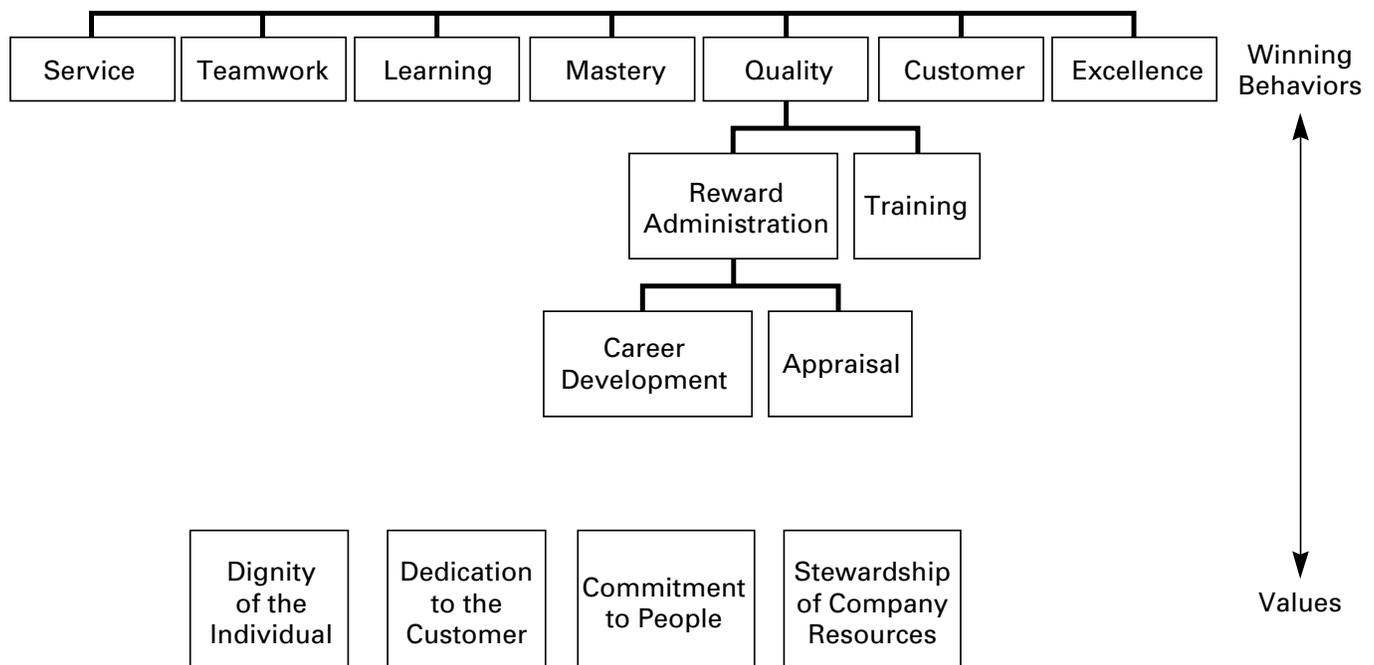
Presales customer service systems support such services as sales information, ordering, and market research (see Table 25.1). These are both outbound and inbound services, since they involve service representative-originated calls to customers and customer–originated calls for service. In the diverse universe of differing products and services that are addressed by this section, the term *call* should be understood broadly as referring to both personal calls, such as calls on a customer by a salesperson, and remote calls, such as telephone calls by a customer to place an order or to request sales information. Postsales customer service systems support such services as complaint handling and problem solving; again, refer to Table 25.1. These systems are usually primarily inbound services, involving calls from the customer or from installers or maintenance personnel to the support system.


FIGURE 25.5   Human resource architecture.

Examples of configurations of such systems are included later in this section. A wide variety of tools is in use to help the customer service personnel and to help the customers. Examples of tools, organized by category, are shown in Table 25.4.

The configuration of customer service tools to execute the customer service process can take a variety of forms. Two of these are illustrated in Figure 25.6. The configuration in Figure 25.6*a* is a traditional one, where each function is supported by its own work center. The configuration in Figure 25.6*b* is a more advanced arrangement, one that typically emerges from a TQM or a re-engineering initiative.

TABLE 25.4   Some Important Tools in Customer Service Systems

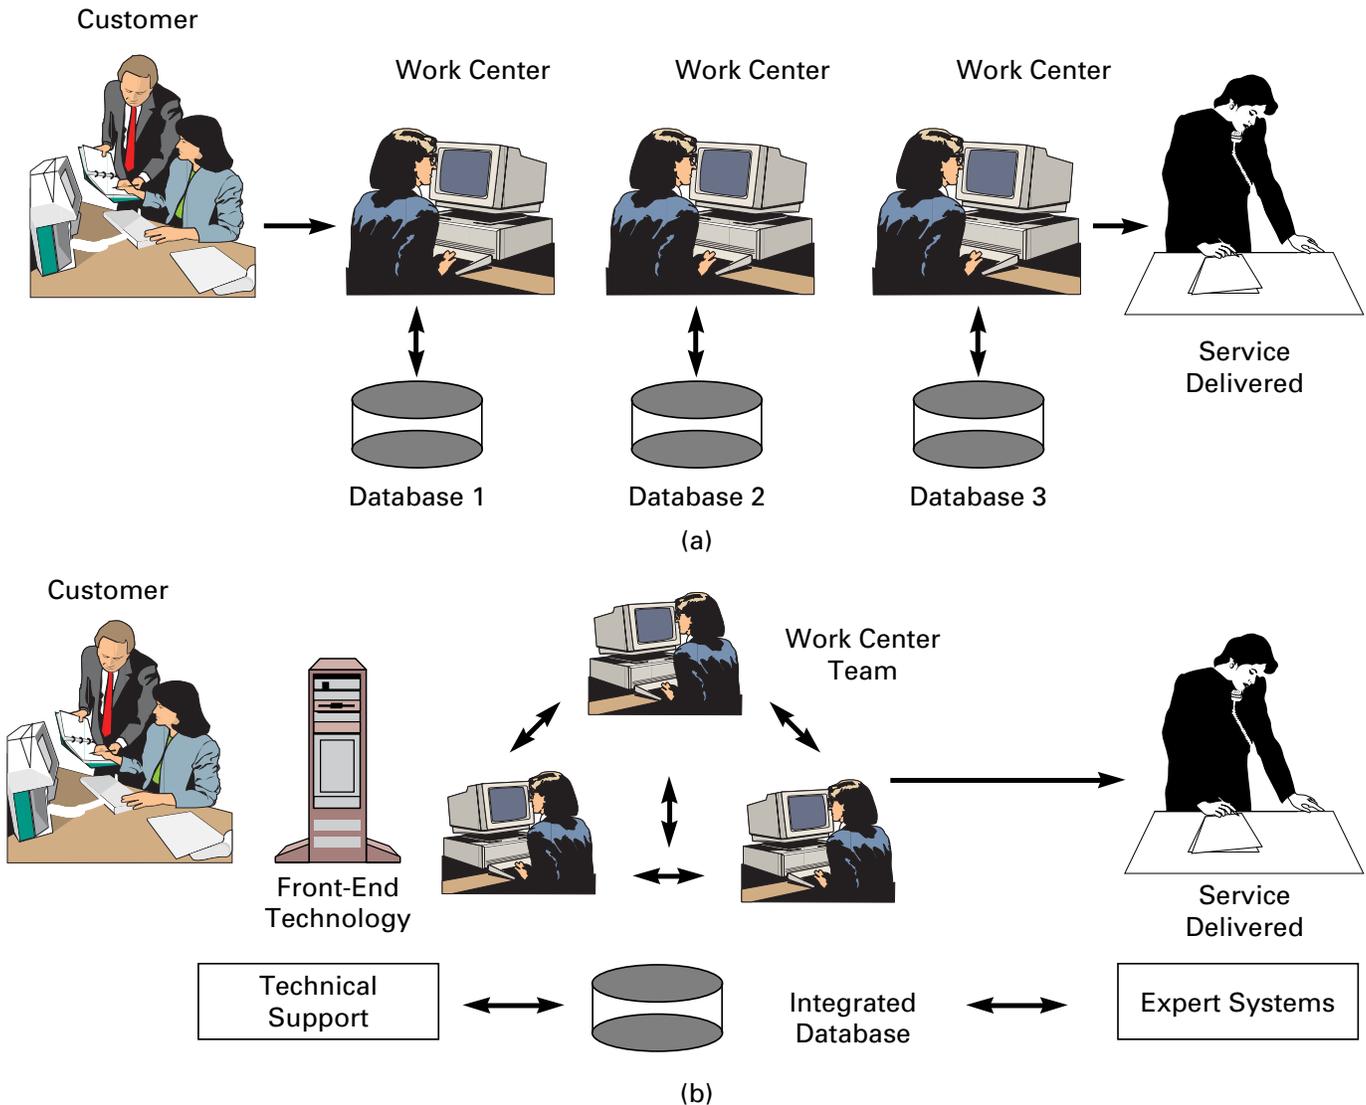
Access tools	Process tools	Enabling tools
Automatic call distributors	Customer information resource databases	Intelligent agent software within the product
Voice-response units	Remote access tools	On-line support services to log requests, check status, etc.
On-line bulletin boards	Outsourcing vendors	User access to knowledge bases
Fax servers		Integrated voice recognition/response


FIGURE 25.6   (*a*) A traditional organization with functional work centers and separate databases. (*b*) A more advanced organization with team work center and integrated database.

The Work Center team is a colocated group consisting of the major work functions required for delivery of customer service from the initiation of a request for service through the delivery of the service. The attributes of the design of the Work Center team for high-quality performance are

- The team includes all the necessary work functions.
- The team bears complete responsibility for satisfying the customer. Performance of the team is measured accordingly.
- The team uses a set of work processes that are formulated in the design step that eliminate rework and review and that meet service delivery quality objectives.
- The team is provided with the technology and systems that enable its members to meet the objectives.
- The team is sized and trained according to the criteria included in the design process.

Structurally, we may think of these teams and associated systems and tools as defining an enterprise in terms of its processes, as shown in Figure 25.7. As we have seen, there are numerous ways in which these processes may be organized to work together.

Consider the customer service process for an enterprise that provides "help desk" or "customer care" types of service to customers who have problems with a purchased product. The product could be an unsatisfactory software package for a PC, or a malfunctioning dishwasher, or a shirt purchased by mail order that is the wrong size. Let's see what the customer service process of Figure 25.7 might look like, in terms of the tools described in Table 25.4, organized in configurations such as those in Figure 25.6. Such a configuration is illustrated in Figure 25.8.

Incoming calls encounter a voice response unit (VRU), which engages the caller in a dialogue to determine the nature and the priority of the call. Based on this information, the call is routed to the first available analyst. The analyst examines the symptoms provided by the call and either resolves the matter or directs the call to a subject matter expert at the help desk. If the problem is complex, the analyst may obtain technical assistance. If the problem is very complicated or unusual, it may require the support of the product vendor for resolution.

Customer Care Center Example. Quality function deployment (QFD) is an effective tool to provide the coupling between the customer satisfiers and the design process. One of the methods used in QFD is the "house of quality." Figure 25.9 is an example of the house of quality developed by a re-engineering team for an enterprise that provides desktop computing services to business customers. The customer requirements data, in the language of the users, were gathered from customer interviews. The data were transferred to the house of quality, and design attributes and performance targets were determined by the re-engineering team. The customer needs were in the categories Knowledge and Responsiveness. Under the latter heading, the customers identified many subcategories: Promptness, Completion Estimates, Status, Access, and Communications. For each performance category, the customers and the re-engineering team agreed on one or more performance measures that appropriately capture the customer need. Then the re-engineering team developed a set of design attributes and priorities that formed the house of quality. Notice that the attributes that comprise the rows in Figure 25.9 fall into three design categories: systems, human resources, and organizational structure.

The design attributes of Figure 25.9 then were translated by the re-engineering team into a design concept, portrayed in Figure 25.10. The specific design concept looks similar to the hypothetical design of Figure 25.8. The key needs that were identified in the QFD exercise, which are emphasized in the design concept, are

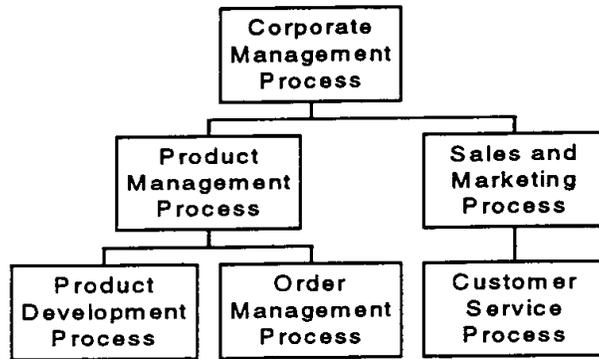
- Increased knowledge on the part of the Customer Care Center associates
- Systems and resources that provide a high degree of responsiveness
- Systems that provide increased accessibility to the Customer Care Center
- Accurate and complete responses to customer questions


FIGURE 25.7   An enterprise described in terms of its major processes.
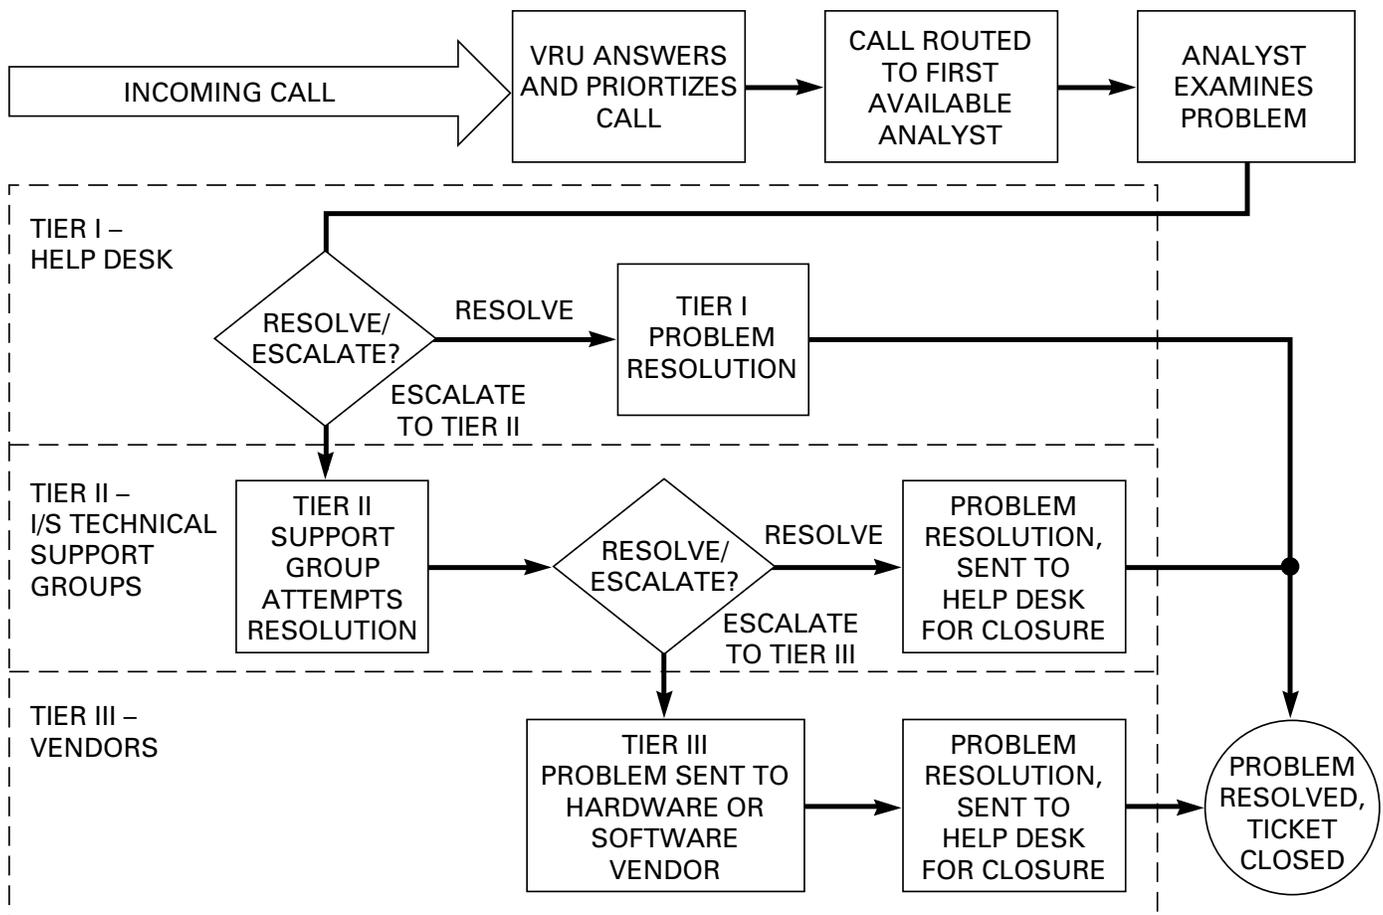

FIGURE 25.8   The "customer care" or "help desk" organization. [*From AT&T Operations (1998).*]

The team also prepared performance objectives for the design concept, which could be used to test the design for compliance with customer needs. These are examples of the objectives for the Call Center:

• The Call Center will be capable of resolving 60 percent of customer service requests without the need for second- or third-tier support.

• An average call to the Call Center will take about 10 minutes to resolve.

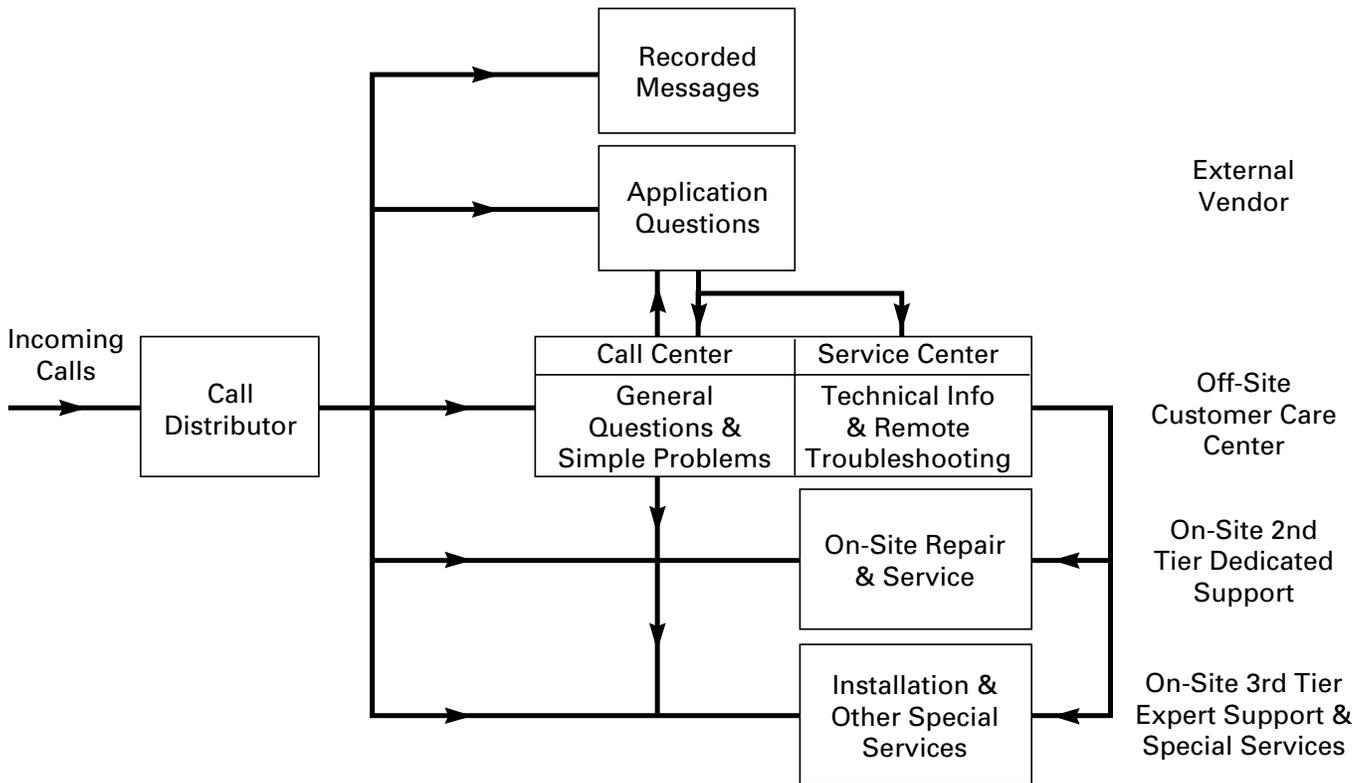
25.15


FIGURE 25.10   Process-design concept model. [*From AT&T Operations (1998).*]

- The Call Center will function as a learning organization.
- The Call Center will comprise both permanently assigned employees and employees assigned on a rotating basis from the functional service organizations supported by the Call Center.
- Permanent employees will provide general customer service and also will be responsible for quality and training functions.
- Employees on rotating assignment will provide specialized skills to the Call Center but also will support general customer service to gain familiarity with the "voice of the customer."
- All Call Center agents will be trained in customer contact skills and in the skills required for solution of common problems.
- All solutions to customer problems will be entered into the system knowledge database.
- All transactions with customers will be recorded for analysis to determine root causes and to support quality improvement.

OPERATIONS

The last important area where quality must be considered is the operational area. This is where results are achieved, measured, and improved. The ongoing performance of operating customer service processes includes such considerations as human performance, process control, process capability, and process improvement. Performance metrics are important here. These considerations for customer service share quality methods in common with most other business functions. Therefore, interested readers should refer to earlier sections to understand the generic methods. In particular, the following sections are important: Section 4, The Quality Control Process; Section 5, The

Quality Improvement Process; Section 6, Process Management; Section 9, Measurement, Information, and Decision Making; Section 15, Human Resources and Quality; and Section 16, Training for Quality. This section will focus mainly on examples of the operations of well-designed, well-structured customer service capabilities that employ the methods described in these earlier sections.

PROCESSES AND SYSTEMS

The first requirement for successful management, control, and improvement of customer service processes is to have well-defined, well-understood processes. Often, steps to manage and improve quality are undertaken without process definitions because no one has taken the time to think through and document, especially in process diagrams, the way work is done. Ideally, the initial versions of such documents are produced as part of the service design. An example of process diagram for the process described in Figure 25.10 is shown in Figure 25.11.

The process diagram uses a particular flowcharting convention (*AT&T Operations Engineering Workbook*). There are many available process flowcharting conventions and tools. The particular conventions used here are summarized in Figure 25.12.

A detailed understanding of the conventions used in Figure 25.11 is not important here; the words and arrows convey enough meaning for our purposes. It is important to remember that it is not possible to control and improve customer service operations without process descriptions and associated metrics. Attempts at control and improvement without process descriptions and metrics are only guesswork. And metrics without defined processes only make for busywork, with no real value. Worse yet, lacking processes, it is tempting to measure the performance of the people who provide customer service. The consequences of so doing are severe. The people will do their work to make the metrics look good rather than providing customer service that maximizes customer satisfaction. And the people will lobby strongly for weak metrics that may very well be irrelevant to customer needs or business requirements.

In addition to process control and improvement, it is important to recognize that as an enterprise grows or as customer services are extended and augmented, process capability must be monitored. This involves continuous oversight of customer service processes in search of stress cracks that may be caused by saturated processes, by changes in customer needs, or by other considerations not congruent with the design intent and implementation criteria. Process capability studies are addressed in Section 4. When the demands of the process exceed the process capability, the process must be reengineered. Process reengineering also may yield improved efficiency or effectiveness, especially when it incorporates new or improved technology.

OUTSOURCING

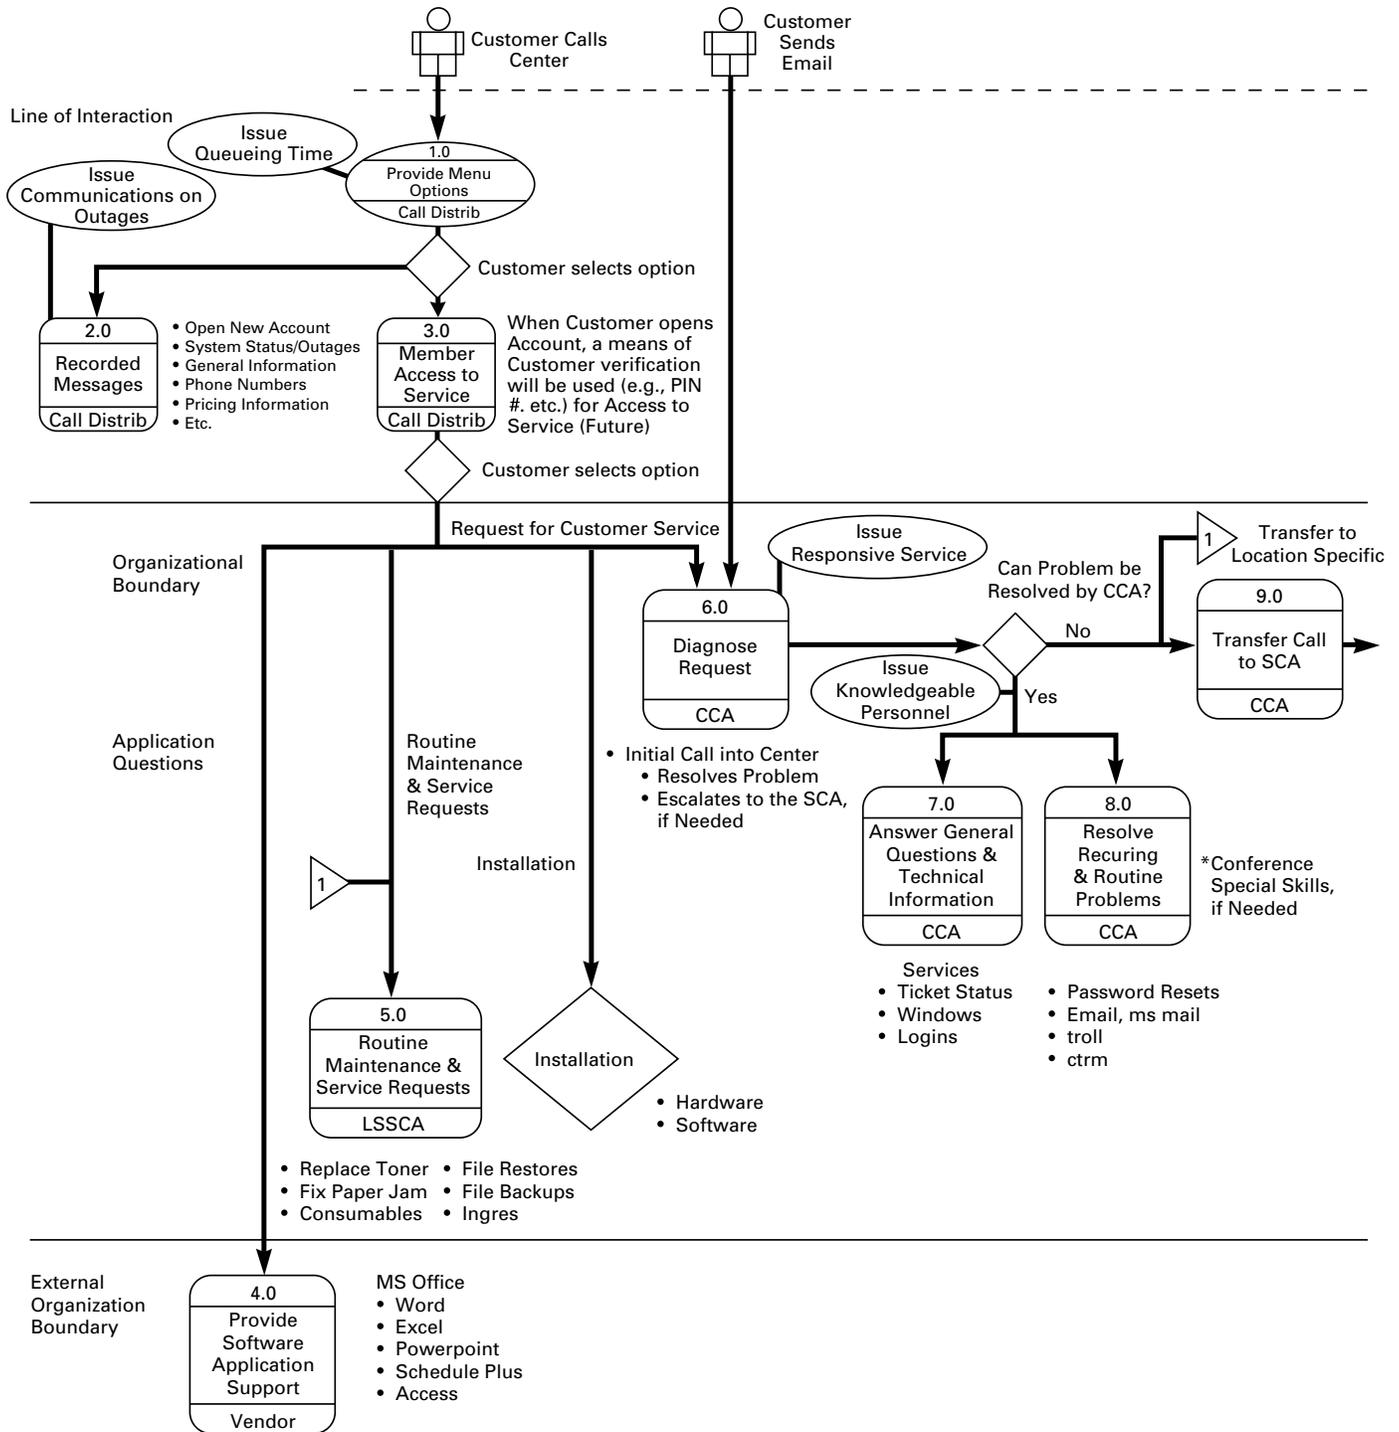
In many enterprises, business process re-engineering (BPR) initiatives introduce issues relating to legacy migration and outsourcing. *Legacy migration* is a term used to connote the migration of customer service systems from their traditional (legacy) processes and associated systems to modern, leading-edge processes and systems. Traditional approaches have legacy hardware, software, training, and cultures that must be overcome to replace them effectively with modern approaches that provide competitive advantages. The corollary issue is whether the customer service functions should be done at all inside the enterprise, or whether the enterprise should *outsource* the functions to companies that specialize in performing them. Companies that provide customer service functions on an outsourced basis are prominent in the customer service arena, performing many of the associated functions at superior levels. The conventional wisdom on this question is that if the customer service functions are strategic to the enterprise's business strategy, as defined earlier, under Strategic Intent, then the functions should be performed internally. This


FIGURE 25.11   The customer care center: high-level overview. [*From AT&T Operations (1998).*]

is easy to understand, since the functions are part of a strategy to be better than the best competitor in some critical dimension of service. On the other hand, if the functions are not strategic, then the question of whether they can be performed at levels of quality and at costs that are comparable with those of the *outside* companies is a valid one. Customer service functions of many quality-award-winning companies are provided by outside companies unbeknownst to the customers.

MEASUREMENT AND METRICS

Common to all approaches designed to achieve excellence in customer service operations is instrumentation for the collection and analysis of information. We must begin with some basic definitions.

- *Metric:*   Unit of measurement. Common metrics in everyday life are miles (or kilometers) to measure distance and pounds (or kilograms) to measure weight.
- *Statistical metric:*   The result of a calculation procedure. For instance, the most commonly used statistical metric is the arithmetic average of a set of numerical values. One could easily calculate the average weight of people riding in the elevator with you by asking them their individual weights, adding the numbers, together with your weight, and dividing the sum by the total number of people in the elevator. Of course, the people in the elevator may not know their weights exactly, so the calculated average would be an estimate.
- *Data:*   A set of individual measurements. The data are usually the input to a statistical metric. For instance, the weights of the individuals in the elevator comprise a set of data.
- *Analysis:*   Structured ways of comparing data and statistical metrics. For instance, Tom weighs more than the average of the people in the elevator.

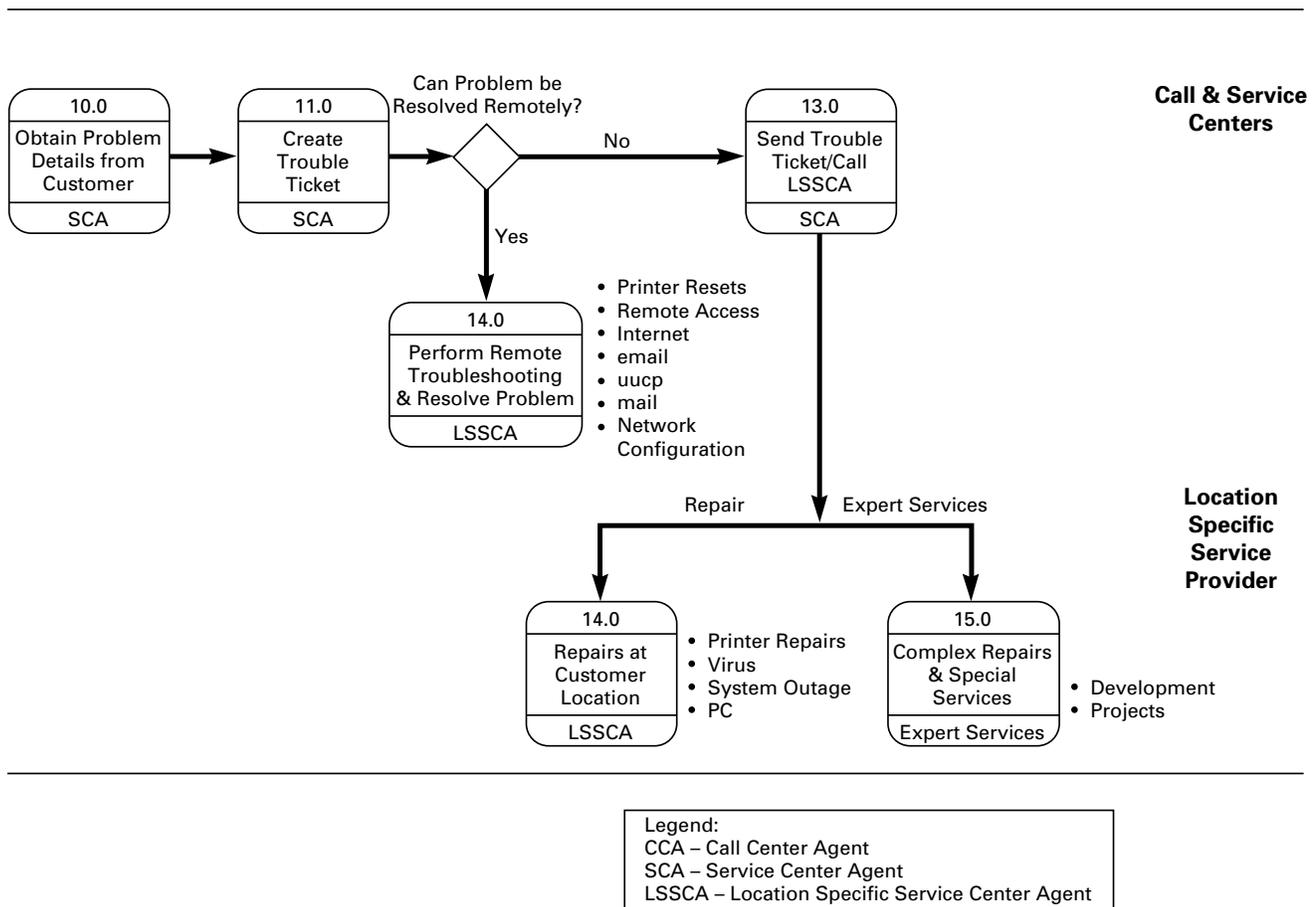
With these definitions in mind, we are ready to view Figure 25.13, a process diagram for defining, collecting, and analyzing metrics (I am indebted to the AT&T OE Process Management Consultants for most of this material on this topic.). In the following explanations, it is assumed that


FIGURE 25.11   (*Continued*)

SYMBOLS

OEW flow-charting symbols are designed to capture a maximum amount of information and still maintain an uncluttered appearance for the resulting flowcharts. They also ensure a consistency and uniformity between process descriptions.

Processes are represented by large diamonds with the name of the process written inside.

Processes external to the process to be improved are depicted as diamonds with "cut corners". The name of the external process is written inside the diamond.

The names of organizations external to the process to be improved (e.g., Customer or Vendor), are shown as a aquare with "cut corners".

Functions performed by organizations or work centers are symbolized by a vertical rectangular, with rounded corners. The rectangle is divided into three areas. The top area contains the acronym and function number. The middle area contains the name given to the function. The bottom area identifies the organization performing the function.

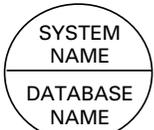
A function which has been improved will have a asterisk (*) before the function number.

Functions performed solely by computer systems are depicted by a circle divided into three areas, The top two areas are as described above; the bottom area contains the name of the computer system.

There are two types of interfaces (inputs/outputs). A solid line is used for information. A dashed line is used for material. The name of the information or material is written on the line.

Support systems are depicted by a circle containing the name of the information system. This symbol is used when the system is supporting a function. Two parallel, vertical lines show input and output flowing between the system and function.

FIGURE 25.12   Flowcharting: symbols and conventions. [*From AT&T Operations (1998).*]

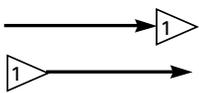
SYSTEM NAME / DATABASE NAME


A small circle divided into two sections depicts a specific database that is being accessed by a system. The top half contains the name of the computer support system, and the bottom half contains the name of the database.

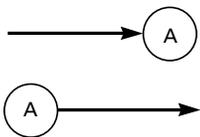
ISSUE

Any issue identified within a process is shown in an oval above or below the point at which it occurs. The point is marked by an X and is connected to the oval by a line.

Any metric associated with part of a process is shown in a rectangle above or below the point at which the metric is measured. The measured point is marked by an X and is connected to the rectangle by a line.

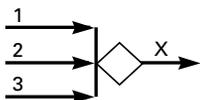
METRIC


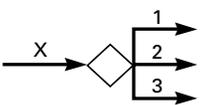
Feedback symbols are used to prevent flow-charts from becoming too cluttered. Feedbacks are always labelled numerically. Identical labels must be given to both ends of the feedback flow.

A


Connector symbols are used when the splitting of a flow must be divided between pages. The symbol is a small circle with a capital letter. The identical letter is given to both sides of the division.

DECISION POINTS:

Decision points are shown as small diamonds. These are points at which choices are made based on pre-specified conditions called decision rules. They are generally given as supporting function descriptions (see p. 8).


In this case, a decision rule in an upstream sending function, based on outputs 1, 2 and 3 dictates what occurs at X. For example, the decision rule may be: if 1 and 3 are both present, then send 2 to X, otherwise take no action.


In this case, a decision rule in an upstream sending function, based on the output x, dictates what occurs at 1, 2 and 3. For example, the decision rule may be, if X is greater than 10 send X through to 1, if it is between 5 and 10 send through to 2, otherwise send through to 3.

OE Flow-charting conventions assure that complex flow-charts are interpreted in only one way. They also help to ensure consistency and uniformity between projects.

DIRECTION: Process flow-charts show the time sequence of the functions performed. The progression is from left to right.

The following situation could arise when constructing process flow diagrams: Five functions; A, B, C, D, and E, are considered. Functions A and B receive materials from external suppliers and perform separate operations on them. Their products go to a "storage" function C where they are kept for some time before being sent to D for further processing. When the product of function D is ready, it goes to C for storage for additional time, before being sent to E for final test and shipment to an external customer.

FIGURE 25.12   (*Continued*)

the activities identified on the far left end of Figure 25.13 have taken place; process descriptions exist, and business needs, in the form of goals and objectives, have been defined as part of the strategy formulation and service definition.

The first steps leading to the deployment of customer service metrics are to identify the requirements for metrics and to define the specific metrics that satisfy the requirements. Usually, metrics address some or all of three process considerations:

- *Customer service process effectiveness:*   Does the output of the process step meet customer needs? One approach to this metric is to quantify the defects that escape the process.

- *Customer service process efficiency:*   Does the process make good use of resources? One approach to this metric is to quantify defects internal to the process, such as rework.

- *Supplier effectiveness:*   Do the inputs to the process meet its needs? An approach to this metric is to quantify incoming defects.

The metrics recommended in the preceding paragraph all focus on defects. In the sense intended for these metrics, a *defect* is anything that does not meet or exceed the requirements of the customer, the business, or the process. Since the focus on defects is primarily on internal defects, rather than on defects that affect the customer, the emphasis on defects is a preventive approach, eliminating problems before they have any effect on the service provided to the customer. Therefore, it is important to have a realistic threshold for what is called a *defect.*

When defining the metrics, it is important to ensure that the data required to calculate them can be collected readily and reliably. The metrics team should think through the sources of the data, the likely methods of collection, how defects will be identified, the amount of effort required, and the cycle time for data collection. All the key characteristics should be represented with metrics, even though all of them may not be implemented initially. The metrics team should think through how each method may affect behavior and be modified if required to ensure that the metrics will drive the desired behavior.

IBM Corporation.   Large companies that emphasize customer service, such as IBM, approach the measurement process in a comprehensive way (Edosomwan 1988). Customer service quality measurements at IBM address four areas that affect customers:

- Customer requirements

  1. Customer partnership
  2. Quality assurance
  3. Reliability
  4. Empathy
  5. Durability
  6. Responsiveness

- Task requirements

  1. Supplier options
  2. Vendor options
  3. Operational options
  4. Department options
  5. Interfunctional options
  6. Cross-functional options
  7. Production options
  8. Delivery options
  9. Consumption options

- Organizational requirements

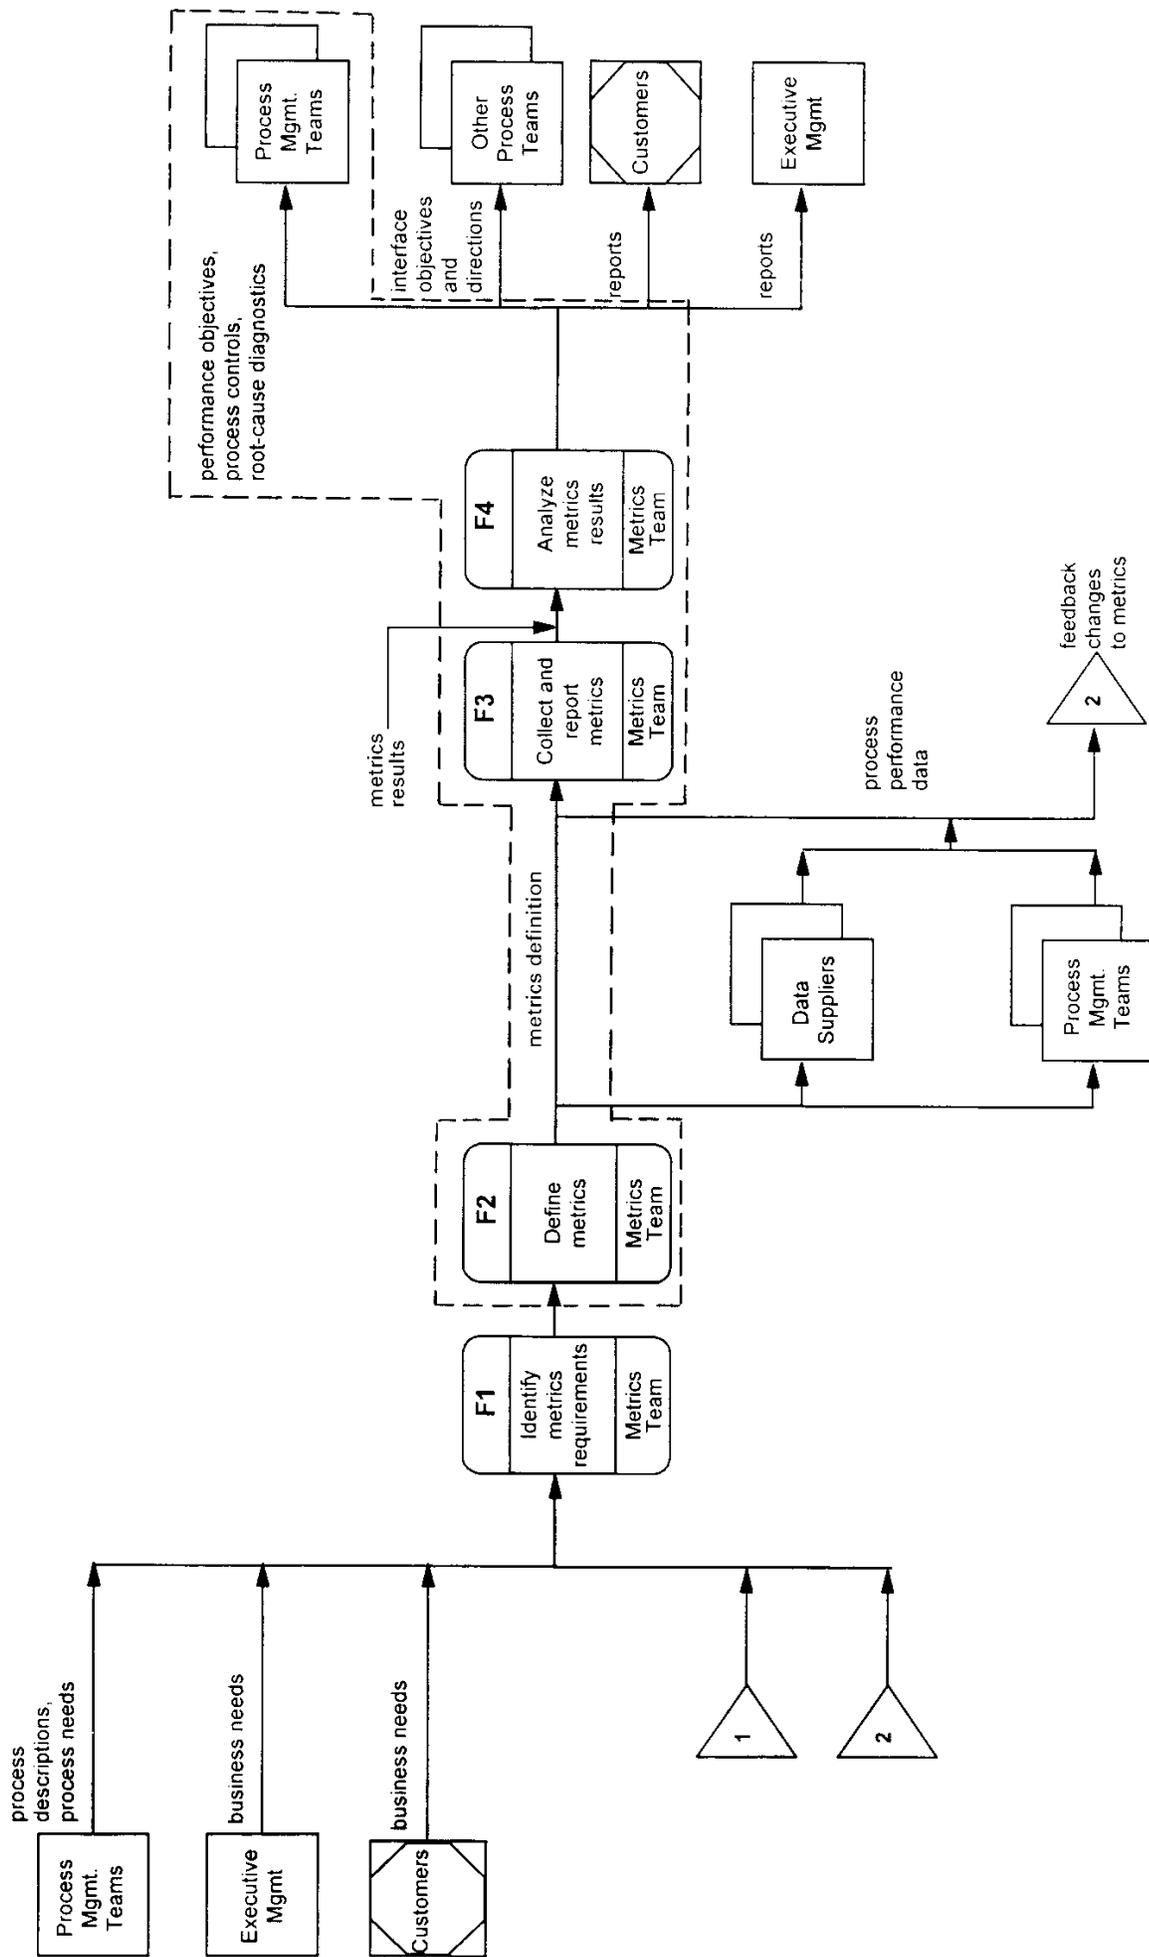
  1. Management commitment
  2. Education and training


FIGURE 25.13 Defining, collecting, and analyzing metrics.

25.23

   3. Defined roles and responsibilities
   4. Recognition and reward
   5. Communications
   6. Goal-setting process

- Process control requirements

   1. Measurement tools
   2. Evaluation tools
   3. Improvement tools
   4. Information
   5. Resource allocations
   6. Planning
   7. Feedback mechanisms
   8. Environment-monitoring tools

Each of the four areas is conceptually addressed at five levels, as shown in Table 25.5. Examples of specific types of metrics that IBM uses to implement the preceding structured approach are summarized in Table 25.6 (Edosomwan 1988).

The examples include objective metrics, such as defect levels and error rates, and subjective measures, such as competitive quality ratings. In both cases, the usefulness of the data are determined by the effectiveness of the definitions of what constitutes a defect or an error, how the customer questionnaires and surveys are designed and implemented, and how the data are analyzed and used to drive control, improvement, and planning efforts. Therefore, education and training of all levels of personnel are critically important. According to IBM, the education and training requirements summarized in Table 25.7 are appropriate for a medium-sized division. Recall that the content, allotted times, and budgets are those which were given in 1988.

The education and training summarized in Table 25.7 do not include the specialized training that is given to the customer-facing customer service personnel. The training for the customer service personnel is tailored by business unit to the particular approaches, systems, and strategies employed for the products and services sold and supported by the business unit.

TABLE 25.5   Impacts of Quality in Customer Service

Level of service quality	Potential areas of impact
Fitness for use	Customer
Fitness for standard	Operational processes
Fitness for demand	Cycle times
Fitness for planning	Planning service quality variables
Fitness for control	Protecting customer requirements

HUMAN RESOURCES

The human resource (HR) issues for enterprises that focus on excellent customer service involve both the customer-facing staff and all the associates in the enterprise who support the customer-facing staff and the customer service strategies and processes.

The key issues concerning the customer service staff are summarized in Table 25.8. The operational framework for the customer service issues summarized in Table 25.8 should include goals, metrics, and improvement approaches for each HR issue. Examples of such a framework are summarized in Table 25.9.

EMPLOYMENT CONSIDERATIONS

Quality Progress reported a study by Abt Associates of 50,000 customer service employees. The study found that customer satisfaction depends on the degree to which customer service employees believe that they have the capability, the tools, and the organization's support to provide for the customers' needs (Struebing 1996). The same article reported an expert assessment that customer service initiatives can be headed for success or failure at the very first step, the recruiting of customer-facing employees. Here, personality is the critical characteristic.

CONTINUOUS IMPROVEMENT

The philosophy, methods, and tools for the continuous improvement of customer service are similar to those for other functions and are generally covered in Section 6. It is important to remember that continuous improvement involves incremental improvement when appropriate and discontinuous improvement when required. Part of the improvement process involves continual environmental scans in search of early warning signs of changing markets, of new opportunities, and of new competitive threats. In some cases the improvement needs or opportunities will be customer-driven, in some cases they will be competitor-driven, and in some cases they will be driven be emerging technological capabilities. In any of these cases, improvement may be emphasized by including it as part of the strategic planning process discussed earlier in this section.

TABLE 25.8   Human Resources: Quality Initiatives for a Customer Service Organization

Human resource issues	Key operational initiatives (examples)	Key strategic initiatives (examples)
Recruiting	Active relationships with suppliers of customer service recruits	Identify competencies and skills required for customer service job functions
Education and training	Conduct skill assessments and gap analyses	Develop and deliver functional skills and people skills
Tools and technology	Instrument the information technology and tools to provide metrics for improvements and rewards	Acquire and deploy information technology and tools in support of customer service functions
Involvement	Implement feedback and incentive building processes	Develop team-centered customer service organization structures
Empowerment	Provide leadership, role models, and examples for institutionalizing empowerment	Create stakeholder relationships between customer service associates and the enterprise
Performance and recognition	Provide immediate, visible feedback and reward for exemplary performance	Ensure that recognition and reward processes emphasize desired behaviors and business results

TABLE 25.9   Human Resources: Operational Framework for Quality Initiatives

HR issue	Goal	Metric	Improvement approach
Recruiting	100% follow-up within 48 h	Cycle time to yes/no decision	Process improvement for cycle-time reduction
Education and training	Fully qualified front-line staff	% Customer service staff with up-to-date education and training milestones	Cascaded goals and objectives for policy deployment
Technology and tools	Provision systems to permit answering 100% of incoming calls within 15 s	% calls with answer times greater than 15 s	Associates and managers review performance daily at start-of-shift meeting
Involvement	Cascaded personal and team goals and objectives for everyone	Suggestions for improvement per associate	Customer service teams
Empowerment	Every associate has the authority and the tools to satisfy the customers	Leadership survey scores	360-degree assessments
Reward and recognition	Every associate has documented SMART goals (*S*pecific, *M*easurable, *A*greed-to, *R*ealizable, *T*ime-bound)	Associate and management performance assessment scores on goal setting and realization	SMART goals include shared team goals and individual goals; some goals are SMAST (S=*S*tretch)

L.L. Bean.   The first step by L.L. Bean to initiate an environment of continuous improvement in its customer service operations was to assign a full-time facilitator to help the customer service manager in the effort (*Customer Service Newsletter* 1995). A transition team was formed to re-engineer the customer service process to include a continuous improvement capability. The team was formed based on expertise in four essential competencies.

- *Customer focus:*   Are team members committed to meeting the needs of external and internal customers, and can they build effective relationships with all customers?
- *Team play:*   Are team members willing to share knowledge and information with others? "We don't want people who are going to try to build job security by hoarding information," noted the team facilitator.

- *Good communications skills.*
- *Flexibility and adaptability* to changing work conditions.

The team began by understanding the current customer service process. The team discovered that it was based on hand-offs, many of which were unnecessary. The hand-offs were especially problematic whenever there was a transaction that a front-line employee could not handle. In those cases, the employee transferred the customer to another department. The transfer took place off-line. The receiving department did the necessary work and then got back to the customer with the resolution. In most cases, this took 2 or 3 days to complete.

The team developed a pilot prototype program before trying to initiate changes throughout L.L. Bean. It decided that it was too risky to apply untested process improvements to 1200 people at one time. The changes involved a new front-line customer service organization structure that possessed the following characteristics:

- *External-customer focus:* It maximized convenience for customers by eliminating unnecessary hand-offs, moving the customers quickly and efficiently to the person that can meet their needs.
- *Process-oriented structure:* The prior organizational structure was functionally oriented. In the new structure, the customer service representative is accountable for the entire transaction from the initial customer interaction to the final resolution.
- *Learning organizational structure:* The minimum hand-off, end-to-end accountability design emphasized learning opportunities. The service representatives were now enabled to build reservoirs of knowledge sufficient to identify the root causes of customer service problems and ways to prevent their occurrence at the sources. The Customer Service Department became a forum for discussing the day's activities, what went wrong and what went well, with a focus on preventing problems from recurring, rather than getting better at resolving them.

Two months after initiation of the pilot program, the productivity of the pilot customer service team increased by 38 percent. This was a surprise to the team leader, who had budgeted for an initial decline in productivity. The most important discovery made during the pilot effort was that productivity, good service, and job satisfaction are complementary results.

SECTION 26
ADMINISTRATIVE AND SUPPORT OPERATIONS

James A. F. Stoner
Charles B. Wankel
Frank M. Werner

INTRODUCTION

Exceeding customer expectations involves numerous activities throughout the organization. In the early years of the quality "movement," attention was devoted predominantly to those activities which most directly influenced the nature of the product or service (e.g., design, purchase of materials, fabrication, inspection). However, there are many activities that, though indirectly influencing quality of product or service, have a major impact on customer satisfaction. As dramatic improvements in product and service quality have become more widespread, increasing attention has been devoted to improving the quality of these less directly visible contributors to customer satisfaction or dissatisfaction.

A broadly accepted generic term for these activities has not yet emerged in the literature or in organizational practice. In this handbook, the term *administrative and support operations* will be used to designate these activities. Responsibility for these activities is normally located in "staff" or administrative functions, such as Finance, Human Resources, or Corporate Law. Examples include the Human Resources Department's handling of the payroll so that employees get paid and the Legal Department's support to researchers in the Research and Development (R&D) Department in preparing and filing patent applications. These operations are defined more extensively later in this section, but we will not emphasize the distinctions between *administrative activities* and *support activities* because, by their nature, the role of all administrative and support activities is to support the rest of the organization in creating and delivering products and services that exceed customers' expectations.

Summary and Conclusions.

In organizing to achieve and sustain revolutionary rates of improvement in quality and customer satisfaction, companies find that organizational structures, systems, relationships, and all parts of the organizational culture change greatly (see also Sections 5 and 15). These changes are no less profound in administrative and support departments—such as Finance, Human Resources, and Legal Services—than they are anywhere else in the organization. This section of the handbook looks at how administrative and support operations within organizations can be and are being improved as part of the global quality revolution and how the functional departments that are the traditional homes of these operations are changing.

Introducing quality into administrative and support operations produces three broad types of change. Some change relates to the processes of administrative and support work, some to the content of that work, and some to the context within which that work is performed.

Process: Well-established ("traditional") administrative and support operations are examined using the tools of quality management and are often significantly improved.

Content: The work of administrative and support functions changes as new operations are undertaken and old operations are eliminated or transferred to other organizational units.

Context: The roles of administrative and support personnel and their relationships to the rest of the organization change—and new roles and relationships emerge—as administrative and support areas become more concerned about serving both external and internal customers, as the nature of their work changes, and as they increase their rate of learning from the rest of the organization.

The major conclusions of this section are

Administrative and support functions can and do use essentially the same quality improvement tools in essentially the same ways with essentially the same results as other parts of the organization.

Increases in customer satisfaction arise from improvements in traditional services—with the improvements showing up as defect reduction, cycle-time reduction, and cost reduction—and the development of new services.

Beneficiaries of these quality improvements include both internal and external customers.

Role and relationship changes that departments and their members undergo are particularly important.

In general, the functional departments that provide these administrative and support operations follow rather than lead the production and operations functions, sometimes with a considerable lag.

The kinds of changes in functional departments described in this section are likely to continue to evolve in new ways as organizations invent and discover new structures and relationships more consistent with a total quality culture (see also Section 15, Human Resources and Quality).

These conclusions suggest that all organizational members should expect and should plan for revolutionary rates of quality improvement in all administrative and support operations, just as they can and should expect and plan for such improvements in the products and services they provide to their external customers.

Defining and Identifying Administrative and Support Processes. The processes that make up the administrative and support operations of an organization can be looked at as occurring in three related areas: administering the internal activities of the organization, supporting members of the organization in serving external customers, and supporting external customers—defined broadly to include suppliers and other outside stakeholders—in doing their business with the organization.

The administrative side of these activities encompasses operations required for the organization to sustain itself as an ongoing entity so that it can serve its customers. Administrative activities involve processes that affect primarily or exclusively internal customers. They may affect internal customers in their roles as employees of the organization or in their roles as producers serving external customers. An example of an administrative activity with an impact on employees as internal customers is human resources' handling of the payroll so that employees get paid. Other examples include managing pension funds and retirement programs, career systems, compensation programs, training systems, health care programs, and so on.

Administrative processes that affect employees in their roles as producers involve developing, maintaining, and using systems and activities—such as management information systems and plant maintenance—that enable the organization's members to do work that serves the ultimate customer. An example is the contribution facilities management groups make in maintaining clean and comfortable working conditions.

The support side of these activities encompasses operations that contribute more directly to the work of other departments as they serve the organization's external customers or do other necessary activities to ensure competitive health. An example would be the Legal Department's support to researchers in the R&D Department in preparing and filing patent applications. Support activities also assist customers and other stakeholders in dealing with the organization; examples include invoicing and processing payments from external customers.

Some activities that we have treated as administrative and support operations may not fit easily into this category because their connection with external customers—or at least stakeholders—is quite strong and direct. For example, investor relations functions, frequently located within the corporate finance staff, prepare annual reports and deal with securities analysts. We have treated these activities as support activities because they assist external customers in dealing with the organization.

The Need for Improvement. In the preceding edition of this handbook, Gryna (1988) suggested that significant improvement opportunities exist for the reduction of error rates and cycle time in the execution of useful and effective administrative and support systems. He reported a study in an electronics firm that showed that "50 percent of time cards were in error," "40 percent of all travel reservations made in one month were changed" and two were changed nine times, and 10 percent of performance appraisals sampled in "one month were returned because of lack of signatures." He noted that "little work has been done to quantify the extent and cost of errors in support operations or administrative operations. It is the author's belief that the cost of poor quality for these activities is as great as the cost of poor quality associated with the product."

As Gryna suggests, the costs of defects and of slow cycle time in useful and valuable administrative systems may be quite large. However, these costs may be lower than the costs arising from ineffective and unnecessary administrative processes. One of the costs of poor quality that has not been quantified is the interference in the organization's work that arises from the existence of outdated, unnecessary, and ineffective administrative and support operations. Administrative and support procedures that do not add value can easily arise and then become encrusted parts of organizational systems and programs. Ineffective or useless systems waste not only the resources of the administrative and support personnel who administer and execute them but also the time and energy of those who collect the data demanded, fill out the required forms, wait for the required approvals, and so on.

Beyond opportunities to reduce the costs of poor quality, there is a need to improve administrative and support operations to make them consistent with the organization's emerging quality management systems and culture. Administrative and support processes inconsistent with the rest of the organization can generate significant drag on many activities; processes aligned with other organizational units and processes can enable superior performance.

Relation to Other Sections of This Handbook. Because administrative and support operations employ the same types of quality tools and implementation processes used in other parts of the organization, Sections 3, 4, 5, 6, 12, 13, 14, and 45, on Quality Planning, Quality Control, Quality Improvement, Process Quality Management, Benchmarking, Strategic Quality Planning, Total Quality Management, and Statistical Process Control, are particularly relevant to this section. Because the changes in the work, roles, and relationships of administrative and support members can be quite large and are part of broad cultural changes in organizations, Sections 15 and 16, Human Resources and quality and Training for Quality, are also quite relevant to this section.

PROGRESS IN ACHIEVING QUALITY IMPROVEMENTS IN ADMINISTRATIVE AND SUPPORT SERVICES

Overview. Although progress in improving administrative and support operations historically has been slower than in many production operations, progress can be dramatic once the changes are started. Recent evidence suggests that organizations can expect rates of quality improvement in administrative and support operations comparable with what they achieve in production. Errors in issuing paychecks can be reduced from hundreds a month to one or two, cycle time to complete credit analyses or to draft contracts can be reduced from weeks to minutes, and the cost of closing the corporate books of large multinational companies can be reduced by tens of millions of dollars per year—with fewer errors and greatly reduced cycle time. This part of this section begins with a historical perspective on improvements in administrative and support operations. It then discusses reasons why quality progress in administrative and support functions has tended to be slower than in areas more directly in touch with the final customer and how these historical reasons are changing, yielding the current situation in which rates of improvement in administrative and support services can be similar to those in other activities.

Historical Perspective. The manufacturing or service company's mission is to produce a continuing flow of products and services that exceed customer expectations, to market and support these products and services effectively and efficiently, and thereby to generate income that sustains the organization and rewards its various stakeholders.

An early awareness of the effect of product and service quality on income led companies to establish quality control departments within their traditional operations. These activities focused initially on final inspection of completed products and then quality assurance during production. These quality control operations developed most rapidly and extensively in manufacturing companies. Moreover, within manufacturing companies, they were most highly developed on those aspects of product progression which are most obvious to users and producers, such as materials, manufacturing operations, and final performance features. The effect of administrative and support operations on product quality and customer satisfaction was less obvious, and this less obvious connection may have contributed to the slower development of quality controls in these "indirect" activities.

Sullivan (1986) has described the development of companywide quality control as a seven-stage process. In his model, administrative and support functions are likely to become actively involved in the third stage, but not before. The first stage is "product-focused," involving "inspection after production, audits of finished products, and problem-solving activities." The second stage is "process-oriented," involving "quality assurance during production including SPC and foolproofing." In the third stage, attention shifts to the rest of the organization. In this stage, which he refers to as "systems-oriented," all departments are involved. Although he cites only design, manufacturing, sales, and service, an increasing systems orientation would logically include administrative and support operations.

Sullivan's remaining four stages are (4) "humanistic," changing "the thinking of all employees through education and training," (5) "society-oriented," "product and process design optimization for more robust function at lower costs," (6) "cost-oriented," which involves integrating Taguchi's societal loss function concept into the design process and into the total management system to produce

products and services that are fully competitive on a total cost-to-society basis, and (7) "consumer-oriented," involving "quality function deployment to define the `voice of the customer' in operational terms." [All quotations are from Sullivan (1986).]

The ways quality management has evolved in companies in the late 1980s and 1990s may be considerably different from the process Sullivan described in his 1986 article, but his framework does suggest many of the changes occurring in administrative and support functions. Sullivan's framework seems particularly accurate in describing a follower rather than a leader role for administrative and support operations in adopting quality approaches. A number of historical barriers to quality improvement in administrative and support operations have contributed to this follower role.

Historical Barriers to Quality Progress.   Perhaps the most important factor contributing to this follower orientation has been the historically noncompetitive nature of support and administrative operations in most companies. Administrative and support activities primarily served captive internal customers who often were without access to other suppliers. These internal suppliers were not exposed to a clear competitive wakeup call like the ones that occurred in many industries as their products competed unsuccessfully against the dramatically improved quality of foreign competitors, most notably the Japanese. Administrative and support activities were shielded from the competitive forces that drove the quality revolution in its spread across companies, industries, sectors, and nations.

Other factors that contributed to this follower role include a lack of information about the quality dimensions of administrative and support processes, a lack of alertness to the profit impacts of administrative and support operations, a lack of success stories about improving these processes, a lack of experienced leaders for making the improvements, and a lack of process awareness.

The connection between ineffective administrative and support activities and company competitiveness and profitability has been much less clear than the connections between product quality and cost and organizational profitability and competitiveness. The early success stories that energized quality improvements in many companies occurred overwhelmingly on the plant floors of close competitors and led to attempts to achieve similar gains. The experienced quality experts who spread quality approaches from one company to another usually were production experts; rarely were they experienced in improving administrative and support processes. In fact, a widely held belief was that companies could not "do quality" in finance, in marketing, or in legal activities. Many administrators also have been slow to recognize that administrative and support operations accomplish their missions through productive processes, just as do all other parts of an organization. With its strong emphasis on improving processes, the quality approach seemed less relevant to people who did not recognize that they were, in fact, involved in processes.

This lack of awareness of processes in administrative and support functions is particularly interesting and may have existed for a variety of reasons, including

Lower levels of training in subjects that relate to systems and processes, such as engineering and other science-based disciplines

Processes that are not highly visible because they are episodic and infrequently repeated (e.g., drafting legal contracts, analyzing major investment projects, dealing with turnover of team members on a project team)

The belief that administrative and support activities are not processes at all but are "an art rather than a science," depending primarily on creative or professional skills (e.g., preparing an advertising campaign, preparing a patent application, managing an investment portfolio)

The existence of traditional functional silos that interrupt the natural flow of processes and obscure their interconnections across functional activities, supported by the belief that functional silos are desirable or inevitable (e.g., assuming that it is appropriate for all market research activities to be concentrated in a department of expert market researchers)

Falling Barriers and Rising Expectations and Pressures.   Many of these barriers to quality improvement are falling rapidly while expectations and pressures for quality improvements

are rising. Successes in using quality management approaches to make improvements and to change to more effective roles have shown that progress is possible and profitable. Training and consulting resources for improvement inside and outside the organization have increased greatly. Many individuals in administrative and support activities now recognize the existence of processes and the importance of serving their internal and external customers.

In addition, two related changes in the 1980s and 1990s—increased competitive pressures on companies and the rise of outsourcing—may be reducing the "follower gap" in administrative and support operations and contributing to the much more aggressive adoption of quality approaches that has been occurring recently. As companies have faced progressively more competitive situations, the pressure to "do more with less" has fallen heavily on administrative and support operations. At the same time, increased attention to the potential value of outsourcing has reduced the protected nature of these operations. Members of administrative and support functions increasingly face the choice of making dramatic improvements in quality, cycle time, and cost-effectiveness or allowing their operations to be supplied by contracts with outside organizations that can provide their services at lower cost and higher quality [see, for example, Alexander and Young (1996), Harkins et al. (1996), and Lacity et al., (1996)]. Because of these changes, quality improvements in administrative and support operations are increasing at a rapid pace.

CHANGES FROM QUALITY IMPROVEMENTS IN ADMINISTRATIVE AND SUPPORT SERVICES

Overview.   To a large extent, the types of quality improvements achieved in administrative and support operations are the same as those achieved in other parts of the organization. However, there is one type of improvement that is moderately "special" to administrative and support operations in the sense that it is more likely to occur in those operations than in other organizational operations. In this part of this section we discuss the first three broad categories of changes and illustrate them with examples drawn from the various administrative and support operations. We then discuss the more unusual improvement area. We also identify the opportunity for quality champions elsewhere in the organization to contribute to quality in administrative and support areas.

Three Types of Quality-Based Improvements.   Quality-based improvements in administrative and support operations may be grouped into three broad and well-recognized categories: (1) improvements arising from examining traditional activities and doing them better, (2) improvements arising from doing different things, and (3) improvements arising from changes in roles and relationships. (See also Section 15, Human Resources and Quality.)

Figure 26.1 is a model of these three types of improvements. The organization's administrative and support operations are shown in transition, from operating within a system of traditional management (TM), represented by the steep pyramid, to functioning within systematic quality management (SQM), shown as a flattened and inverted "plate." The plate, flattened to represent the elimination of unnecessary organizational layers and inverted to symbolize the changing role of managers from commanding to supporting the rest of the organization, represents the current state of the art of quality management—the best practice of companies such as the Deming and Baldrige Prize winners of the late 1990s.

The figure also shows a dotted arrow continuing upward to the right and leading toward an amorphous object. This part of the diagram suggests the continually evolving nature of the quality management paradigm toward a state of management practice not yet reached by any existing organization. The path of that dotted arrow might be the evolution of organizations from total quality to learning to world class discussed by Hodgetts et al. (1994).

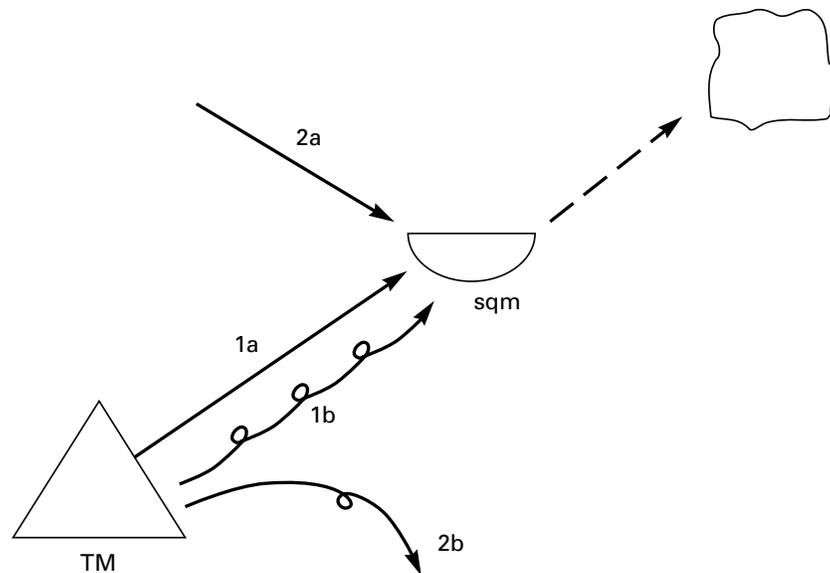
In the diagram, two arrows indicate improvements from examining traditional work through the quality management lens; some work (arrow 1a) is left unchanged, whereas other work (arrow 1b) is redesigned. The other two arrows represent improvements from doing different things,


FIGURE 26.1 Types of quality-based improvements.

either by undertaking new value-adding operations (arrow 2a) or by eliminating non-value-adding activities or transferring work better performed elsewhere to other organizational units (arrow 2b). Surrounding the diagram is the rest of the organization, symbolizing the third type of improvement, changes in the roles and relationships of administrative and support personnel (Stoner and Werner 1992*b*).

Improvements from Doing the Same Things Better.   The first type of change begins with the study of what the organizational unit is presently doing to locate opportunities for improvement. While some activities in the unit already may be consistent with best practice and systematic quality management, more often there are numerous opportunities to improve quality and customer service and to reduce costs. This is done both through small-scale continuous improvements [what Imai (1986) calls *kaizen*] and through large-scale, discontinuous improvements (what Imai calls *innovation* or others have called *re-engineering.*

Kaizen involves continuously improving existing operations in incremental steps. For example, many organizations have used quality improvement teams to improve their handling of reimbursement for travel expenses. Federal Express redesigned its expense reporting system by replacing manual forms with a computer screen that eliminates missing data and mathematical errors. As a result, it now reimburses employees within 1 day and in the process has eliminated the need for most cash advances (Stoner and Werner 1993, p. 44). Of course, over time, a series of small changes may aggregate into very large changes.

Imai's innovation involves dramatic, discontinuous, large-scale changes in what the function does or how it does it. As Section 6 discusses, innovation—or re-engineering—is the redesign of existing processes to accomplish the same (or different) tasks in significantly different ways. When IBM Credit Corporation studied its credit approval process to understand why it took a full week to process a customer request, it found that much of the week was wasted while the documents waited for the next specialist's time. IBM Credit threw out the existing process and designed a completely new system built around a single customer representative responsible for each part of the process. Now, with one person handling the documents, the loan request is processed within a few hours (Hammer and Champy 1993, pp. 36–39).

Improvements from Doing Different Things.   The second type of improvement involves doing different things: adopting new activities and eliminating those which are found to add little or no value. When these changes are quite large in scope and impact, they also may be called *re-engineering.* These changes increase the effectiveness of the organization by reducing the inefficiencies, frustrations,

and waste of time and effort that occur when administrative and support groups undertake work better done elsewhere in the organization (or not at all!) or do not perform operations that they are best suited for. For example, one major form of inefficiency occurs when administrative and support groups perform inspections, sign-offs, and policing functions that create delays and costs without adding commensurate value.

As administrative and support personnel begin to question the value added by their activities, they often discover new products and services they can provide to other parts of the organization (or perhaps to external customers). American Standard Companies discovered an opportunity to improve its internal business processes by modeling them after the quality processes that had been adopted successfully in their manufacturing activities. The company created a transformation team that conducts 5-day workshops at its administrative offices around the world to teach and install these new methods.

In administrative and support functions, one of the largest changes involves stopping activities that have outlived their usefulness. For example, early in their quality improvement initiatives, many finance functions find that they are producing periodic reports—often at considerable expense—that simply are not used elsewhere in the organization. Suspecting this to be true, the CFO of Stanley Tools once stopped sending out all financial reports; his suspicions were confirmed when few recipients complained. Stanley eliminated many of the reports and redesigned the others to provide recipients with the data they truly needed (seminar presentation at Fordham University, October 9, 1990).

Improvements from Changing Roles and Relationships.   The third type of improvement involves changes in the roles of administrative and support personnel and in their relationships with others in the organization, transformations that alter the ways individuals and groups work together. These changes come about as administrative personnel begin to see the organizational units they support as internal customers and increase their rate of learning (or begin to learn) from the rest of the organization.

Keating and Jablonsky (1990) and Stoner and Werner (1993, 1995) have reported large changes in the ways corporate finance members work with other organizational members in some companies. Finance members have abandoned the role of corporate police, no longer seeing themselves as "the only adults in the company." Instead, they act like "business partners" who work collaboratively with other organizational members. Keating and Jablonsky make this point using the analogy of a successful sports team. It is the players on the field who win the games, but a winning team also requires effective coaches and a strong franchise to provide supporting resources. They observe that

> …the unique challenge facing the financial professional…is learning how to become a player and a coach. This is not an insignificant task when individuals have been trained in school and [have] continued professionally to be scorekeepers or independent commentators. Getting close to the business means getting on the field as part of the management team [Keating and Jablonsky 1990, p. 15].

A Bonus from Eliminating Non-Value-Adding Administrative Work.   There is a special aspect of administrative and support operations that has enabled quality initiatives to make unusual—and often major—contributions to the competitiveness of organizations, to their ability to improve customer satisfaction, and to their ability to provide an enjoyable working environment (what W. Edwards Deming called "joy in work"). This unusual type of improvement arises from the elimination of non-value-adding work by administrative and support functions. It is similar to the results achieved when any part of an organization eliminates an unimportant or useless activity, but frequently it is also a bit different.

When the parts of an organization that serve customers directly—the front line—eliminate non-value-adding work, the major beneficiary is usually the unit itself that eliminates the non-value-adding work, although the external customer also may benefit. When administrative and support operations eliminate non-value-adding work, the major beneficiaries are usually others: the customers of the administrative support functions and the entire organization.

This difference in likely beneficiaries arises because administrative and support operations frequently require work to be performed by other parts of the organization to meet government regulations, to conform to procedures and policies, to provide data intended to be useful to others inside and outside the

organization, and so on. Administrative and support functions do not simply serve internal customers; they also impose on other organizational units demands that can get in the way of doing business: reports that require data to be provided by other units, internal audit inspections and requirements for changes that can be onerous or not worth the effort to make, delays in hiring that prevent work from being done, lengthy legal documentation and other steps to prevent or defend law suits, and so on. When ineffectively designed and implemented, these administrative requirements create very real burdens for the rest of the organization and are of questionable value in improving customer service.

Ford discovered the magnitude of the costs imposed by non-value-adding administrative work when it conducted its now well-known study of Mazda in the early 1980s to learn how Mazda could produce higher-quality cars at significantly lower cost. One key conclusion was that "…Mazda's efficiency gains resulted from dispersing many so-called accounting activities to nonfinance functions.…Quoting from the study: 'This environment helps eliminate duplication of effort. Mazda activities handle a broad range of responsibilities related to their operation, and it is not necessary for detailed information to be passed to accounting for processing, data entry and reporting'" (Keating and Jablonsky 1990, p. 79).

Administratively imposed burdens often have a second, perhaps even more perverse effect: They can deprive people of the ability and motivation to improve the organization. One Ford employee related, "People got to the point where they said…it's not my role to control costs, it's what those finance people are for" (Keating and Jablonsky 1990, p. 87). AT&T's Chief Accountant Bernie Ragland, referring to the company's regulated history and associated internal conformance procedures, "argued that the single most negative cost associated with regulation is not the specific dollar outlay required to maintain the complex fiscal accountability system; the most negative cost is the 'conformance mentality that regulation breeds.'" This effect "is particularly insidious because it is pervasive, and over time, becomes an habitual pattern of behavior that, even when recognized, is not easily broken…you cause people not to think about doing things'" (Keating and Jablonsky 1990, p. 168).

Administratively imposed requirements, such as unnecessary reports to staff organizations, are particularly vexing to other organizational members because the administrative departments are nonpaying customers that cannot be avoided. External customers frequently can protect themselves from being forced to do non-value-adding work by taking their business elsewhere, but internal customers rarely have that opportunity. One of the major contributions of the quality approach has been the removal of many non-value-adding requirements from administrative and support functions. Although the savings in time and money within administrative and support budgets may be quite significant, the savings in the other organizational units that are freed of the administrative burdens are frequently much greater. In this sense, this type of change deserves special attention when assessing the value of quality-based improvements in administrative and support operations.

Assisting Administrative and Support Areas. Administrative and support operations offer particularly fertile ground for contributions by the traditional quality champions from production and quality departments. Quality tools and approaches that have become part of the cultures of an organization's production and operations areas can be deployed in administrative and support areas with results comparable with those achieved elsewhere in the organization.

The quality successes achieved in other parts of the organization provide at least three stimuli that encourage rapid progress in administrative and support areas. The stimuli relate to expectations about rates of quality improvement, acceptability of quality initiatives, and resources for making improvements:

Expectations: As other parts of the organization achieve quality improvements, their expectations of high-quality performance from administrative and support functions rise, and they start encouraging or (putting pressure on) those functions to achieve similar improvements.

Acceptability: The successes achieved elsewhere in the organization demonstrate to administrative and support personnel that the techniques actually work in their own company (reducing the "not invented here" syndrome).

Resources: The individuals and teams who achieved progress elsewhere in the organization are available as resources—a pool of internal quality consultants within the company, familiar with the organization and its internal operations.

INTERNAL AUDIT: AN EXAMPLE OF PROFOUND CHANGES IN ADMINISTRATIVE AND SUPPORT OPERATIONS

Overview.   The three types of quality-based improvements (doing things better, doing different things, changing roles and relationships) and the value of eliminating non-value-adding work can be illustrated in all administrative and support activities. However, one of the most impressive illustrations of the scope and impact of these changes is occurring in the internal audit function. For a variety of reasons, it is a particularly interesting example of the ways administrative and support functions are changing as companies progress on their quality journeys.

First, internal audit can be looked at as the quality control unit of the management system, with every bit as much potential for improvement as quality control activities in manufacturing operations. In many companies, however, the audit function has been performed in ways quite inconsistent with the organizational culture, roles, and ways of work necessary for achieving revolutionary rates of quality improvement and increases in customer satisfaction. In these companies, internal audit has been a corporate police force, increasing stress and tension as it proved its value—and superior influence—by finding errors and weaknesses in the departments being audited. Rather than building collaboration and breaking down barriers, such departments traditionally did the opposite. Changes in some internal audit groups represent a virtual reversal of past practices—dramatic changes in ways of contributing to an organization's success.

Second, the changes in internal audit are significantly increasing the value added by that function while reducing the cost of performing it. Third, these changes are permitting other parts of the organization to modify the ways they work, resulting in marked additional cost reduction and work simplification. And fourth, the changes in internal audit serve as models of the changes occurring elsewhere in administrative and support operations.

Examples of Improvements.   The examples that follow are representative of the exciting changes taking place in internal audit groups and illustrate the four types of quality-based improvements discussed earlier.

Improvements from Doing Things Better—Improving Well-Established Processes.   American Standard is one of many companies that have redesigned their audit reports to reduce cycle time. The new process has eliminated drafts and even the traditional audit recommendations. Computer-assisted audit programs have been developed and adopted—and shared with the operating groups—to permit the examination of large data sets without reliance on nonstatistical small samples.

Motorola's internal audit group has successfully applied the company's 6σ and $10\times$ cycle-time reduction initiatives to its activities, redesigning and simplifying its audit processes dramatically. Although the company has grown considerably in recent years, Internal Audit has remained the same size while increasing the scope and depth of its work. In one initiative, Motorola is building internal control processes into its operations to allow its units to audit themselves and to permit Internal Audit to shift its focus from auditing transactions to auditing the self-audit processes. In another initiative, Internal Audit's improvement approaches have been used by Motorola's Public Contracts Compliance Office to collaborate with a key customer, the U.S. Department of Defense. The collaboration has reduced the cycle time of government audits from over 1 year to 2 to 3 weeks while producing audits of higher quality at significantly lower cost to both parties.

Improvements from Doing Things Better—Achieving Traditional Goals in Very Different Ways. The primary goal for internal audit departments frequently has been stated in terms of improving the internal control environment. At Gulf Canada Resources, a process called *control self-assessment* (CSA) has replaced some traditional auditing activities and increased the effectiveness of the ones that remain. In CSA, the unit being audited identifies its own control issues in a team-based meeting using computerized survey feedback methods. Control becomes internal to the operating unit and

intrinsically motivated rather than arriving in the form of an external police force providing extrinsic motivation. The CSA workshops reveal more and different control concerns than traditional audits and provide a broad picture of the corporate culture. CSA produces more audit findings and larger numbers of high-quality audit findings than are found with traditional audits (Makosz and McCuaig 1990*a*) and detects serious, hidden companywide problems ("cultural rogue elephants") that appear as ambiguous problems throughout the company in ways that disguise their seriousness and overall cumulative impact (Stoner and Werner 1995).

Improvements from Doing Different Things—Undertaking New Operations. American Standard's audit group responded to the company's adoption of a just-in-time (JIT) manufacturing system by changing the framing and content of its work. Training of auditors was extended to include the just-in-time concepts, and auditors now spread JIT concepts throughout the company and assist the operating units with the related measurement systems.

An early supporter and adopter of the company's quality initiatives, Baxter International's Internal Audit Group quickly discovered that a key benefit of quality processes is the time and energies freed up to add additional value to its audit customers and the organization. One of the more striking ways it has invested these resources is in undertaking "special projects" in areas as diverse as electronic data interchange, treasury processes, managing overlapping responsibility and authority, and assisting Baxter's ultimate customers. Projects such as these have helped Internal Audit integrate its traditional audit responsibilities with an internal consulting role that has significant cost and knowledge advantages over the use of external consultants. Now the demand for Internal Audit's services far exceeds the group's resources, a significant change from the days when Internal Audit was seen as an adversary.

Improvements from Changing Roles and Relationships—Increasing Organizational Learning and Becoming an Organizational Change Agent. At Raychem, Internal Audit views auditing as a process containing many "continuous learning loops" and interprets its activities as building and strengthening those loops (Stoner and Werner, 1995). At one level, these activities seek to make Internal Audit a vehicle for creating a high-trust, self-regulating, continuously improving control environment. At another level, Internal Audit is working to make itself and the rest of the company superior learning organizations. The continuous learning loops seek at least five types of changes in Raychem's audit process:

- *Anticipatory change:* Responding in advance to audit customer needs
- *Self-control:* Building auditee self-control directly into audit processes
- *Trust:* Increasing trust in the audit process by making it more predictable and win-win
- *Added value:* "Migrating up the value-added food chain" by replacing lower-value-added audit activities with higher-value-added activities
- *Diversity:* Increasing Internal Audit's professional diversity through the use of guest auditors and audit staff members with nontraditional backgrounds

Perhaps Internal Audit's most exciting new role is that of organizational change agent. American Standard has created an innovative analogue to JIT in manufacturing that is moving the company toward a just-in-time office environment. It is aggressively spreading best practices throughout the company—for example, establishing a *kanban* system for corporate office supplies after observing its successful use in manufacturing. And with the luxury of fewer deadlines than other parts of the organization, it is becoming a transformational thinker, playing an increasing and ongoing role in the evolution of the company as a whole.

Improvements from Eliminating Non-Value-Adding Work—Recognizing When Organizational Changes Render Traditional Activities Obsolete. When the American Standard Companies adopted their JIT manufacturing system, its audit group realized that much of its traditional work—such as verifying inventory balances—added little, if any, value to the company or its customers and would naturally disappear as inventory balances were dramatically reduced. Internal Audit responded by eagerly shedding these activities so that it could devote its resources to tasks seen to be truly value-adding.

Improvements from Eliminating Non-Value-Adding Work—Ceasing Activities That Can Be Done Better Elsewhere. One traditional component of an internal audit report is the auditors' "recommendations," the auditors' instructions to the management of the audited unit for improving areas of managerial weakness or inadequate control identified in the audit's findings. Traditionally, the findings and the parallel recommendations have been an important way auditors have demonstrated they were doing their job well. An estimate of the savings achieved from implementing the auditors' recommendations is a metric used by some companies to calculate the value of the audit process. For example, some audit groups have a goal of saving three times the cost of the audit and measure their success in doing so by calculating the value of recommendations that actually get implemented.

Other audit groups, including those at Raychem and American Standard, have concluded that there is significant cost and little added value in these recommendations; they no longer make them. Instead, they issue their reports with the findings from the audit, the actions the unit's management has committed to take to correct the control or managerial concerns raised in the findings, the names of the responsible individuals, and the timetable for completing the actions.

The reasoning behind such changes is interesting. Recommendations are frequently subject to negotiation between auditors and auditees and cause delay both in issuing the audit report and in fixing the problem. For example, when American Standard was studying its audit process, it found that one of the major time consumers in the process was the time it took to reach agreement on recommendations with the auditee. When the auditor and the audited unit differed in preferred ways to resolve control problems, coming to an agreed wording on recommendations often was tedious and time-consuming. Even when there was agreement on the recommendations, it was not always clear who first developed the ideas for improving a situation. The audited unit could easily feel that the auditors were claiming credit for ideas the unit had already formulated or had even already started implementing. Furthermore, audit recommendations that were unnecessarily costly to implement or were at odds with management's insights often were damaging to the relationship between auditor and auditee. American Standard concluded that the long-established practice of including recommendations in the audit report was not actually adding value but was instead creating unnecessary work and delays—a major and very valuable insight of their study of its audit processes (Stoner and Werner 1995, pp. 7–36).

Companies that have eliminated audit recommendations from their reports have concluded that since it is typically the unit's managers and not the auditors who most deeply understand the nature of their business, it is the managers who are in the best position to design improved controls, especially since they ultimately will be held accountable for the success of the changes.

ENHANCING THE QUALITY OF ADMINISTRATIVE AND SUPPORT ACTIVITIES

Overview. The well-established quality planning, control, and improvement processes are as effective in improving and maintaining administrative and support processes as they are in improving other organizational processes. In this part of this section we note some of the aspects of planning, control, and improvement in administrative and support operations that are worthy of special comment.

Quality Planning. The quality planning process for administrative and support operations does not differ inherently in content from the quality planning process for manufacturing, but it does often differ in context and motivation. The basic quality planning steps are described in Section 3 and are summarized by Juran in many places (such as Juran 1988 (Planning), p. 14). In very brief form, they are "Identify the customers and their needs. Develop a product that meets those needs. Develop a process capable of producing the product." These steps are as appropriate for administrative and support services as they are for designing and producing an automobile or for performing open heart surgery.

Although the quality planning process for administrative and support operations may be essentially the same as for manufacturing, contextual differences include the low frequency with which brand-new processes are designed from scratch, the comparatively low power of customers to

demand quality improvements, and the relative ease with which information on key elements of customer satisfaction can be gathered from internal customers.

The infrequency of establishing new systems and the lower power of internal customers to demand quality improvements from their internal suppliers (since internal customers often have difficulty taking their business elsewhere) both tend to reduce the likelihood or ease of systematic planning for quality improvement. On the other hand, the closeness of internal customers simplifies gathering data about their needs, and this makes quality planning easier and perhaps even more effective.

Whereas each new physical product or new customer service offers a clear opportunity to design in quality from the very beginning, administrative and support services tend to experience undisciplined growth and are typically already well entrenched throughout the organization before they receive systematic quality management attention. For example, when a quality improvement team at Aid Association for Lutherans (AAL) studied the organization's billing and collection process in the early 1990s, it discovered many opportunities for improvement. (The AAL experience is discussed further below, under Other Examples of Quality Improvement in Administrative and Support Activities, Finance.) The process had been designed in 1960 when AAL offered only one product, whole-life insurance. As new products were added, each received its own bill with its own billing cycle. "[Billing procedures resulting from] the piecemeal addition of new products proved cumbersome; manual procedures were often required to make payments `fit' into the existing whole-life system. The system made no one happy. AAL found it financially inefficient, and customers got multiple bills and few payment options" (Sharman 1995, p. 30).

A well-known exception to the tendency of organizations to allow administrative and support operations to emerge and grow in an unplanned manner is the AT&T Universal Credit Services (UCS) company that was formed in 1990 and won the Baldrige Prize in 1992. In UCS's case, the company's original business plan was an integrated strategic plan for business and quality that designed high quality internal administrative and support processes from the very beginning (Kordupleski et al. 1993). A year after the card was introduced, senior management used input from associates to revise its values, mission, and vision (Kahn 1995). One UCS administrative process designed from the beginning to be consistent with quality management principles and to support high-quality performance is UCS's compensation and reward system (Davis et al. 1995). This system is discussed later in this section.

Three aspects of quality planning for administrative and support operations that are important to note are the role of breakthrough goals, the use of benchmarking, and the participation of administrative and support personnel on cross-functional process re-engineering projects.

Setting Breakthrough Goals.   Companies that set breakthrough improvement goals to challenge themselves to rethink the way they perform every activity provide an environment in which dramatic improvements in administrative and support operations are expected. Motorola's series of $10\times$ and $100\times$ defect-reduction goals in the 1980s and its $10\times$ cycle-time reduction goals in the 1990s are well known examples. When these goals are companywide, they involve administrative and support operations. For example, Motorola's defect-reduction goals prompted the finance function's first major quality project—reducing the time required to close the corporate books—and also was the initial stimulus for its Internal Audit function to measure its performance in new and creative ways and to demand the same level of quality of itself as the manufacturing side of the company (Stoner and Werner 1994, pp. 153–154). Subsequently, Internal Audit responded to the company's cycle-time challenge by working to reduce the time spent on each audit activity to one-tenth its prior amount (Stoner and Werner 1995, p. 122).

Competitive Benchmarking to Identify Improvement Opportunities.   Competitive benchmarking has become a common practice within administrative and support functions to identify and prioritize operations for continuous and large-scale improvement. In the early 1980s, before competitive benchmarking was a widely used quality tool, Motorola began inviting guests—leaders in their fields—to speak to its people. Motorola gives credit to Westinghouse forteaching Motorola, during an invited visit, how to use quality-improvement task forces (Stoner and Werner 1994, p. 152). One of the conspicuous successes of the task forces was the introduction of competitive benchmarking into Motorola's quality efforts throughout the company. Early administrative and support functions benchmarked were the processing of accounts receivable, accounts payable, and invoices.

When Southern Pacific Transportation Company began its quality journey in the fall of 1990, it made innovative use of the Interstate Commerce Commission's R1 reports, annual submissions from all railroads detailing operating and cost data. The company was emerging from a period of ill-fated expansion that had culminated in a failed merger attempt and 5 years in trust. The R1 reports showed its costs to be higher than those of its competitors in most categories. Southern Pacific's Finance Department responded by comparing the operating and financial information of its competitors with its own R1 data, line item by line item. Included were two calculations of savings—first, the savings if Southern Pacific matched the average performance of its competitors on each line item and, second, the savings if it matched the performance of its best competitor in each activity. Southern Pacific concluded that at least $400 million could be saved by bringing current operations in each activity up to the standards of the competitors most similar on important dimensions to Southern Pacific (Stoner and Werner 1995, p. 213). The comparison, which is redone each year as new data become available, is used as Southern Pacific prioritizes its quality efforts and has been a significant factor in breaking down the belief, previously held by many in the company, that order-in-magnitude improvements in quality and costs were not possible (Stoner and Werner 1995, pp. 205–229).

Cross-functional Process Re-engineering Projects.   Many cross-functional process re-engineering teams include members from administrative and support areas. For example, a team working to improve the order-fulfillment process logically would include members from finance and accounting. This provides an opportunity for administrative and support personnel to learn about and experience quality activities, even if there are no quality initiatives being pursued within their own functions.

By participating on these teams, administrative and support staff are exposed to many of the skills of quality improvement. They experience first hand successful quality applications. They learn to appreciate better the role that administrative functions play in supporting the rest of the organization. And they are often prompted to initiate similar quality efforts in their own processes.

Quality Control.
The classic tools of quality control and the "seven new tools" (Mizuno 1988) are just as useful in administrative and support operations as they are in other operations. Gryna (1988, pp. 8–20) provided a series of examples of the use of the seven classic tools of quality control (flow diagrams, histograms, Pareto charts, run charts, cause-and-effect diagrams, control charts, and scatter diagrams) in administrative and support operations. Figure 26.2 is a flowchart for payroll changes provided by International Paper Company. Figure 26.3 provides a control chart for the time to process a freight invoice.

Quality Improvement.
The quality improvement process challenges the notion that quality problems represent immutable fate (see Section 5). It addresses performance deficiencies in stable processes that have become accepted as inevitable by organizational members, even when those deficiencies are unacceptable. The objective of the quality improvement process is to examine the deficient process for root causes of the deficiencies and remove or mitigate the effects of the root causes—permanently improving process performance and reducing the costs of poor quality associated with the deficiencies. Such improvement is carried out project by project. Quality improvement processes provide a convenient vehicle for accomplishing many goals concurrently, including improving quality, reducing costs, involving and developing people, training in managing for quality, and contributing toward the total organizational transformation required for competing in a global economy based on ever-improving quality.

As noted earlier, systematic quality improvement approaches include both the small-scale, continuous improvement efforts sometimes called *kaizen* and the large-scale, discontinuous improvements usually called *re-engineering.* There has been considerable confusion about re-engineering and its role in managing for quality. Cole (1994) provides a valuable discussion of this confusion and suggests how re-engineering fits into the tools of managing for quality.

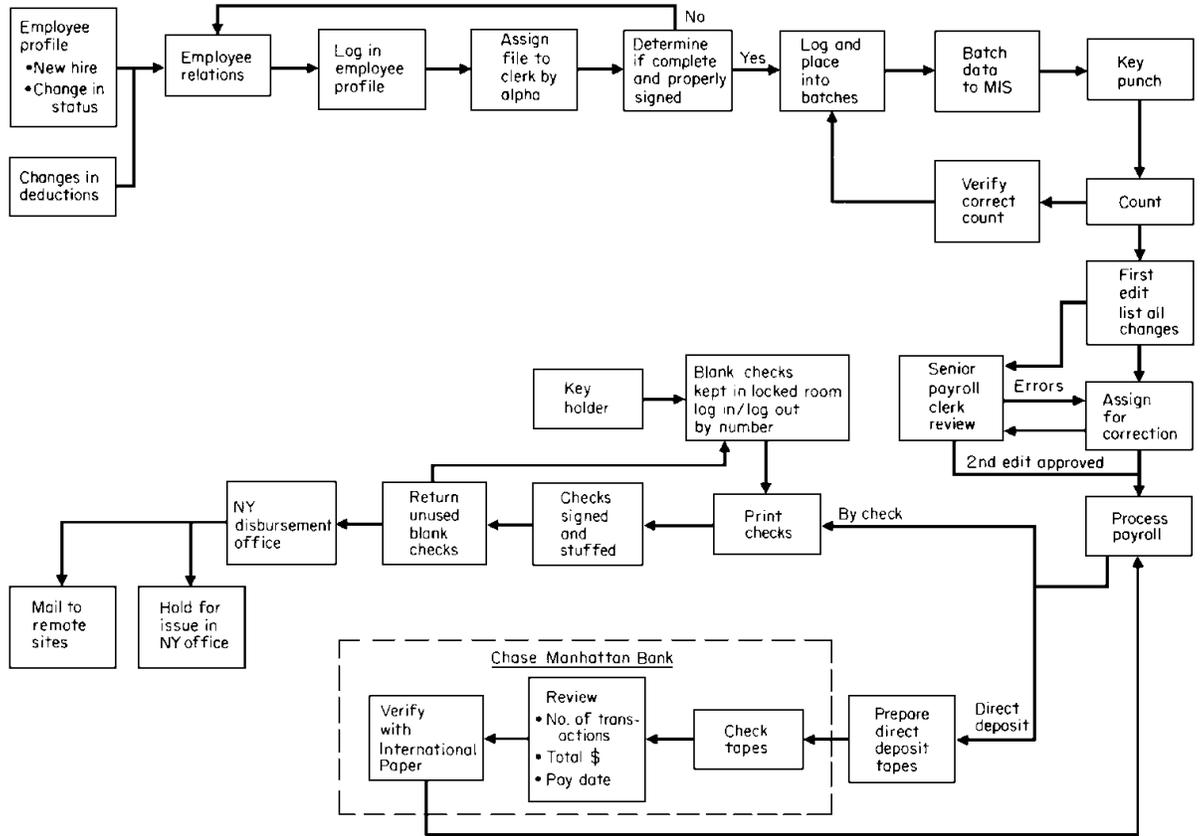
Both these approaches, continuous and discontinuous improvement efforts, are team-oriented and seek to improve process performance. The discontinuous efforts are usually biased toward radical gain through radical change—the "clean slate" approach. Continuous improvement efforts aim at important but less ambitious gains in performance. They are generally applied to the process as it is


FIGURE 26.2   Flowchart for payroll changes. (*Courtesy of International Paper Company.*)
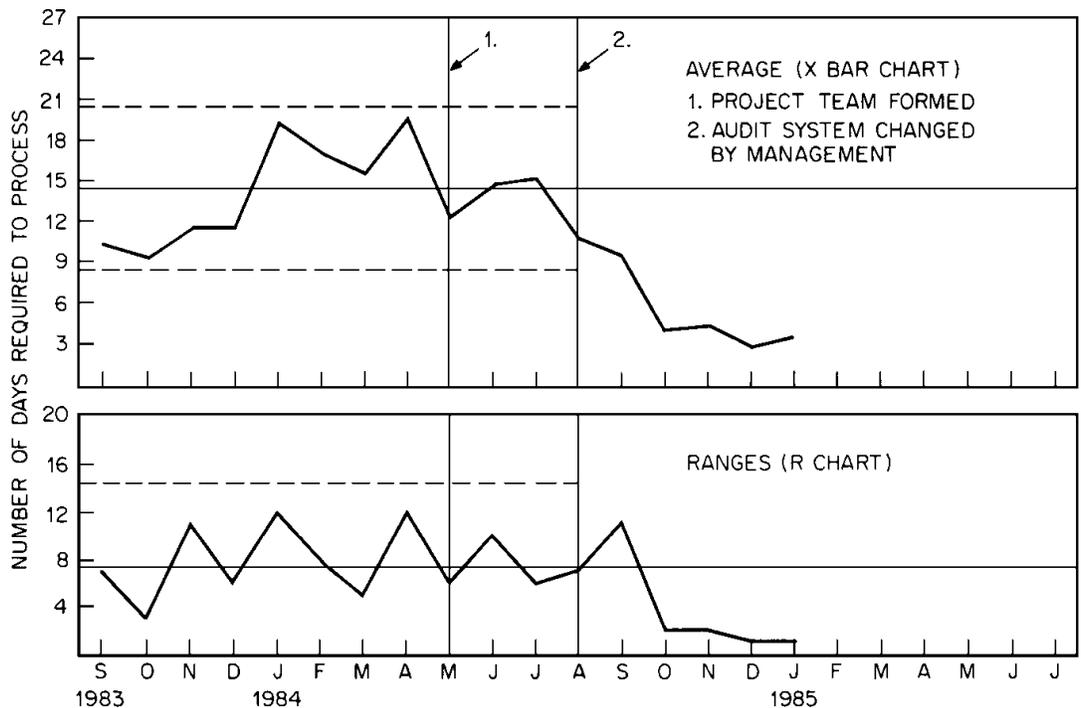

FIGURE 26.3   Control charts for time required to process bills. (*From Baker and Artinian 1985.*)

found and forego the temptation to overhaul the entire process before thorough study. The continuous approach tends to be less disruptive in two ways. First, the changes are usually incremental, leaving in place an improved but still familiar process. Second, the organizational changes required to execute the improved process are likely to be small by comparison with the discontinuous approach. Consequently, there is less near-term uncertainty as to whether the improved process will work. The more far-reaching organizational changes associated with discontinuous approaches bring with them near-term turbulence in the organization and the uncertainty of the new and unfamiliar. Some of the difficulties involved in using the discontinuous approach are discussed in Hall et al. (1993) Hammer and Stanton (1995).

OTHER EXAMPLES OF QUALITY IMPROVEMENT IN ADMINISTRATIVE AND SUPPORT ACTIVITIES

Overview.   In an earlier part of this section we illustrated quality improvement by profiling innovative changes taking place in Internal Audit. In this part of this section we look at other examples of quality improvement throughout administrative and support units.

The examples are organized by functional area: accounting, controllership, and internal audit, finance, human resources, information systems, legal services, and marketing. However, few take place solely within the boundaries of traditional functional silos. To the contrary, many illustrate the power of quality improvements to break down these structural barriers to improved performance.

Accounting, Controllership, Internal Audit.   Accounting's traditional role of measuring and reporting business performance places it naturally at the center of many quality improvement efforts. Since collecting organizational data involves numerous repetitive steps, accounting is a particularly fertile area for process improvement. And since, as many argue, "what gets measured gets managed," accounting plays a key role in communicating what is important within an organization.

Closing the Books.   Many companies have significantly reduced the length of time required to close their corporate books. In doing so, they also have reduced the cost of this repetitive corporate activity and freed up resources for use in activities that add greater value.

One of the earliest and best-known examples is the reduction in time required to close Motorola's corporate books each month. As the project began in the early 1980s, the monthly close averaged 9 working days. As a result, the updated forecast for the coming month was not available until 11 or 12 working days of that month had passed, and the month typically was two-thirds over before the operating committee meeting to review the prior month's activity and the current month's plan.

Motorola found that much of the cycle time was spent correcting erroneous journal entries, waiting for data from overseas units, and entering and correcting data in a headquarters computer. "In the past, the accuracy of journal entries—greater than 98.6 percent—had been considered acceptable. However, the company made some 600,000 entries per month worldwide, and even with 98.6 percent accuracy, 8000 entries each month were wrong. Correcting and reconciling those entries at month's end were enormously time consuming." Improvement efforts led to a decrease in monthly journal entry errors from roughly 8000 to 2. Overseas data started being forwarded directly to headquarters rather than through three intermediary locations that routinely approved the information after considerable delay. The number of local data-entry steps was reduced by bringing back in-house previously outsourced data-entry activity. These and other changes reduced the length of time required to close the corporate books to 4 days in 1990 and to 2 days in 1992. Motorola estimated that the reduction from 6 to 4 days saved $20 million per year, with another $10 million saved with the subsequent reduction from 4 to 2 days (Stoner and Werner 1994, pp. 154–155). Many other companies have initiated similar book-closing projects, e.g., Raychem's Five-Day RACE—Raychem Accounting Close Engineering (Stoner and Werner 1995, p. 158).

Reporting Nontraditional Data.   As the focus of systematic quality management on customers and processes has become more widely understood, organizations have expanded their traditional accounting-based measurement systems to capture and disseminate these new performance dimensions. Customer satisfaction data are gathered through direct questioning and surveys and are summarized in many ways, including Solectron's grading system (described below, under Finance) and AT&T's customer value-added (CVA) indexes, which compare the satisfaction of AT&T's customers with that of its competitors (Kordupleski et al. 1993). Process functioning is typically captured by measuring total errors, often weighted by importance to customers, as Federal Express does with its service quality indicators (SQIs); by measuring failures in relationship to opportunities to fail, as is done by Motorola's widely copied 6σ measurement system; and by computing process cycle time (Stoner and Werner 1993).

Recognizing the importance of these new measures and of making them visible, the chief financial officer of IBM Credit Corporation asked each business unit to support the accounting function in adding one customer satisfaction measure and one process measure to the monthly reports of the unit's performance (interview with Stoner and Werner, November 22, 1991).

Improving Internal Audit.   Changes in corporate Internal Audit in many companies have been so numerous and so dramatic that we used Internal Audit as a comprehensive example earlier. These changes have moved these audit groups from their traditional roles as corporate police to new supportive roles that add greater value to the organization at the same time as they yield greater compliance with corporate control systems.

Finance.   The following examples, typical of quality progress in finance, illustrate successes in improving financial processes, distributing finance's work to place it closer to customers, integrating financial analysis with other operations, and improving the alignment between the organization's financial goals and those of its shareholders.

Improving the Accounts Payable Process.   Early in the 1980s, the Ford Motor Company investigated ways of improving its accounts payable process. Plans to introduce automation were developed that promised an impressive 20 percent reduction in the 500 workers then required to pay the suppliers of Ford's North American operations. A benchmarking study, however, revealed that Mazda required only 5 employees to pay its suppliers worldwide and forced Ford to rethink its improvement plans (Hammer 1990).

A subsequent study of the payables process revealed that department members spent most of their time resolving discrepancies among the three documents required for each buy: purchase order, receiving report, and invoice. If the three documents matched, a check was issued; if not, an investigation was begun to resolve the differences. Since there were 14 data items on the documents, mismatches were common, and investigations could be quite time-consuming.

Ford redesigned its accounts payable process to eliminate the receiving report and invoice and to reduce the number of items needing matching to three: supplier code, part number, and quantity. While a purchase order is still sent to the supplier, it is not copied to accounts payable; instead, the data are entered into a database accessible at all receiving docks. When goods arrive, the receiving clerk checks the computer to see if they match the order. If not, they are rejected and returned to the supplier. If they match, the shipment is accepted, and the arrival information is entered into the database, which automatically triggers payment to the supplier at the appropriate time. The new process requires only about 150 workers and saves millions of dollars every year.

Improving the Billing and Collections Process.   The simple billing and collection process Aid Association for Lutherans (AAL) designed in the 1960s for its single financial product—whole-life insurance—was appropriate for the company's and its customers' needs at that time. However, by the early 1990s, AAL, the largest fraternal benefit society in the United States, was offering to its members life and disability insurance, annuities and retirement products, mutual funds, long-term care and Medicare supplemental coverage, and savings and loan products through a credit union.

Over the years, the company had adapted the old system for each new product and product feature. However, many of the new products and features had billing patterns different from whole-life insurance, leading to unwieldy manual adjustments and software patches. For example, a customer purchasing more than one product received separate bills on different billing cycles for each.

AAL formed a team of managers and specialists in billing and collections that studied and diagramed the process, identified and surveyed customers of the process to identify their requirements, and identified, mapped to customer requirements, and prioritized some 50 product or process features. Customers asked for a single invoice for all their accounts with certain characteristics: clearly identifiable as a bill, accurate, arrives on time, easy to read and understand, and permits a variety of payment options. A parallel analysis identified as major problems various elements of cost of poor quality—internal failure costs (rework within AAL) and external failure costs (rework caught by or affecting external customers).

Over a 15-month period, the team began to re-engineer major parts of the process and also made incremental changes in existing parts. Among the incremental savings: Increased use of electronic funds transfer is expected to save $75,000 per year, and providing greater payment flexibility and improving the posting of retirement plan billing are expected to save another $50,000 to $80,000 annually. AAL expects the re-engineered process to include a single billing account for each customer, electronic transmission of new business applications from the field staff to home office processing systems, and the use of image-processing technology to minimize and automate application processing, all providing significant additional cost savings and customer satisfaction (Hooyman and Harshbarger 1994).

Checking Customer Credit-Worthiness.   Solectron, a recipient of the Malcolm Baldrige National Quality Award in 1991, is a contract manufacturer of electronic components and systems. In the company's early days, there was no need for a formal procedure for checking a customer's credit-worthiness. The company was small relative to its customers and could not afford to extend much credit. Its customers were either large, well-established companies or small firms personally known to Solectron's management. However, by the mid-1980s, Solectron and its customer base had grown to a point where extending credit was becoming increasingly important and appropriate.

Finance responded initially by developing an elaborate and traditional credit analysis process similar to commercial bank systems. The system proved cumbersome, however. Few members of the sales force had the requisite finance skills or wanted to take time from their sales activities, so credit analysis took place within the Finance Department. Salespeople lost considerable time as they contended for the attention of the company's sole credit analyst, lobbied for credit approval, and were forced to wait for the credit decision. It was difficult to be responsive to prospects. Worse, a negative decision meant that the time invested to cultivate a potential customer was wasted, leaving the sales staff and the rejected prospect frustrated and very likely angry.

Solectron simplified the process. Now Finance divides potential customers into three groups: "A customers," those which are large and financially healthy and for which no credit check is required; "B customers," the middle-sized prospects for which it is important to check credit-worthiness; and "C customers," those which are financially weak and are not to be pursued unless a special strategic rationale exists. Salespeople are free to pursue A customers without further financial review. For B customers, Finance designed a credit scoring sheet that uses easily available data, is simple for the salespeople to fill out early in the prospecting process, and sums to a number that translates directly into the credit line Solectron is willing to extend.

The new process has eliminated the frustrations of the prior system. Salespeople no longer waste time pursuing unacceptable credit risks and now know exactly how Finance will respond to a new customer. Because it is so easy to understand, the form itself teaches the sales staff how and why Finance makes the credit decision. Finance staffers are now seen as a support system and no longer as the "bad guys" who interfere with sales. And by distributing finance skills to the sales force, the company's credit specialist has eliminated much routine work and can devote more time to supporting strategic marketing decisions (Stoner and Werner 1994, pp. 186–187).

Capital Budgeting.   Several companies now view their capital budgeting activities in process terms. In 1989, Alcoa began a project to improve the company's capital expenditure decision process in

response to benchmarking and other data that indicated that the company lagged behind its competitors in efficiency of capital utilization. A 16-person, cross-functional, cross-divisional, high-level team, including 7 vice presidents, reviewed past data and studied potential causes of suboptimal capital expenditure decisions. The team concluded that the company's request for authorization process was seriously flawed because it did not consistently provide the right technical and business information to make the decision, reveal the underlying quality problem-solving process used to arrive at the recommendation, provide quantitative data to allow project results to be verified, or provide appropriate accountability for project success. Among the improvements was the development of a decision analysis summary to provide project reviewers with more detailed analyses and strategic, market, and manufacturing process context (Rosenfeld 1990).

The *business case approach* (BCA) is a project analysis process used by Federal Express that emphasizes a broad companywide focus rather than a narrow financial or departmental one and the building of a team bringing diverse perspectives into the analysis at early stages. Most of the financial analysis takes place during repeated iterations as the project concept and design evolve rather than at the end, when the project design has been completed. Along the way, financial models of the project and its implications are assembled, so the repeated iterations may be analyzed as alternative approaches. The BCA process does not end when a completed proposal is presented to senior management nor when senior management makes its decision. Rather, the modeling and documentation are retained so that implementation alternatives can be evaluated at key decision points if the project is accepted, or the project can be reconsidered as new technological or market data emerge if the project is rejected (Stoner and Werner 1994, pp. 131–137).

Targeting Shareholders. The search for superior service for shareholders has led to innovative approaches in the investor-relations function. A growing activity within these functions involves creating a better match between a company's financial goals and breadth of public ownership and the investment needs of the company's shareholders.

Founded as a long-distance telephone carrier, MCI Corporation initially attracted investors looking for that industry's historic pattern of high dividends and low earnings volatility. As the company diversified into local telephone service, media services, and communications outsourcing, however, its earnings and dividend patterns could no longer be predicted to adhere to those patterns. MCI's investor-relations group responded by creating and using a database of institutional shareholder preferences to locate potential new investors (Brenner 1996).

The stock of EMC Corporation, a manufacturer of technologically innovative computer data storage systems, initially attracted a large number of short-term-oriented technical traders when the company was growing at a very rapid rate. As EMC's growth rate settled down, the company made a concerted effort to pursue shareholders with a long-term investment horizon (Brenner 1996, pp. 60–61).

In 1992, GATX Corporation began a project to create additional liquidity for its investors by expanding its shareholder base. At that time, five institutional shareholders owned 51 percent of the company's outstanding stock, and their trading activities often caused significant price fluctuations. By 1986, that 51 percent was owned by 28 institutions, another 20 percent was owned by retail shareholders, daily trading volume had increased significantly, and large institutional trades were being made without an appreciable effect on the company's stock price (Brenner 1996).

Human Resources. In Section 15 of this handbook, the term *human resources* (HR) is used to refer to the culture, relationships, and behaviors within organizations that are necessary to achieve high-quality performance on a sustained basis. This part of this section builds on Section 15 by addressing how corporate- and divisional-level human resources functions contribute to achieving these types of culture, relationships, and behaviors.

Human resources functions play key roles in enabling organizations to achieve the types of skills, attitudes, values, and other cultural changes that are required to move from traditional command and control management systems to modern quality-based management systems. The deep cultural change involved in making this transition requires that a great amount of "people change" must occur. Human resources functions are especially well placed to contribute to this transformation because the function is actively involved in designing and administering many of the levers of organizational

change—such as recruiting, selecting, training, developing, rewarding, compensating, and promoting. The function is also well placed to contribute because the values that have long been "preached" by HR professionals—teamwork, collaboration, power equalization, courage in risk-taking, integrity, respecting people, seeking excellence, etc.—are far more consistent with the emerging quality-based management systems than with traditional command and control management systems.

Although some well-established human resources activities will continue to be performed much as they have been performed in the past, a large amount of change in HR practices and philosophy is needed in virtually all organizations if these functions are to play important roles in the organization's quality transformation. In some companies, these changes are taking place. Schonberger (1996) discusses how HR premises and practices are changing in organizations that are approaching world-class manufacturing status and provides many examples. Blackburn and Rosen (1993) studied the HR practices of eight Baldrige Award winners and reported "evidence of a paradigm shift in the HR policies by those organizations" (p. 50). They found that the companies had developed "portfolios" of human resource management policies to complement their strategic quality management objectives. Other companies seem to be lagging far behind. For example, a survey of human resources functions in 245 companies from a wide range of industries and regions of the United States indicated that most HR managers "talked the talk" well but were very slow in "walking their talk" (Blackburn and Rosen 1995).

The discussion below addresses ways in which traditional human resources operations are being improved; how HR's philosophy, ways of doing its traditional work, and traditional roles are changing; and a new role that is emerging for human resources functions.

Improving Traditional Human Resource Operations.   Well-established human resource operations have provided rich grounds for improvement using classic quality improvement approaches. Leonard (1986) reports how a cross-functional team developed flow diagrams to analyze and improve the process for recruiting exempt-salary personnel at Rogers Corporation. The quality improvement process also has been used to reduce employee dissatisfaction with savings and investment plans and to reduce the costs of administering these types of plans. Since very early in its existence AT&T Universal Card Services has used quality teams on an ongoing basis to improve quality process measures such as how quickly Human Resources responds to job résumés and issues employee paychecks (Hall et al. 1993).

Changing HR's Philosophy and Ways of Doing Its Traditional Work.   A number of HR functions have been wrestling with the changes necessary to bring their philosophy and practices more into alignment with the needs of quality-driven companies and the requirements of a quality-driven global competitive environment. Haddock et al. (1995), for example, used previous empirical and conceptual studies to develop a list of characteristics of the HR philosophy of organizations deeply committed to quality management. These characteristics, listed in Figure 26.4, include treating employees as valuable resources and as partners, taking a long view of the ongoing personal fits of employees to the organization, involving employees actively, and encouraging employee growth and contributions that go well beyond traditional job descriptions (Cardy and Dobbins 1996).

The differences between the HR philosophy and practices appropriate for the traditional command-and-control, Tayloristic management system and those appropriate for quality-driven organizations have been discussed by several writers, including Petrick and Furr (1995). Compared with traditional management systems, information is shared more readily and widely, customers and employees are attended to much more, and education and training go beyond a narrow job focus.

Blackburn and Rosen (1993), Haddock et al. (1995), Petrick and Furr (1995), Schonberger (1996), and other authors have suggested many HR practices consistent with managing for quality. These include

- *Staffing* (*recruitment, selection, and utilization*):   Going beyond screening largely or exclusively on technical job skills to looking for recruits with interest and skills in teamwork, problem solving, and quality improvement; looking at employees' fit with the larger organization rather than with a particular job; emphasizing the ongoing development and effective utilization of the organization's human resources

- Employees and professionals are treated as valuable resources, and their central role in improving quality is emphasized.
- The psychological contract between employee and employer becomes more of a partnership in which employees are recognized as key sources of competitive advantage.
- The personal fit of employees with the organization and the taking of a long-term perspective are consistently emphasized.
- Ideas and techniques of employee involvement that fit the specifics of an organization's situation are integrated or coordinated with continuous quality improvement efforts.
- Employees are encouraged to develop and to accomplish as much as they can, both qualitatively and quantitatively, within the framework of organizational needs rather than to focus on what the specific job requirements are.

FIGURE 26.4 Human resources philosophy consistent with managing for quality. (*Adapted from Haddock et al. 1995, p. 144.*).

- *Performance measurement and evaluation:* Emphasizing developmental feedback rather than judgments of current performance, using customer and peer evaluations, placing greater emphasis on team and organizational goals than on individual ones

- *Compensation:* Providing a "basket of values" tailored to each individual rather than only base pay and benefits (Schonberger 1996), emphasizing team and organizational incentives rather than individual incentives, emphasizing nonfinancial rewards including opportunities for self-management and recognition, paying for skills mastered rather than basing pay on job titles, experimenting with ways to avoid the problems of linking performance appraisal to compensation, experimenting with ways to avoid the problems of weakening intrinsic motivation by focusing on extrinsic rewards (Kohn 1994)

- *Training and development:* Providing comprehensive and continuous education and training, setting progressively more aggressive goals for the amount of training provided to all employees every year, preparing for cross- and interfunctional work, providing training in group and quality improvement skills

- *Management development:* Preparing managers for roles as facilitators and coaches; training in team building, strategy, and vision development techniques; training in leadership, self-leadership, and self-management (DiPietro 1993)

- *Relationship to organized labor:* Seeking collaborative rather than adversarial relations with unions, particularly in activities related to quality and continuous improvement (Redman and Mathews 1998, Wilkinson et al. 1998).

- *The role of the human resource function in management:* Emphasizing HR's key strategic role in acquiring and developing human resources, deemphasizing HR's traditional preoccupation with routine personnel activities, training employees to carry out many traditional human resource management activities on their own, seeking ways to enable employees to carry out newly emerging HR activities.

Changing Roles and Relationships. Schonberger has noted many changes in roles and relationships in HR departments of companies becoming world-class manufacturers. HR is more involved in high-level and strategic decisions while simultaneously shrinking in size. The more mundane bureaucratic orientation of HR in traditional organizations, centered around activities such as creating job descriptions and classifications, becomes less of a priority. Instead, an increasing emphasis is placed on selection and development. HR professionals shift their emphasis to team-based and self-directed training and education rather than making HR the main "trainer" of other employees and managers. The facilitator role of HR professionals also becomes more significant (Schonberger 1996). One approach used by organizations such as IBM has been to diffuse the HR function over each major unit to enable greater customization of services rather than a "one-size fits all" approach (Caudron 1993).

On the basis of a study of HR functions and quality management in the United Kingdom, Wilkinson et al. (1993) identified five phases of an organization's transformation to quality and suggested important

roles the HR function can play in each. At the beginning of the transformation—the "formulation or developmental" phase—HR can help shape the quality management approach the entire organization chooses to follow. When the organization has committed to a quality management approach—the "introductory" phase—HR's role shifts to training managers and facilitators in quality management techniques and developing vehicles to communicate the move into quality management. When significant progress on a variety of quality initiatives has been achieved, the "maintenance and reinforcement" phase has been reached, and HR's role involves maintaining momentum and sustaining a high profile for existing and new quality initiatives. One important measure to do so would involve providing incentive-compensation structures to reward progress in quality management and to evaluate and improve those structures over time. Two other phases—a companywide review and a review of the HR function's activities—overlap or are concurrent with the first three phases. In the companywide "review" phase, HR's contribution involves ongoing evaluation of the quality management infrastructure through such techniques as internal surveys and external benchmarking. Finally, in the review of HR's operations phase, HR assesses and improves both its standard HR operations and its support of its internal customers in their implementation of quality management.

Undertaking a (Almost) New Role.   The variety of roles HR can play in the various phases Wilkinson et al. (1993) describe suggests that HR functions are ideally placed to play major roles in moving their organizations from the traditional command and control management system to a modern quality-based system. Wilkinson et al. note that HR can play a "change agent" role by operating with a "high profile" at the strategic decision-making level in the organization. This potential change agent role can be similar in impact to the role designed for the Organizational Development (OD) Departments and teams from the 1960s onward—departments that frequently were located within human resources functions or closely related to them in the organizational structure. Although some "OD change" efforts were dramatic successes, many were not. Part of the difficulties OD Departments experienced arose from lack of sustained top-level support and commitment (similar to Deming's call for "constancy of purpose"). However, another major factor was surely the lack of a powerful, integrated management "technology" like the one that has created the global quality revolution (Mooney 1986, Stoner and Wankel 1990, 1991). With this new global management technology now becoming progressively better understood and with its competitive power progressively more obvious, HR functions are now very well placed to play the organizational transformation role originally intended for their organizational development departments.

Information Systems.   Jurison (1994) points out that for continuous improvement, information systems' role is "that of support, providing data collection, analysis and decision support functions" (p. 13). "Considering the fundamental importance of statistical data to quality improvement initiatives, it follows that information technology, with its ability to capture, process, and disseminate data, must play a key role in [continuous quality improvement]" (Jurison 1994, p. 4).

In making significant process change, information technology is often "an essential enabler without which the process could not be re-engineered. It has the potential to reduce organizational complexity, eliminate unnecessary work, simplify and streamline communications and coordination, and facilitate teamwork. Many re-engineered processes make use of [information systems] in replacing outmoded processes that originated before the advent of modern computer and telecommunications technology" (Jurison 1994, p. 13).

In addition to the important role of information systems in improving processes, they also are critically important in many other aspects of managing for quality. These include gathering customer satisfaction data and disseminating them throughout the organization; establishing effective communications processes such as electronic data interchange between the organization and its customers, suppliers, and other stakeholders; and enabling effective internal communications among individuals and teams with e-mail, team-based groupware, and other computer networking vehicles. For example, many quality organizations have linked their information systems with those of their customers and suppliers. Now, when a customer places an order, the company and its suppliers immediately see and can respond to the implications for deliveries of materials and scheduling of work. This type of seamless system reduces the delays and errors that might occur if requirements

analysis, ordering, materials delivery, and production planning had to await other, more complex, and more error-prone flows of information. Many other examples of the use of information systems and technologies to achieve quality goals appear throughout this handbook.

Legal Services.   One of the more exciting areas of quality improvement in support operations is the corporate legal activity. For some corporate pessimists, the term *legal services* is an oxymoron, and efforts to achieve high quality in legal services seem doomed to failure because of the attitudes of many attorneys. In an article on the Malcolm Baldrige National Quality Award, David Garvin (1991, p. 86) noted that "examiners use various techniques to assess horizontal deployment" (the spread of quality practices across an organization). "One examiner noted that, on site visits, he heads immediately for a company's legal or maintenance group to see how it has responded to the quality effort."

In some companies the examiners would find dramatic improvements led by attorneys who are deeply committed to the quality ethic. Lyondell Petrochemical Company, Motorola, and AT&T are three companies whose Legal Departments have achieved solid successes in using quality approaches.

Jeffrey Pendergraft, general counsel and vice president of Lyondell, described the evolution of quality management in Lyondell's Legal Department as having occurred in successive stages: customer focus, teamwork, empowerment, process analysis and problem solving, benchmarking, and supplier partnerships (Stoner et al. 1993, pp. 9–10). When the company applied for the Baldrige Award, the Legal Department "got involved in the Baldrige process and…began to understand what process analysis was all about."

> As far as process analysis is concerned, we are using what we call the "potato analysis" (the Pareto analysis is too sophisticated for us lawyer types). Everybody in the department is keeping checklists of time consuming functions. Those functions with the most checks get analyzed. The difficult thing was forcing the staff to take the time to think about the process because they were so busy putting out fires. When they did that, they found tremendous opportunities for improving productivity (Stoner et al. 1993, p. 9).

The Legal Department greatly simplified the approval of feed stock purchase contracts (which frequently were being reviewed and approved by attorneys on both sides of the transaction months after the transaction had been completed), sponsored a task force of the American Corporate Counsel Association to prepare a draft crude oil purchase agreement that would be standardized and available for use by all companies in the industry, and shortened the time to negotiate long-term contracts for petrochemical sales dramatically by turning the contracts around in 2 days. Negotiating these contracts often had taken so long that sales had been taking place for a year before the attorneys had formed an agreement.

> We were able to [turn the contracts around in 2 days] by standardizing the terms and documentation of the business transaction. We were able to set up the documentation on a document assembly system so that every contract looked like an original—not a standard form. The document assembly system was developed by a legal assistant, and it has become a key competitive advantage in the industry (Stoner et al. 1993, p. 20).

Richard H. Weise, former senior vice president, general counsel and secretary of Motorola, has written that when Motorola embarked on its quality journey:

> Quality became a religion and the law department was expected to follow. We started by going through the motions of creating law department initiatives which seemed to line up with those of the corporation (constant respect for people, uncompromising integrity, development of criteria by survey and benchmarking, six sigma quality, measurement, cycle-time reduction, process design, etc.).
> To my surprise, I found that each corporate initiative and imperative actually applied to the legal function very well. We began to design systems and develop processes which changed the way we were doing our work. We saw and measured increases in productivity and cost effectiveness and we witnessed marked increases in the quality of our work product, the quality of our morale and the quality of our thinking (Weise 1993–1996, vol. I, p. xxvii).

Improving the Patent Protection Process. In 1990, Vincent Rauner of Motorola reported on the Legal Department's "first trial" of Motorola's quality improvement process—the preparation of patent applications (Rauner 1990). The importance of patents to Motorola's global competitiveness would be hard to exaggerate, and Rauner noted that the company "has dozens of attorneys preparing hundreds of applications per year," a major effort for the company and for its Intellectual Property Department. Rauner described how the project began initially with a focus on what happened within the Legal Department and then expanded—like so many quality improvement initiatives—to encompass a much broader recognition of the determinants of quality in the process. The department

> …mapped the activity in the Intellectual Property Department, initially starting with the receipt of an invention disclosure, then an optional search of the prior art, next the start of the patent drafting job, then obtaining the patent drawings, getting further information from the inventor, finalizing the documents, getting inventor signatures, and finally filing the documents in the U.S. Patent and Trademark Office. We looked at the times involved in these various steps and the particular steps where quality improvement would be significant. Then the thinking began to expand and the real issues became clearer
>
> First, we saw that the entire process from start to finish must be mapped. The starting point really is the conception of the idea by the engineer, then his initial record making, his testing of the idea, or experimentation, the decision to pursue or not to pursue for patent, all of which must occur before the project even reaches our department. Then after we file the patent application there is, of course, prosecution or arguing with the Patent Office Examiner, usually followed by patent issuance, all before the real test is encountered. The final proof of the pudding is whether the patent stands up in infringement negotiations or in a court action.
>
> Second, in our preliminary analysis, we noted the times for the various steps and the fact that such times were unnecessarily and harmfully long in many cases.
>
> Third, the customer situation was apparent. One customer is the inventor, i.e., the patent write-up must satisfy him. Another customer is the Patent Office Examiner who must be satisfied or the patent will never issue. Finally, an infringer must accept, and not find defects in the patent or it will not be protecting technology. If litigation is necessary, the judge must not find defects either (Rauner 1990).

This first patent process initiative yielded a series of improvements in quality and cycle time. The map of the process led to development of a patent-filing template that standardized "the format and the manner of writing up the application document." The template saved time and increased the likelihood that the application would be acceptable, with a minimum of modification, in most countries. The improved process allowed "better focus and more time for the difficult part of the preparation which is the drafting of claims and analyzing an optimum definition of the invention"—the place where the "'art' of the patent attorney comes into play."

In less than a year, the length of time between the date of conception of an invention and the decision to pursue a patent was reduced by about 30 percent, and the metric used by the company to indicate how rapidly the Legal Department acts on the invention idea once it is received fell by 74 percent, even with additional time taken in the critical parts of drafting of claims and defining the invention (Rauner 1990). These improvements in quality and cycle time have continued during the 1990s.

One of AT&T's many quality initiatives in its legal function also involved large investments in intellectual property. With a portfolio of approximately 25,000 active patents worldwide, the income from patent licensing was large and important to the corporation. In 1994 an Intellectual Property Process Quality Improvement Team was formed. The team was chartered to conduct a comprehensive review of AT&T's intellectual property–related processes and to determine whether those processes were maximizing the value of the corporation's patent and technology assets (Greene 1995). One of the team's conclusions was that "AT&T could earn more than five times the economic return on its intellectual property assets than was being achieved" (Greene 1995, pp. 4–34).

The original team led to seven process QITs dealing with such processes as patent assertion (defining and improving the process for identifying patent users and enforcing AT&T patent rights), licensing process (defining licensing process improvements to guide Intellectual Property Teams and the newly organized cross-functional Intellectual Property Department in licensing efforts), and collection process (monitoring and ensuring compliance with Intellectual Property Agreements). Greene concluded "that aggressive application of quality principles in a corporate headquarters division

can yield dramatic improvements, even though headquarters divisions typically face shifting stakeholder expectations and budgetary uncertainties" (Greene 1995, pp. 4–30).

Reusing Knowledge to Improve Contract Preparation Processes.   In the early 1990s, Motorola's Legal Department sought to achieve a "step function improvement in the computer and communications abilities of the department." In doing so, it simultaneously addressed the tendency for attorneys to keep reinventing the wheel in repetitive processes, such as drafting contracts.

Two major initiatives to improve the contract-drafting process—the development of a set of model contracts (the "forms freezer") and an accessible inventory of best-practice contractual clauses (the "clause closet")—are described in Figure 26.5. The figure is taken from an end-of-1990 report on improvement activities in the Legal Department. Both the forms freezer and the clause closet continued to be extended and improved in the 1990s. And recently, the department has developed mechanisms for capturing detailed analyses of substantive legal issues (Substantive Advice Memoranda) in computer databanks and making them more readily accessible for future use.

Preventing Quality Problems.   In addition to improving many of their legal processes, Motorola's Legal Department has placed a strong emphasis on preventing quality problems in at least four major ways: moving from a reactive stance to a proactive stance, moving from dispute resolution to dispute avoidance, establishing a matrix management system, and improving the management development process in the Legal Department. Suggested procedures and the philosophy underlying each of these approaches are discussed in Weise (1993–1996).

The Motorola Legal Department's many initiatives in customer satisfaction, quality improvement, defect reduction, and cycle-time reduction all contribute to the shift from a reactive to a proactive stance. Two initiatives that require special mention are in the areas of crisis management and conducting annual client review meetings to manage the department's relationships with its internal customers.

The Legal Department has taken the lead in working with other parts of the organization to anticipate and plan for areas in which crises are likely to occur. When potentially disruptive events can be anticipated and prepared for, they are no longer considered crises, since they can be avoided or since plans and training for effective response can be in place when they do occur. In the same mode, pre-planning and generalized crisis-management training reduce the damage from crises that cannot be anticipated. A key factor in such preparation involves training corporate officers and line personnel not trained in the legal issues and implications of crisis events well before those surprises occur (Weise 1993–1996, vol. III, chap. 22).

The Legal Department also has taken a more proactive stance by holding client review meetings with its major corporate customers, the operating divisions. These meetings are used to assess customer

---

LAW DEPARTMENT
1991 OMDR
Key Focus Areas for Accelerated Organizational
Change and Improved Performance

The Law Department is continuing to implement a fundamental change in the manner of carrying out its function. The focal point is a step-function improvement in the computer and communications abilities of the department.

A major part of the Law Department's function is the drafting of contracts. Recognizing the cycle-time reduction and quality improvement possibilities of computer-aided drafting, we made excellent progress during 1990 on two separate computer-aided contract drafting projects.

The first project was the development of a "forms freezer." This consists of more than 100 "fill in the blank" contracts on floppy disks available to all Motorola attorneys with PCs. The "forms freezer" works best for relatively simple standardized contracts.

For more complex, customized contracts, the Law Department developed a "clause closet." This is a computerized drafting system that uses the smallest reusable components of the Law Department's best contracts indexed on a computer so that they can be quickly retrieved and used interchangeably. These components as such are reusable in many more instances than when they were hidden in a specific contract form. We expect to continue increasing the "clause closet" database and thus continue to increase the quality and shorten the cycle time in preparation of contracts.

FIGURE 26.5   Creating a "forms freezer" and "clause closet" at Motorola. (*From Weise 1993, pp. 11–27, exhibit 2B.*)

satisfaction, report on costs charged for the services supplied, assess the effectiveness of the services, jointly develop plans for improved service at lower cost, and anticipate and plan for the coming years' legal work for the division (Weise, private communication, June 11, 1996; Weise 1993–1996, vol. I, chap. 8; Stoner et al. 1993, pp. 30–33).

One of the greatest payoffs from the Legal Department's investments in quality management has arisen from the department's success in building the alternative dispute resolution (ADR) philosophy and mechanisms into Motorola's corporate culture. ADR involves two major approaches to resolving disagreements: one involves adjudicatory procedures—such as arbitrators, referees, or private judges—that replace the traditional binding decision of a judge or jury. The second involves facilitated or structured negotiations, such as settlement conferences, summary jury trials, minitrials, and mediation (Weise 1993, vol. I, pp. 6–23). ADR offers many advantages over the slow, costly, and relationship-damaging traditional litigation process. In addition to large savings in time and costs, the ADR process is also more conducive to effective intraorganizational and interorganizational learning, improving the chances that individual or collaborative steps are taken to avoid similar disagreements in the future (Weise 1993, vol. I, chap. 6).

Redesigning the Legal Department.   Motorola's Legal Department is using matrix management approaches to reduce the dangers of bureaucracy in the department. Weise believes that

> …matrix management needs to be addressed in all corporate legal departments. Lawyers don't need traditional management, and corporate law departments are very likely to be over-managed. Law firms have traditionally been filled with legal entrepreneurs, and have been vertically strong, but horizontally weak. As corporate law departments grow, they tend to become bureaucratic and this tendency has to be avoided (Weise, private communication, June 11, 1996).

Efforts to develop a more fluid organizational structure and less hierarchical and formal working climate include strong support for participative management practices—long a part of Motorola's management approach—the use of many quality improvement teams and task forces, and training and empowering nonattorneys to take over work traditionally done by attorneys—when that work cannot be eliminated altogether. Initiatives like these at Motorola are consistent with Samborn's (1994) description of ways paralegals contribute to and benefit from efforts that empower nonattorneys to perform work normally reserved for attorneys and to participate in quality improvement initiatives. Samborn reports that many paralegals embrace systematic quality improvement approaches, and some have become quality leaders in legal departments and law firms.

One of Motorola's recent major initiatives involves improving the professional and management development process in the Legal Department. In 1993, the department undertook a major review and redesign of those processes when survey results of the Legal Department's members showed considerable concern about the extent to which they had understandable, meaningful, and satisfying career plans and paths. The review of existing "personnel-type" programs yielded a surprisingly large number of programs with significant amounts of overlap in intents and purposes but without clear job descriptions and comprehensive job performance criteria. A flowchart of legal organization personnel-related activities was developed and helped the department conclude that a complete overhaul of the processes was required. A management task force was commissioned that developed a comprehensive professional performance system (Weise 1993–1996).

Marketing.   Hurley (1994, p. 45) suggests that marketing organizations are often slow to embrace systematic quality efforts, due, in part, to a belief that marketing is already "doing quality" given its traditional focus on the external customer. However, there are many areas in which substantial progress is being made.

Hearing "the Voice of the Customer."   Companies adept at systematic quality management place few barriers between the voice of the customer and all parts of their organization. This principle played an important role as Toyota Motor Sales USA constructed its marketing function. All quality information is kept in a central database accessible to all parts of the organization, and customized

reports and graphs from this database can be generated at workstations in all field locations. Data are collected through hundreds of thousands of contacts—surveys, telephone calls, etc.—with customers annually. The data are broken down by dealer and downloaded to each dealership to spur local corrective action in response to customer dissatisfaction. A customer satisfaction committee meets monthly to assess satisfaction levels, review plans to improve satisfaction, and communicate status and progress to top management. Based on these findings, senior management sets priorities and allocates resources to improve customer satisfaction (Hurley 1994, pp. 47–48).

Xerox USA surveys every customer after installation of one of its machines, conducts random telephone interviews with customers throughout the year, and benchmarks its service against its competitors on key dimensions every other year. Senior executives also are assigned to take customer complaint calls on a rotating basis (Hurley 1994, p. 48).

Solectron asks its customers to complete and fax back a weekly report card asking about the company's performance on the dimensions of product quality, on-time delivery, communication, service responsiveness, and overall company performance. Customers score the company on a letter-grade scale with a matching point score for each letter: A (100 points), A− (90), B (80), B− (75), C (0), and D (−100). The only acceptable score is a straight A. Solectron holds weekly early-morning meetings, open to all employees, at which the data are discussed, responsibility for investigating and remedying low scores is taken, and improvements are reported and shared (Stoner and Werner 1993, p. 98).

Defining Quality in Customers' Terms. Companies that explore their customers' needs in-depth often learn how to expand their definition of their own products and services to their competitive advantage. Federal Express learned to see its service as going beyond package delivery to include package tracking and sophisticated ordering and billing options. Texas Instruments Defense Systems and Electronics discovered that its customers want a total-value solution and not always the one that is most technologically elegant. Toyota USA realized that its customers are as interested in the quality of their purchase and service experiences as they are in the car itself (Hurley 1994, p. 49).

Marketing research in quality organizations helps define the relative importance to customers of various quality dimensions. For example, Xerox discovered that there were three segments to the market for copiers, each with a different definition of quality. Customers in the low-volume segment (<5000 copies per month) primarily wanted reliability. Customers in the high-volume segment (>100,000 copies per month) valued reliability but also wanted service features such as fast response time in the event of a breakdown (Hurley and Laitamaki 1995, p. 65).

Federal Express conducts surveys to compile its "Hierarchy of Horrors," a list of the service failures of most concern to its customers. These are weighted according to their importance as reported by the customers and are then used to create a daily service quality indicator (SQI), a measure of companywide service quality that is posted throughout the organization. Federal Express's goal is to drive the SQI toward zero by systematically eliminating failures in meeting customer expectations, with an emphasis on those failures most distressing to its customers. (Hurley 1994, p. 48; Stoner and Werner 1993, pp. 42–43).

AT&T conducts surveys to discover the relative importance to its customers of each of its business processes and their characteristics and then uses these data to prioritize its quality-improvement efforts (Hurley and Laitamaki 1995, p. 66). Texas Instruments, Toyota USA, and Xerox are among the companies that use forms of quality function deployment (see also Section 3) to align their goals and plans with customer needs (Hurley 1994, p. 49).

Nurturing Long-Term Customer Relationships. One change in marketing practice driven by systematic quality is a move away from "short-term conquest marketing, in which potential customers are reacquired each period, to a long-term approach that creates loyal buyers over the company's life span by consistently delivering quality and value to them." Federal Express identified its most profitable customers and organized around understanding and meeting their business needs. Globe Metallurgical creates cross-organizational teams composed of both customer and Globe staff to align its operations with its customers' strategic plans. Marriott's computer system tracks the preferences and purchases of its best customers so that employees can personalize their conversations with these customers and anticipate their requests, creating a stronger relationship (Hurley 1994, p. 46).

Improving Marketing Processes. Zytec Corporation redesigned its order process to reduce cycle time and cost when it discovered that it took longer for a salesperson to process an order than for the company to manufacture the product (Hurley 1994, p. 44).

After reducing the manufacturing cycle time for its pagers to well under 1 day, Motorola discovered that it had created an opportunity to redesign its order process. In the new process, a salesperson with a portable computer can take an order in the morning, transmit it by modem to the factory by midday, and promise delivery by air express by the next morning.

Competing via Quality. For some companies, having a well-functioning quality program is becoming necessary to compete successfully. Many companies, including Federal Express, Ford, and Xerox now expect, and sometimes demand, that their suppliers meet increasingly higher quality standards. These same companies report that their own, well-recognized quality programs provide greater access to potential customers by increasing their credibility (Hurley 1994, p. 47).

CONCLUSION

Systematic quality improvement in administrative and support operations historically has lagged behind quality improvement in production and operations activities. However, an increasing number of organizations are discovering that the opportunities for quality gains in administrative and support areas are often as great as opportunities elsewhere in the organization. Administrative and support functions are learning to use the same quality improvement tools in the same ways as other parts of the organization. The results are the same as well: increased quality, customer satisfaction, and revenues and decreased costs through defect reduction, cycle-time reduction, the development of new services, and the elimination of burdens placed on customers and suppliers. The beneficiaries of these quality improvements include both internal and external customers.

In implementing systematic quality management, administrative and support personnel find that both they and their departments undergo significant changes in roles and relationships with others. Perhaps the most fundamental change is from a traditional role of scorekeeper and corporate police to team member and facilitator.

The kinds of changes described in this section are likely to continue to evolve as organizations invent and discover new systems, structures, and relationships more and more consistent with a total quality culture. All organizational members should expect and plan for revolutionary rates of quality improvement throughout administrative and support operations, just as they should expect and plan for such improvements in the products and services they provide to their external customers.

SECTION 27
PROCESS INDUSTRIES

Donald W. Marquardt

QUALITY MANAGEMENT IN THE PROCESS INDUSTRIES

In the process industries, as in other sectors of the economy, Quality Management is the umbrella framework for managing the quality of a product. The philosophy, managing procedures, and technology should provide an operational system in which Marketing, Research and Development, Production, and Support personnel can work together to meet increasingly stringent customer requirements.

The system must deal with all facets of a product's life span from the product's conception through commercialization and subsequent improvements, as shown in Figure 27.1. When a product initially is developed, the emphasis is on designing quality into the product through optimizing functionality and producibility. For established products, the emphases are on maintaining and continually improving product conformance to quality requirements.

The most significant quality improvements are accomplished in those businesses that broadly implement a quality management system. The "system" feature:

- Provides an implementation process
- Interconnects the operational techniques
- Requires and expedites communications in the organization.

The system feature is the vehicle that drives quality improvements as a business strategy. The system approach is particularly important in the process industries.

CHARACTERISTICS OF THE PROCESS INDUSTRIES

The "process industries" have special needs in the technology for quality management. The process industries typically have continuous processes, or batch processes with many batches per year of a given product type.

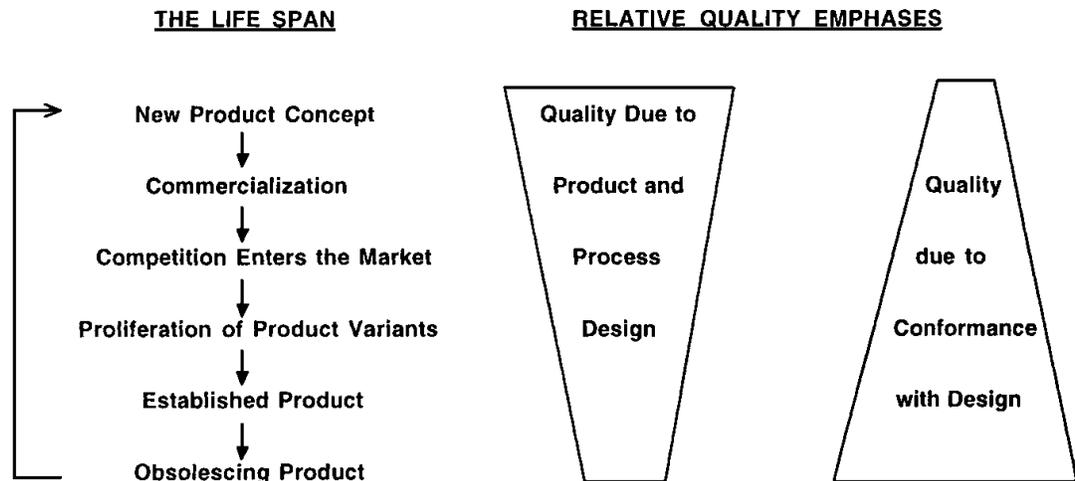

FIGURE 27.1   The product life span. [*From Marquardt (1991).*]

Typical products of the process industries are:

- Solid materials:

  Pieces, particles, powders

  Discrete or continuous sheets

  Chopped or continuous filaments

- Liquid materials:

  High and low viscosity

- Gaseous materials:

Such products can be sampled in specified volumes or weights at specified production points to measure a quality property. The property value may vary throughout a volume or quantity of product, and may change with time. Often the relationship between a measured property and the functionality of the end-use product is not fully understood.

Frequently, the process industry product is an input material for the customer's process. The product must meet this customer's processing requirements as well as requirements of the end user of the ultimate product. Such products are examples of the generic product category called "processed materials."

The foregoing features distinguish the process industries from the mechanical industries, where the emphasis is on the making of parts or the assembly of parts, that is, products of the generic product category called "hardware."

Most existing quality control methodology was developed for hardware products of the mechanical industries, so it may not be too surprising to find that emphases and methodologies in this section are often different from the traditional quality control literature. However, small parts made in large quantities often benefit from the statistical methodologies for processed materials.

DEALING WITH LARGE MEASUREMENT VARIABILITY

A primary difference between the process industries and the mechanical industries is the amount of variability associated with measurement processes. In the mechanical industries, measurement variability often is, or is perceived to be, small or negligible, usually less than 10 percent of total variability. Many measurements in the mechanical industries are based on properties that have absolute or near absolute reference standards, such as dimension, weight, or electrical or optical properties.

These measurements often are of a nondestructive nature, so that the same sample of material can be measured multiple times.

In the process industries, measurement variability is typically larger, often about half, and occasionally as high as 80 percent of the total variability. Most process industry measurements are complex, highly specialized, and not traceable to absolute standards. Examples are measurements of:

- Relative viscosity of a polymer
- Dyeability of a textile yarn
- Speed of a photographic film
- Strength of a plastic film

Many of these measurements involve destructive testing as well, so that local product nonuniformities cannot be disentangled from the measurement variability. In the process industries, measurement variability must therefore be taken explicitly into account in virtually all quality management activities. These include setting product specifications, control of the production process, product characterization and release, and planning experiments to seek improvements.

In recent years, products of the mechanical industries increasingly require tighter manufacturing tolerances, and incorporate components or mechanisms that have process industry characteristics. The technology in this section should be particularly attractive to mechanical industry producers facing such trends.

FUNDAMENTAL CONCEPTS

Generic Product Categories.   International standardized terminology (e.g., ISO 9000-1:1994) recognizes that the term "product" encompasses four "generic product categories:"

- Hardware
- Software
- Processed materials
- Services

(See Section 11, Table 11.4, for further detail.)

Every Product Is the Result of a Process.   The term "production process" has wide applicability. For example, the product units from a production process may be:

- "Processed materials" from a process industry company
- "Widgets" from a hardware manufacturer
- "Test results" from a laboratory
- "Confirmed reservations" from a travel agency
- "Sales made" from a sales organization
- "Deliveries completed" from a distribution organization

Each of these situations involves a production process. Each process creates product units that have measurable properties relating to quality as perceived by the customer. For example, the customers of a distribution organization may perceive quality in terms of the timeliness of deliveries, delivery to the proper destination, and physical condition of the delivered item.

It is important to approach the subject of quality from this viewpoint that *all work is accomplished by a process,* whether in Marketing, Manufacturing, Delivery, Research and Development, Personnel, or other functions. See ISO 9000 (1994).

Facets of Quality.   Discussion and communications about quality have often been unproductive because of failure to distinguish among the four facets of quality (see ISO 9000 1994). The four facets are described in Section 11. Two facets (quality of product design and quality of conformance with product design) receive explicit discussion in this section because of specific needs in the process industries.

Quality of Product Design.   To meet customer needs a product design has to provide the intended characteristics and functionality. For example, when different chemical forms of processed materials are designed for the same markets, we may judge a particular product to have superior quality of product design because it offers additional or enhanced features that improve functionality. Quality of product design can be quantitatively measurable characteristics such as strength, speed, chemical resistance, or subjective characteristics like styling, texture, or odor.

There is an important link between quality of product design and quality of conformance with design. If a product consistently provides its intended functionality despite typical variations in the environments in which the product is produced and used, the product design is said to be "robust." The attainment of robustness in product design has received a great deal of emphasis in recent years.

Quality of Conformance with Product Design.   Quality of conformance with design (or, more simply, quality of conformance) refers to the uniformity of the characteristics and the consistency of functionality of all product units produced day after day. Good quality of conformance means that the characteristics, properties, features, and functionality consistently satisfy their intended specifications.

A BALANCED APPROACH TO ACHIEVE EXCELLENCE IN QUALITY

The Quality Management Success Triad.   Quality management requires three coequal and interrelated facets (Marquardt 1984):

- Quality philosophy and policy
- Quality management systems
- Quality technology systems

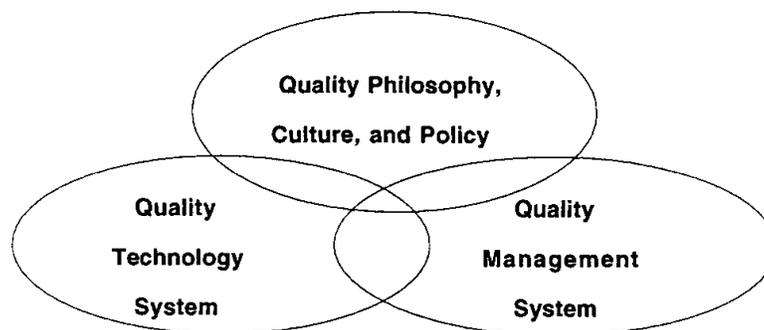
These three facets form the quality management success triad (Figure 27.2). The achievement of continued excellence in managing the quality of products requires that balanced attention be given to all three facets and the linkages among them. Too often, quality management systems have emphasized only one or two of these facets.


FIGURE 27.2   The quality management success triad. [*From Marquardt (1991).*]

Quality Philosophy, Culture, and Policy.   The operation of any enterprise reflects the underlying philosophy of those who lead it. Thus, philosophy is the first facet. It affects the operation of financial systems, the choice of product types, the attitudes on external social issues, the approach to employee safety and health, and many other aspects of the business. In short, the management philosophy shapes the culture of the organization.

The process that is most central to the role of top management is the strategic planning process. If quality management principles are effectively applied in top management's strategic planning, that process can be a mechanism to drive quality leadership throughout the enterprise. (See Section 14, Total Quality Management.)

Quality Management System.   The second facet is the management procedures that are used to achieve, monitor, control, and improve the functional, financial, and human relations performance of the enterprise. Management procedures include mechanisms for allocating, organizing, and improving resources.

Management procedures should incorporate quantitative metrics and other criteria ("report cards") to monitor and evaluate the performance of the organizational units and personnel. Metrics which have exclusive focus on costs, yields, and output, provide disincentives toward achieving high product quality. Thus, report-card design is a key element of quality management. This is an important but difficult area because many disincentives are subtle and not easily foreseen during quality systems design (Marquardt 1994).

Quality Technology System.   Quality Management strategy is complete only when we include the third facet—technology elements that are used to achieve, monitor, control, and improve the quality of the products. To appreciate the importance of this third aspect, we need only look at the effect that new technology has had throughout world history. Repeatedly, new technology has been the driving force behind great changes in the arts, in philosophy, in life style. New technology gives birth to new tools, which affect economic costs and opportunities, and are the driving force behind changes in the strategy of competition between individuals, businesses, or nations.

QUALITY PROBLEMS IN THE PROCESS INDUSTRIES

Systems Problems Versus Worker Problems.   Many quality professionals of wide experience (Deming 1967, 1972, 1982; Juran 1974), have observed that about 85 percent of quality problems are management or systems problems and only 15 percent are worker problems. This experience applies to the chemical process industries. A management or systems problem is one that the individual production worker did not create, has no influence over, and usually does not have the proper information and tools to diagnose. Diagnosis and correction of such systems problems are management responsibilities, although production workers often play a crucial role.

Chronic Quality Problems.   In processed material manufacturing it is particularly important to distinguish between chronic problems and rare-event quality problems. For an established product that has been in production for some time, a good quality management system can dramatically reduce or eliminate "chronic" quality problems. (See Section 5, The Quality Improvement Process,) Some symptoms of chronic quality problems in the process industries are

- A large proportion of total production is affected.
- A large proportion of product is downgraded from first quality, using euphemistic labels such as "special lots," "subcodes," etc.
- A regular practice exists of segregating product for shipment to specific customers on the basis of their specific quality needs.

- First-pass yields to first-grade product are chronically low.
- Complex pricing arrangements persist for specific customers and/or lots, where the prices do not stem from actual differences in mill costs or marketing costs.

  The most severe symptom (and consequence) of chronic quality problems is

- Erosion of market share, specifically due to better quality of competitive product

True Rare-Event Quality Problems.   In sharp contrast to chronic problems are the true rare-event problems. A true rare-event quality problem is a source of product nonconformity presumed to be entirely absent in all normal product. In processed materials these typically are nonconformities that occur because of occasional equipment malfunctions, occasional bad supplies of raw material, and the like. These rare-event problems are often called sporadic problems. (See Section 5, The Quality Improvement Process). The key symptoms are

- A very small proportion of total production is affected, typically only a small fraction of 1 percent of product units over a year's time. True rare-event problems are not representative of the usual production population.
- Each instance of quality breakdown can be presumed to be due to a specific unusual malfunction. These malfunctions should be sought out and corrected. Often the cause can only be diagnosed by analysis of patterns of rare-event failures whose occurrences have been recorded over an extended period of time.

Routine sampling of products will never be frequent enough to detect and weed out a majority of the "true rare events" that do occur. When detection is necessary because of a high economic stake for a particular type of rare event, it is usually better to monitor the appropriate production process conditions continuously and to trigger an alarm (or better still, initiate an automatic corrective action) when a process breakdown occurs, rather than attempt to discover the "needle in a haystack" by extensive testing of final product. The responsibility for elimination of rare events should be focused toward personnel in product design, production process design, and maintenance, rather than toward the process control and product release personnel, who can neither detect nor correct most true rare events in the normal course of their work.

Chronic Quality Problems That Appear to Be Rare Events.   Often in the process industries quality problems appear to be rare events, but really are chronic quality problems. These "apparent rare events" arise as follows:

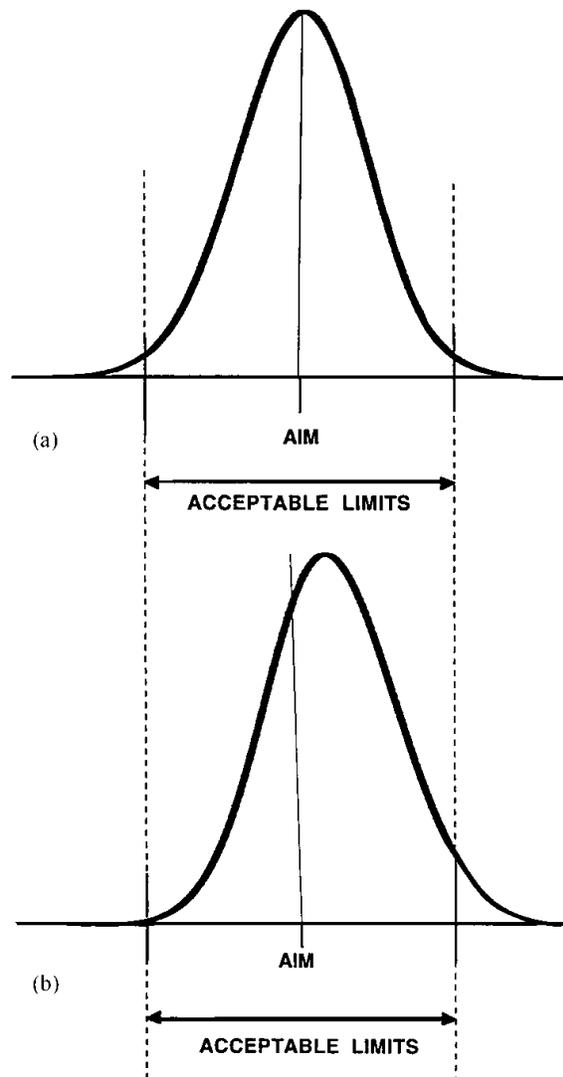
- *Slippage of the process average:*   As illustrated in Figure 27.3*a,* the output from an "on-aim" process will have a distribution of values for any product characteristic (i.e., property). If, as in Figure 27.3*b,* slippage occurs causing the process average to deviate from its aim point, then a small fraction of the product coming from a tail of the distribution may be outside acceptable limits. If the quality management system does not alert production personnel to the slippage of the average, these apparent rare events may only be detected by the customer, and may result in customer complaints. These apparent rare events are representative of the usual production population when such slippage occurs, and the occurrence of such problems can be detected early and can be eliminated by standard quality management procedures using regular sampling methods.
- *Low-count defects:*   Many important product characteristics, such as defects or nonconformities, are quantifiable only by counting their frequency of occurrence in a sample of the product. A product characteristic that gives a low count (perhaps fewer than one nonconformity per sample on the average) may, nevertheless, be a phenomenon that is continuously or usually present in normal product, even though only infrequently counted in a typical routine sample. Such counts are representative of the usual production population and when their frequency increases (a form of process slippage), the problems can be detected and can be eliminated by quality management procedures.


FIGURE 27.3   Effect of slippage of process average.
(*a*) Process average is on-aim; negligible proportion of
product is outside acceptable limits. (*b*) Process average
is off-aim; larger proportion of product is outside accept-
able limits. [*From Marquardt (1991).*]

In many production organizations, the "firefighting" effort spent chasing after both true and
apparent rare-event problems exceeds the effort spent on actually solving the chronic problems.
Some firefighting is almost inevitable, but the bigger danger is that the chronic problems often are
not recognized as problems to be solved, but come to be viewed as a necessary way of life.
Nevertheless, chronic problems usually carry the larger economic stake, by far.

On-Aim Control Contrasted with In-Limits Control.   The implicit process control
concept that has traditionally been employed in many process industry production sites is "in-limits"
control. Under this concept, process measurements are taken periodically. If the measured data fall any-
where within the acceptable limits for the product, the process status is considered to be acceptable.
Commonly, the "within acceptable limits" decision is made on the basis of each successive
single measured test result, or the average of a small subgroup of test results. This procedure disregards
the inherent variability, which gives rise to the distribution shown in Figure 27.3 even when the process
average is held constant. Under the "in-limits" control paradigm the acceptable limits usually are equat-
ed with the product specifications and are usually wider than the inherent process variability. The

process is allowed to run indefinitely in the condition shown in Figure 27.3*b*. Customers of such producers of processed materials may learn to accommodate to the tail of the distribution that is above the upper limit. For example, customers may adjust the conditions of their own production process to compensate for the actual location of the producer's process average. Subsequently, a change in the producer's raw material or process procedures may cause the process average to shift to a value below the aim point—but still within the acceptable limits. Now the customers must contend with a distribution having a tail that goes outside the opposite limit, or with a transition-period mixture of the two distributions. Such shifts are a sure way to cause customer complaints and loss of business.

The "on-aim" control concept, which is central to good quality management, does not allow indefinite operation with the process average displaced from its aim point. As soon as the accumulated evidence from the statistical process control scheme shows that the process is off-aim, action is taken to bring the process back to its aim point. This is based on the understanding that customer satisfaction and marketplace performance are better when the product is maintained close to its aim point.

DESIGNING THE PRODUCTION PROCESS

Strategic Aspects of Economy of Scale.   In the process industries, the design of the production process has an enormous impact on the ability to achieve consistently high product quality. Both the intended characteristics and the uniformity of the product are affected by production process design. Achievement of the desired average characteristics of the product is a major goal in production process design. Likewise, the achievement of product uniformity during continuous process operation with a single product variety is also a major goal in production process design. Unfortunately, achievement of product uniformity under discontinuous operation due to multiple product varieties has not often been adequately incorporated as a major goal in production process design. The resulting quality problems and their penalty on long-term financial performance have often been severely underestimated.

The economies of scale in production process design are always obvious to the designer. They lead to process designs with large single-line continuous processes, or batch processes with very large batches. Typically, at the time of process design for a new product, or for expansion of capacity for an existing product, the new capacity requirement appears to focus on only one or a few product varieties. Hence, the tendency is to design a large single-line continuous process or a batch process with very large batches. The potential for good product uniformity may appear to be high for such process designs due to inherent blending of the large process holdup volumes and the economic feasibility of sophisticated instrumentation and control. However, as a product line matures, it is typical for the marketplace to demand a larger number of product varieties. Good marketing strategy will hold proliferation of product varieties to a minimum. Nevertheless, a mature market usually involves many important segments requiring different product varieties.

Building Flexibility into the Production Process.   The only fully satisfactory answer is to build flexibility into the original production process design. To "design it right the first time" means recognizing the inevitability of proliferation of product types. It means designing the process with

- Small in-process volumes
- Short lag times
- No blending vessels
- Quick, reliable transition procedures

One promising strategy is to construct a series of small-volume plants, bringing smaller increments of capacity on-line only when needed by the current product volume, and retaining design flexibility to incorporate features needed by the evolving mix of product types demanded by the market. Each

continuous process production line, or each batch facility, would then be small enough to allow (for each product variety it produces) a production run length that involves sufficient sampling intervals for effective process control. Multiplant production strategy can then encompass both a flexible multivariety product mix and consistently good quality of conformance. Long-term financial performance should be favorably impacted.

The concept of Continuous Flow Manufacturing (CFM) can enhance this strategy. Under this concept the equipment and facilities in each smaller-volume production line are dedicated full time to that product. If multiple product types are simultaneously produced, each has it own full-time dedicated equipment. This eliminates unnecessary variability introduced into the product by using different combinations of equipment each time the product is run. The dedicated equipment strategy (and often personnel, too) facilitates prompt diagnosis and correction of off-aim results due to specific pieces of production facilities.

Process controllability is fundamental. A continuous process that runs year-round on a single product variety is ideal from a controllability viewpoint. A batch process that produces hundreds of batches of a single product variety year-round is comparable. In both cases, the regular, frequent opportunities to sample and measure intermediate and final product make it feasible to employ control strategies that detect small quality deviations or trends before they become serious, and to feed back corrective action to prevent serious deviations. Production run lengths for controllability purposes must be measured in numbers of sampling intervals. For good controllability, a production run must be much longer than the combined effect of all lags in the system. These include inherent process lags caused by physical holdup volume or chemical reaction time, lags due to sampling and measuring the product properties, and lags due to the response time of the control procedure. Usually this means a minimum production run of several weeks for good controllability in large-scale production lines. Small-scale production lines with fully automated computer-controlled sampling, measurement, and feedback may achieve good controllability in shorter production runs.

Another promising strategy is to construct a higher-volume plant whose design focuses upon quick, reliable transition procedures. Production facilities capable of such transitions between product styles have been devised and implemented in a number of mechanical industries. There are examples in automobile assembly operations. Modular process design is employed, permitting quick, reliable exchange of modules for the differing product styles. Computerized changes in control settings may be involved. The key requirement is that the process will reliably start up on-aim for all product properties immediately after changeover.

In the process industries, continuous process designs with small in-process volumes, short lag times, no blending vessels, and quick reliable transition procedures are a direct analog of the flexible manufacturing systems (FMSs) that have been successful in the mechanical industries. FMS supports the goal of just-in-time (JIT) inventory management. However, just-in-time cannot function properly unless the supplier has a flexible production process. Without a flexible production process, combined with an effective quality management system, efforts to comply with JIT for customers will merely result in the customer's raw materials inventory being carried by the supplier as a final product inventory. In that event, the general economy is in no better position than before.

The process industries, by and large, have not yet implemented process designs with this degree of modularity so as to achieve quick, reliable changeover.

THE ROLE OF PRODUCTION SCHEDULING AND INVENTORY CONTROL

An existing production facility built with large continuous processing equipment, or large batch equipment, will be forced to adapt to the evolving multivariety product mix. Production planning personnel tend to adopt production strategies that optimize only the direct cost of inventory, customer response time, and the like. They often ignore the indirect cost of inadequate product quality. The inevitable result in a continuous process is a production strategy calling for frequent rotation among all product varieties. This requires many short production runs. Serious quality problems are

certain to result because each production run may be nearly over before it is possible to attain and maintain on-aim operation. The large process holdup time may inherently defeat all process control strategies From such a situation, the "transition" product made at the beginning of each run (in a continuous process) is a large fraction of the total production. Various approaches have been used in attempting to cope with these problems:

- Large mixing vessels can be used to blend final product for the purpose of smoothing out property variations, especially those due to transitions. This adds to the mill cost of the product due to increased investment, larger in-process inventory, and increased manufacturing labor. Moreover, the functionality of processed material blended to a nominal average property level usually is not the same as the functionality of product made uniformly at the intended level.

- The transition material can be reworked or recycled to bring it within specifications after further processing. This adds to mill cost and decreases net production capacity. Moreover, reworked processed material usually does not have the same functionality as material originally made to specifications.

- A portion of transition or recycled material can be included with, or blended into, regular shipments of on-aim product. This increases inventory and handling costs and increases the risk of nonfunctionality in customer use.

- The transition or recycled material can be discarded or sold at a reduced price. This has obvious economic penalties.

Analogous problems occur in a large-batch facility that must produce many product varieties. Each variety may require only one or a few batches per year. This degrades the ability to keep production personnel and procedures tuned to a constant state of "standard process" operation. Every batch is handled like an experimental run. The typical result is large batch-to-batch variability.

Whether continuous or batch, the symptoms of chronic quality problems are then encountered. Obvious partial answers are to reduce the number of product varieties being marketed, to revise production planning to require longer production run lengths (continuous processes) or increased number of like batches run each year, and to improve start-up control strategies to get the process on-aim as promptly as possible. The principal part of the answer must come from better production process design strategy.

THE PRODUCTION PROCESSES CRITICAL FOR QUALITY MANAGEMENT

Especially in the process industries, several processes within the "production" operation are critical in accomplishing quality of conformance. Critical production processes generate and use data. The information flows in various paths throughout the network of processes.

In Figure 27.4 the critical production processes are diagrammed. The production process itself is one of five types of processes that operate together:

- Production process
- Sampling processes
- Measurement processes
- Decision/control processes
- Computing processes

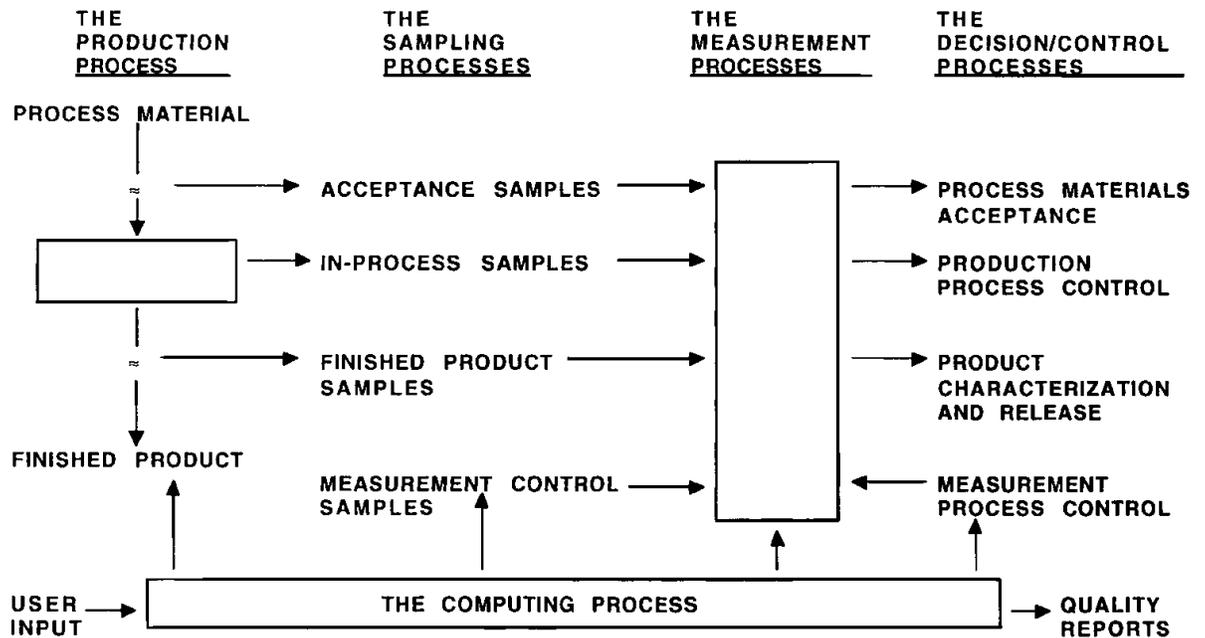
The shipped product cannot have consistently good quality of conformance unless all of these critical processes work together properly. In addition to the production process, each of the other processes also must be considered.


FIGURE 27.4   Critical production processes. [*From Marquardt (1991).*]

The Sampling Processes.   When samples are taken for any of the purposes shown in Figure 27.4, the required structure and size of the sample must be determined quantitatively. This sampling plan will depend on where the major sources of product and measurement variability are present. Moreover, the sample must be taken in a way that makes it truly typical of the material which it must represent, so that:

- "Acceptance samples" of incoming materials may be required to verify conformity to their required specifications. In a well-developed quality system, suppliers' measurements can be relied upon, which minimizes the amount of acceptance sampling required, thus reducing redundant costs in the value-adding chain from supplier to producer.
- "In-process samples" are needed for production process control.
- "Finished product samples" are needed for production process control, for product characterization, and for product release.
- "Measurement control samples" are needed to keep the measurement processes accurate.

The samples that result from these processes must be tagged with identifications telling where they came from and how and when they were obtained.

Most quality management procedures are applied to a single property at a time. Although a single physical test sample is, in practice, frequently used to obtain test results for multiple product properties, the term "sample" in this section normally refers to a single product property sample.

The Measurement Processes.   The output of the measurement processes is numbers (the measured property values for each sample submitted). Some measurement processes are conducted in the laboratory, while others are done on the production floor. Some are highly automated, while others are labor intensive. The measurement processes often are as complex as the production process, and are just as capable of going out of control. If reported test results have large measurement error, they may cause improper actions to be taken in the decision processes. This can cause the product uniformity to be poorer than if the process were left alone.

The Decision/Control Processes.   The decision processes are of two types:

- "Process Control" decisions leading to actions to maintain the production process and the measurement processes on-aim.
- "Accept and Release" decisions leading to actions regarding product disposition to ensure that only conforming process materials are used and only conforming product is released.

The Computing Processes.   Computer hardware and software typically implement parts of all of the preceding processes. Data from the measurement processes may be entered and stored in a computer database, either manually or by automatic instrument data entry. Automated instrumentation may be used to produce sample measurements. Data collected from these processes are then used as input to the control and decision processes. Diagnostic data analysis software may be used to produce graphs, reports, and other quantitative summaries to detect quality problems and monitor quality status.

The computer hardware and software processes involved in these tasks may be complex. The reliability and adequacy of the hardware and software used in these computing systems need to be given attention.

CONCEPTS OF STANDARD PROCESS AND STANDARD PRODUCT

Production Process Specifications.   To ensure the production of a product that consistently meets customer requirements, the production process must be consistent, for example, from day to day and month to month. The set of product properties listed on the product specifications should, to the best of the producer's knowledge, encompass all the characteristics of the product that affect its ability to satisfy the needs of customers. However, it is not enough to rely upon the consistent satisfaction of established product specification limits. There are two reasons for this:

- The product properties for which specification limits have been established may not capture all the important characteristics of the product that affect its functionality in anticipated applications.
- Some customers may use the product in end uses or environments not anticipated by the producer, and these may be suitable end uses, but the producer's tests do not directly ensure consistent functionality in these applications. In such situations, there may be failures in quality of conformance despite the producer's best intentions. An "insurance policy" is needed.

The Standard Process as an Insurance Policy.   Insistence upon a uniform production process is the principal mechanism by which a producer can ensure against the unknown risks just described. A uniform production process from one point in time to another, and from one production facility to another, tends to ensure the consistency of the product properties the producer does not measure, in the same way that it tends to ensure consistency of the properties and characteristics the producer does measure. Thus, there is need for "production process specifications" which define a "standard process." These complement the product specifications. The "standard process" is an essential tool for achieving conformance capability. Standard process protocols should be documented and readily available to all production personnel. In an organization that operates in compliance with the International Standards ISO 9001 or ISO 9002 (ASQC 1996), these protocols are among the "procedures" and "work instructions" available to all relevant personnel. If the standard process is treated as a secret, there can be no standard process.

For each process and each product type, "standard process" conditions should be specified, together with fixed "process limits" for each process setting or processing procedure. The standard process and process limits should be documented formally as "standard operating procedures."

Moves of manipulatable control variables within the documented "standard operating conditions" are permitted for process control, but limited as to allowable magnitude and authorization level required for the move. If more than one process line is producing the same product type, the lines may be operated at different conditions within the standard process if this is required to maintain on-aim control of product properties on each process line.

Definition of the process limits must sometimes be a matter of judgment; but wherever possible, the process control variable limits should be determined by conducting a statistically designed process calibration experiment surrounding the standard process conditions as a center point. (See Section 47, Design and Analysis of Experiments.) When limits for process control variables are specified on the basis of judgment, a rule of thumb is to set limits that exclude the most extreme 2 percent of process conditions used during extended past periods during which a consistently acceptable product was produced.

The concept of standard process also includes the following:

- No change may be made in the operating conditions of any production process for "testing" or "experimental" purposes without prior notification of all potentially affected organizational functions. By definition, product made under test or experimental conditions is not made under the standard process.
- No change may be made in:

    design of the product itself (or introduction of a new product)

    production process equipment

    raw materials or incoming parts (except routine replacements-in-kind of expendable items or materials)

without prior notification of all potentially affected organizational functions. By definition, product made after such changes is not standard product until the changes have been qualified, that is, it has been verified that the product meets all customer requirements and meets product specifications for all regular finished product characteristics for an extended period of time.

Control of Both Production Process and Measurement Process.

Continual on-aim control of the production process is a part of the standard process and is a fundamental concept of good quality management. The production process control scheme is designed to promptly detect a shift of specified magnitude by the process average away from the aim point. System design procedures should ensure that the values of the specified shift and the product specification limits are mutually compatible.

Continual control of the accuracy of the measurement processes also is an essential part of the standard process concept. System design procedures should ensure that a measurement drift of specified size will be detected more promptly than is required for detecting a comparable drift in the production process. In that manner, measurement problems are discovered and fixed before they can cause problems in production process control or in product release decisions.

Every Process in a Quality Management System Must Be Audited.

A quality management system enables objectivity and integrity in assessing the true status of product functionality. Its role is parallel to the financial system which enables objectivity and integrity in assessing the true economic status of a product.

Periodic financial audits are universally accepted as a means to ensure integrity of a producer's financial management system. Likewise, periodic audits of every process in a quality management system are essential to maintain continued system integrity.

Conforming Product.

"Conforming product" is, by definition, product that is in conformance with product design specifications and is produced from standard materials in conformance with the standard process. It is the ultimate purpose of a quality management system to

produce only conforming product. It is important to provide tools to assess product conformance and to deal with situations where existing process performance does not consistently meet performance goals.

QUALITY EVALUATION BASED ON TRUE PRODUCT VARIABILITY FOR CRITICAL PROPERTIES

Each product property can be classified according to how it will be administered within the producer's quality management system. Critical properties are those properties for which the made-product total variability is so wide as to cause persistent difficulty in meeting current or near-term anticipated customer's needs. The lower and upper limits between which a critical property must fall in order to conform to specifications can be called "unit tolerance limits." These are limits on the scale of true product values with which shipped product units are to comply. The product specification format in Figure 27.5 shows the information needed to state adequately the quantitative true product value unit tolerance limits.

Both the customer and the producer evaluate product quality on the basis of final product characteristics. The customer needs to determine how well the product received will meet user needs. The producer needs an accurate evaluation of the quality of the product shipped. Variability in critical product characteristics is the enemy of quality of conformance. Variability in the measurement of critical product properties can make attainment of quality extremely difficult. Every quantitative value observed, however, is subject to variability introduced by the process of sampling and measuring the product characteristics. That is, every observation has the following structure:

$$\text{Observed value} = \text{true value} + \text{measurement error}$$

The statistical term "measurement error" refers to the net effect of all sources of sampling or measurement variability that cause an observed value to deviate from the true value; the term does not imply that an error or mistake has been made. Thus, the true value of a product characteristic is a value that does not contain any sampling or measurement error. A fundamental quality management system concept is the notion of quality evaluation based on true value for critical properties.

The customer and the producer both seek a common basis for discussion and evaluation of the product quality, a quantitative "true value" basis free of any sampling or measurement error. Straightforward statistical methods provide procedures for quantifying separately variability due to true product and variability due to measurement. These procedures require some extra effort. They are cost-effective for those critical, hard-to-control properties where quality of conformance really counts in the marketplace. Use of procedures to characterize product quality of conformance on a true value basis is valuable for both producer and customer

The inevitable presence of measurement variability is one reason for the necessity of using statistical methods in product quality work. The other reason is that the true property values of product units also vary from unit to unit. Thus, we are always faced with the necessity of making decisions about a variable product in the face of noisy measurements on that product. Especially in the process

Property	Product unit	Intended value	Unit tolerance limits		Test method

industries, it is not uncommon to find that the measurement variability is as large as, or larger than, the true product variability. Statistical analysis of variance techniques are used to break up the total variance observed for a product property into useful "variance components." It is then possible to quantify true product variability separately from measurement variability and to estimate the proportion each variance component contributes to the total variance. For critical properties it is desirable to express the product specifications on a true-value basis.

IMPORTANCE OF OBJECTIVELY DESCRIBED PRODUCT SPECIFICATIONS

To design and produce a product that will meet customer requirements, we must be specific about what those requirements are. The necessary content and format of a product specification form a primary vehicle by which a producer and a customer can communicate about the satisfaction of customer requirements. The product specifications document the best approximation of the translation of customer needs and requirements into measurable product properties which can be used by the producer to manage the production process. Especially in the process industries, a small set of defined measurable product properties cannot always fully describe the needs and requirements of all end users. Consequently, the product specifications must be seen as an ever-evolving document reflecting the current understanding of the producer and customers as partners in the translation process.

Three crucial matters have often been ignored by producers in setting specification limits:

- Definition of the product unit
- Definition of the test method to be used
- Appreciation of the role of component sources of variability

Meaningful, technically sound product specification limits can be developed only when the product unit, the test method, and the variance components are all taken into account.

Product Specifications — Content and Format.   A product specification serves both as a documentation of the (specified or implied) agreement between the customer and a producer and is a compendium of information on the product (ASQC 1996b). Ideally, the customer is directly involved in setting product specifications. In many situations, the agreement is between the producer's Marketing and Production organizations, with Marketing representing many customers' needs. The specification contains two types of information:

- *Descriptive information on the product:*   Name, identification code, chemical composition, engineering designs and drawings, uses and functionality, units of measurement, delivery units and conditions, and other qualitative characteristics of the product as well as proper, safe handling and storage information.

- *Quantitative specifications for measurable product properties:*   Numerical values of intended levels of properties and ranges or limits. Most products have from 10 to 100 such measured properties listed on their product specifications. Many products have one, or several properties in their "critical few." These quantitative specifications (intended values and limits):

  Document the best current definition of the product, in measurable terms, that is expected to meet the needs of customers and that can be supplied commercially by the producer with current technology and facilities

  Are for a prescribed measurement method

  Can apply only to properties that can be measured on shipped product

The specifications are incomplete unless all of these items are provided. The entry under "test method" usually is a code reference to a document describing the standard test method (including test equipment, materials, and protocol). For some critical properties, such as impurity levels, only a lower or an upper one-sided tolerance specification may be needed.

Three terms may be interchangeable in some contexts, but may be numerically different in other contexts (Figure 27.6). For clarity of meaning, use each term where appropriate.

The value of the aim point X_0 used in production process control usually is set equal to the intended value.

For noncritical properties, the unit tolerance limits on the product specification format are replaced by observed value limits, usually 3 to 4 standard deviations of a test result above and below the intended value. The format shown in Figure 27.7 can be used.

Definitions of Product Unit Terms.

A product may be gathered into various unit quantities for specific purposes, for example, a warehousing unit, a shipping unit, or a customer-use unit. It is important to define precisely a "product unit" of finished product to which product specifications will apply. This is essential for quantitatively defining product quality and applying the correct sampling system and statistical procedures. The term "product unit" applies equally to a physical product, a software product, or a service. For processed materials selection of the appropriate unit of finished product in a given instance should take into account two features:

- The physical units (bags, rolls, bottles, pallets, etc.) in which the finished product is handled by the producer.
- The physical units in which the customer will use the product.

The product unit for product specifications is best selected as the smallest conveniently handled quantity of product within which a customer will likely detect a significant departure from intended functionality, if such departure exists. Considerable discretion often is available in selecting a product unit for quality management purposes. The product unit may be as small as the "unit

Term	Usage
Intended value	The value of a property which specifies the product functionality *intended by the product design* (and documented in the product specification) for every product unit.
Aim value X_0	The value of a property which specifies the value *intended to be achieved by the production process* for every product unit made.
Average value	The value of a property which specifies the *average* value actually achieved by the production process, averaged over many product units.

FIGURE 27.6   Definitions of product specification terms. [*From Marquardt (1991)*.]

quantity of sampled material" from which a single "test result" is obtained, or it may be many "adjacent" multiples of that unit quantity. Although the product unit choice could vary from property to property, it is operationally helpful to select the same product unit for all product styles and properties in a given product line.

Generic Concepts of Product Unit and Unit Tolerance Limits.   The terms "generic product unit" and "generic unit tolerance limits" (GTLs) may be used in this discussion for true product value quantitative specifications without reference to any specific form of product unit. In most of the illustrative discussions, the product is a processed material that can be sampled and measured at various points in the product unit. The GTLs apply to the true average of the property over an entire product unit. If the product is an item whose property is only realizable and measurable at one point in the product unit, then the GTLs apply to the true value at that point. Accordingly, these product-unit-concepts apply equally to process industry products and mechanical industry products.

Definition of product specifications for product properties that are subject to aging requires special clarification. The term "shipped product" is not usually meant to include aging shifts, except for the aging that occurs in the normal time lag from production until sampling for product characterization and release, usually less than a few days. In each such instance where aging is involved, the time lags should be part of the product specifications.

Unit Package—the Common Case.   In the most common case, the appropriate choice of product unit is "unit package." The unit tolerance limits for critical properties then apply to the true average of the shipped product property for the entire unit package. The unit package should be a unit of product such that within-package variability is not a predominant source of variability. It can be noted that product from the process industries often undergoes physical blending during normal use by customers, resulting in some degree of averaging of property values that may vary throughout each product unit.

Examples of such products and their typical unit package definitions are presented in Figure 27.8.

The continuous filament yarn example needs special discussion. It is an example where the end-use product (a textile fabric) is constructed from multiple unit packages by a process (knitting or weaving). Some "blending" occurs because of the random allocation of yarn tubes to adjacent yarns in a fabric, but the continuity of each threadline is maintained. The resulting blending is not as effective in reducing visual fabric defects as is the blending of staple fiber where each filament is short and is separately blended. Nevertheless, extensive experience indicates that a tube of yarn is an operationally desirable product unit for quality management purposes.

Unit tolerance limits are, in this case, unit package tolerance limits. If within-package variability must be controlled, it can itself be treated as a property of the package. To simplify presentation of concepts and terminology in this section, the discussion is restricted to the package structure. Other product unit definitions should be selected only for special needs.

Variance Components for the Unit Package Case.   The terms "variance" and "variance components," respectively, describe the overall, total variability and the meaningful component sources of variability of product properties and measurement methods. These terms have precise mathematical definitions that are used in computations.

Product	Unit package
Staple fiber	Bale of staple
Powdered pigment	Bag of powder
Pelletized elastomer	Bag of pellets or pallet of bags
Paint	Can of fluid or carton of cans
Insecticide	Metal drum of fluid
Continuous filament yarn	Tube of yarn
Photographic film	Box of film sheets or roll of sheet material

FIGURE 27.8   Typical products and their unit packages. [*From Marquardt* (*1991*).]

When the product unit is a package, the product variance components are defined as shown in Figure 27.9. These components are always present, although their magnitudes will differ from one product and property to another. For any choice of product unit, measurement variance components are always present.

The time interval corresponding to the "same nominal test time" must be defined in context. In many cases, it should be one laboratory shift. Typically, a "nominal test time" is the time interval over which a group of samples, submitted at the same time, would normally be tested. VST, defined in this manner, includes all short-term sources of measurement variability that affect a test result, including differences among multiple instruments or multiple operators that may typically be assigned to analyze the several samples. If the measurement is a destructive one, the VST component inextricably includes the local product variability associated with the quantity of product used to measure a test result, as well as the short-term measurement variability itself. VLT includes all long-term sources of measurement variability.

A "test result" is a single numerical value that is the end result of carrying out a test method for a specific property. A "test method" is a specified (documented) set of test equipment, test materials, and test protocol, whose input is a specified unit quantity of sampled material. The test protocol may require more than one test specimen to produce one test result. For example, the protocol may require averaging measurements from several test specimens.

The five variance components for the package unit can conveniently be visualized in the nested structure shown in Figure 27.10.

Variance component	Symbol
Lot-to-lot variance about the true process average	VLL
Package-to-package variance about the true lot average	VPP
Within-package variance about the true unit package average	VWP
Short-term measurement variance of nominally identical, disguised samples tested at the same nominal test time	VST
Long-term measurement variance; all measurement variance in excess of short term	VLT

FIGURE 27.9   Definitions of variance components for the unit package. [*From Marquardt (1991).*]

Total variance	Total true product property variance	External to lot (VLL)	
		Within lot	Package-to-package within lot (VPP)
			Within package (VWP)
	Total measurement variance	Short-term (VST)	
		Long-term (VLT)	

FIGURE 27.10   Components of variance structure for the unit package. [*From Marquardt (1991).*]

Product Specifications and Market Requirements.   Historical practice in setting product specification limits has varied from one situation to another. In the process industries, defining both customer requirements and requirements for incoming materials has been difficult because the requirements are rarely known precisely, and have been based on experience and judgment.

The problem of basing specifications on incomplete information is particularly acute when one organizational unit gains a monopoly on input to specification setting. Where specifications have been provided initially by Research and Development, they may reflect the technical judgment of the Research and Development group based on the limited experience of the laboratory and pilot projects. Where specifications have been provided by Marketing, they may reflect Marketing's desire to meet customer requirements, without regard to technical capability to do so in Production. And where Manufacturing dominates the setting of specifications, those specifications are likely to be easily met in production but ignore the needs of the customer, or fail to take into account the conditions imposed by a new technology. None of these unilateral procedures can ever be totally satisfactory because none of the involved parties has all the information necessary to make the proper judgment. That is why, in everyday production and marketing practice, the product specification limits often have become a source of friction or have been ignored altogether.

Whenever customer needs for a critical property are known, the specifications should be based on these needs. If customer needs are not precisely known, the specifications should result from a consensus-forming process among Production, Marketing, and the customer. Research and Development should play an explicit supporting role in this process. Production should provide data describing the inherent magnitude of variability in the finished product and in the measurement procedures, based not upon idealized process or measurement capability, but upon the actual historical performance. All parties should understand that wider specifications could increase the producer's yield and conformance and reduce production costs. Narrower specifications, on the other hand, may result in a more competitive product and larger market share and should reduce customer complaints and claims paid to customers for shipped product that does not perform as expected.

In practice, there is not usually a sharp point of demarcation between good product and bad product. Product having actual product levels not far outside the specifications may perform adequately for its intended use, in most instances. Hence, companies should use the terms "conforming" and "nonconforming" to specifications and avoid, in this context, terms such as good, bad, and defective. This usage is consistent with current terminology in quality systems standards (ISO 8402:1994).

As process improvements are implemented, the product variability should decrease and become clearly narrower than the specification limits. Some customers may develop uses for the product that depend upon the "de facto specification limits" that are narrower than the documented specification limits. It will then become necessary to agree on narrower specification limits to recognize the new trade needs. Alternatively, the property might be removed from the "critical property" list because the process performance is now consistently better than trade needs.

Often, in the process industries, the trade need is not well known, or there are so many different end uses, each with its own specification limits requirement, that it is impractical to develop quantitative data on trade need for all segments of the market. In this case, the producer's process performance can be used as input to discussions between the producer and customer (or between the producer's Production and Marketing organizations so long as the customer is properly represented), where the intent is to arrive at mutually agreeable specification limits.

MEASURING QUALITY OF CONFORMANCE WITH PRODUCT DESIGN

Quantitative Definition of Conformance.   "Conformance" is defined quantitatively as the percent of product units which meet product specifications, assessed over a suitable period of time. This quantitative definition of conformance applies to critical properties whose product specifications are on a true product value basis. In various contexts, we need to distinguish:

- "Conformance of product made," which refers to the percent of all product units made which meet true product value specification limits
- "Conformance of product shipped," which applies to the product units released for shipment and refers to the percent of released product units which meet true product value specification limits. When a formal lot release procedure is in place, the product units shipped may not include all product units made.

In this section, the term "conformance" always means conformance of product made, unless explicitly stated to mean conformance of product shipped. Both conformance of product made and conformance of product shipped can be estimated using appropriate computing methods. The definition of "conformance of product shipped" carries with it an assumption: the product units shipped are the same as the product units released.

Goal Conformance as a Fixed Reference for Product Specifications.

An appropriate "goal conformance" level should be selected. Once selected, the goal conformance becomes the fixed reference point against which product quality of conformance is thereafter reckoned.

Typical values of goal conformance are 99 percent or 99.7 percent, but the appropriate value depends upon product characteristics and other factors. For marketing and internal administrative convenience the goal conformance level should be the same for all products within a product line. As uniformity improves for a given product, the width of the product specification range can decrease, with goal conformance held constant.

The approach recommended here differs from the "6σ" approach used widely in the mechanical industries. The "6σ" approach keeps the specifications constant, and strives to continually improve the percent conformance to become virtually 100 percent. The approach recommended here keeps the goal conformance constant at a value (99 percent or 99.7 percent) that can be quantitatively assessed with moderate sample size, and strives to continually narrow the width of the product specification range. Both approaches have the same ultimate intent.

Experience Curves as Measures of Continual Improvement.

To display progress (or lack thereof) in continual improvement, a useful tool is a plot of the standard deviation for a single product unit (package) versus calendar time. Such plots are examples of "experience curves."

Experience curves can be plotted for properties whose specifications are on a true-product value basis or an observed value basis. In the latter case, the plotted standard deviation contains both true product variability and measurement variability. Various forms of experience curves can be useful.

For example, for properties having true product value specification limits, the width of the product specification range provides a formal measure of quality of conformance. The width is a specified multiple of the standard deviation of true product unit values for any specific property. The width of the specification range should become smaller periodically as the product uniformity is improved.

REFERENCE BASES FOR MEASUREMENT CALIBRATION AND PRODUCT CONTROL

Hierarchy of Reference Bases.

Each routine test measurement method is itself an on-going process subject to all the ills that befall production processes. Each such process needs a reference basis. The measurement process is the reference basis for the production process. "Recognized standards" and/or "control samples" are used as reference bases for the measurement process. Reference bases are used for the purpose of maintaining measurement procedures and equipment in satisfactory condition to run routine analyses.

Recognized Standards as Reference Bases. Many test methods are direct measurements of dimension, weight, time, temperature, electrical quantities, and the like. Such measurements usually are the most important properties for many products of the "mechanical industries." These measurement methods periodically must be calibrated within each manufacturing plant and each test laboratory against secondary standards of high accuracy, stability, and uniformity. The secondary standards are, in turn, calibrated against primary standards of ultimate accuracy, for example, at the National Institute of Standards and Technology (NIST), in a traceable sequence of steps. The end result is that such measurements can have small variance and small bias if suitable attention is given to

- Periodic calibration against recognized standards
- Test equipment maintenance
- Standardized test procedures
- Operator training

Some products require high absolute accuracy of such direct measurement; this may present serious problems. Elaborate metrology programs may be required to ensure adequate calibration, standardized procedures, maintenance, and training.

Control Samples as Reference Bases. In the process industries, many test methods are incapable of direct traceability to recognized standards. Since they are simulations of customer-use conditions, they are indirect, multistep, unique to a product, or otherwise nonstandard.

These test methods usually involve some direct measurements that can be accurately calibrated individually but not collectively as a total test procedure. Adequately maintaining these test methods requires more than just a good metrology program, more than just periodic calibration, equipment maintenance, standardized procedures, and operator training. For these test methods "control samples" must be used as reference bases, and control procedures must be used to maintain control.

A control supply is a quantity of regular first-grade product, properly characterized and validated, that is retained for use in testing subsequently manufactured product. Many issues in measurement control center on the proper choice and use of control samples and the control supplies from which they are taken.

CONTROL OF THE MEASUREMENT PROCESS

Test Method Administration. Good test method administration, whether physically located in a laboratory or elsewhere, requires regular calibration of test instruments against recognized standards. Examples are

- A standard weight to calibrate the zero setting of a weighing scale
- A standard white reflecting plate to calibrate a colorimeter
- A standard solution to titrate a chemical test instrument

It must be clearly understood, however, that these calibration procedures are not subject to many of the actual sources of variability and bias in taking, preparing, and conducting measurements of routine production samples. Consequently, virtually all test methods need statistical process control such as Twin Metric control or Cumulative Sum (CUSUM) control of the full measurement process. (See Section 45 for a discussion of CUSUM control.)

Twin Metric control, a form of CUSUM control, offers exceptionally favorable balance among control scheme performance, simplicity, and intuitive user interface; this section refers to Twin Metric control (Marquardt 1993, 1997; Marquardt and Ulery 1991, 1992) as a prototype for state-of-the-art statistical process control in today's computerized working environments. (See Section 45, Statistical Process Control for additional discussion of statistical process control.)

Availability of Means of Calibration.   By employing a suitable control supply for a measurement process, procedures such as Twin Metric control can be used very effectively to detect drifts, level changes, and sensitivity changes, so that appropriate corrective action may be taken. Quite analogous to production control applications, Twin Metric or CUSUM for measurement control are equally valid for situations where a predetermined calibration knob exists and for situations where no such designated control variable is available.

Specification of Aim point X_0.   The measurement process control, such as Twin Metric, will normally use the nominal value of a control supply as the aim point, X_0. Often, the true average is not as important as the uniformity of measurements by different instruments using that control supply or by a single instrument using that control supply at different times. Thus, it is important that the control supply property level remain stable with time, or at least that any changes of the control be adequately characterized. The measurement control aim point, X_{0M}, should be near the production process aim point, X_0. Multiple measurement control supplies and statistical process control schemes may be necessary to satisfy this objective when the measurement is used for several products which have different property levels.

Specification of Other Statistical Process Control Parameters.   The relationship between the design of the measurement process control scheme and the design of the production process control scheme is important.

The acronym ARL (for *a*verage *r*un *l*ength) is commonly used (Bissell 1986; Champ and Woodall 1987; Kemp 1961; Lucas 1973, 1976, 1982, 1985*a*, 1985*b*; Marquardt 1997, Page 1961) for the average number of process control sampling intervals before a control scheme will produce a signal. ARL(0), the value of ARL when the process average is on-aim, should be large. ARL(1), the value of ARL when the process average is off-aim by one multiple of the process standard deviation (SPROC), should be small. For example, the classic Shewhart chart with control limits at ±3 SPROC has ARL(0)=370, ARL(1)=44. Twin Metric control and CUSUM control provide combinations of ARL(0) and ARL(1) that are far better than Shewhart charts. ARL, measured in this (dimensionless) way in number of sampling intervals, can be converted to units of elapsed time or units of production volume if desired. To ensure product quality in routine production the relationship between production process control and measurement process control should be an explicit element of design. Figure 27.11 displays the correspondence between parameters of production process control and parameters of measurement process control.

The standard Twin Metric design procedure described by Marquardt (1997) is used in selecting the parameters for both production process control and measurement control. However, different criteria are applied.

Production process control parameter	Translation	Measurement process control parameter
X_0	Process aim point	X_{0M}
ARL(Δ)	Average number of measurements to produce a signal when process is off-aim by (Δ) (SPROC)	ARL$_M$(Δ)
SPROC	Process standard deviation	SPROC$_M$

FIGURE 27.11   Parameters for production and measurement control. [*From Marquardt (1991).*]

A measurement process control scheme should be designed so that a measurement level change from X_{0M} will be signaled and corrective action is taken before the change results in a production process control signal and an unnecessary adjustment in the production process.

Let D be a fixed magnitude of production process shift that is important to detect promptly in the measured product property level.

Further, let $\Delta = D/\text{SPROC}$.

$\text{ARL}_M(\Delta)$ should be smaller than $\text{ARL}(\Delta)$. A practical place to begin is to set $D = \text{SPROC}$ (i.e., $\Delta = 1$), and try to have $\text{ARL}_M(\Delta) \leq \frac{1}{2} \text{ARL}(\Delta)$, where ARL and ARL_M are expressed in the same units of time. The intent is to allow time to correct the measurement problem after its detection before a production process signal occurs.

To satisfy the desired inequality, the following design variables are available:

- *SPROC and SPROC$_M$:* SPROC$_M$ is likely to be smaller than SPROC for the same sampling interval, sample size, and structure because the measurement control supply is likely to be more uniform than routine product made, even during periods of good production process control.

- *ARL(Δ) and ARL$_M$(D):* Since the ARLs are to be compared in the same units of elapsed time, the inequality can be satisfied more easily if the sample interval for measurement control is shorter than the sample interval for production process control.

- *ARL(0) and ARLM(0):* It is usually possible to have a value of $\text{ARL}_M(0)$ (for the on-aim measurement process) which is smaller than the value of ARL(0) (for the on-aim production process). This is because false alarm signals on the measurement process can usually be tolerated more readily than false alarm signals on the production process. Having $\text{ARL}_M(0) < \text{ARL}(0)$ pushes the relationship between $\text{ARL}_M(\Delta)$ and $\text{ARL}(\Delta)$ toward satisfaction of the inequality.

This discussion of the effect of design variables on ARLs applies to all forms of statistical process control (e.g., Twin Metric, CUSUM, or even Shewhart charts).

SPROCM Estimation.   A simple, robust estimate of the measurement process standard deviation SPROCM can be determined by the mean square successive difference (MSSD) method. Marquardt (1993) discusses the MSSD method and useful generalizations.

Sampling Frequency and Test Protocol.   As a general rule, samples for Twin Metric or other statistical process control of a measurement process should be tested each day (or each shift), preferably at a random time. An exception would be infrequently measured properties for which control samples need to be taken only when routine production samples are being processed through the measurement process. Another exception would be a test method that tends to require frequent recalibrations. In that case more frequent measuring of the control supply may be needed.

Test results from the measurement control supply should be obtained using the same test protocol as is used for test results from production samples.

SELECTION AND PREPARATION OF CONTROL SAMPLES

Control Supply Selection.   Control supplies for measurement control should come from regular product typical of routine production. Candidate control packages should be "validated" before final selection as the control supply. The validation process should include several criteria:

- The production process should be qualified as within "standard process" limits and as operating "on-aim" during the period when the control packages were produced.

- Test results from the candidate control packages should fall within the product specification limits for all properties.

- Samples used to estimate the values of X_0 and SPROC$_M$ of the control supply should span many nominal test times to ensure that long-term measurement variability is well represented. Normally, the value of X_0 must be estimated by the average of a series of measurements on the control supply itself, covering at least 30 calendar days. This value of X_0 should be based on at least 60 sets of measurement data covering at least 90 days.

- Where the control supply is to be used at more than one production site, validation may be appropriate on an interlaboratory basis.

Control Sample Preparation.
The control supplies should be stored in an environment that will prevent damage and minimize degradation. If the product is a discrete, particulate, or liquid material, the control samples for measurement on a given day should each represent a random sample from the original package(s), either by virtue of being taken from a random location in the package(s) each time, or by virtue of thorough stirring or blending of the control package(s). If the product is a continuous sheet, filament, or the like, then control samples used for the actual measurement should be spaced widely enough to be a representative sample of the whole package. When this is not practical, use of multiple or composite control samples is especially important.

Control samples should be identified in a manner that does not call special attention to them as distinct from regular production samples. The goal is to avoid special treatment (hence distortion of level or variability) by measurement operators.

Composite, Multiple, and Staggered Control Samples

Composite Control Samples.   Some measurement methods allow sample quantities to be obtained from several control packages and then plied, blended, or composited into a single control sample to give a single test result. When plying, blending, or compositing is feasible, it provides a useful procedure to reduce the contribution of within-control-package variability and (provided two or more packages are composited) the contribution of between-package variability to SPROCM. Compositing does not reduce the contribution to SPROCM from short- and long-term measurement variability.

Multiple Control Samples.   Using the average of separate test results from multiple control samples is more effective for reducing SPROCM than a single test from a composite control sample. The average of separate test results from multiple control samples reduces the contribution of within- and between-control-sample variability to SPROCM, to the maximum degree feasible, and also reduces the contribution from measurement error, especially the short-term measurement variance component. Typically, this greater effectiveness of multiple control samples outweighs the cost savings from composite control samples.

Staggered Control Samples.   Where the control supply uses multiple control packages, they should be replaced preferably on a staggered schedule rather than all at once. For example, if eight control packages are maintained (whether for compositing or for multiple control samples), a practical scheme would be to replace (the oldest) two at a time. Such staggering is helpful to maintain a stable control supply average age, hence a stable control supply average level, when consistent control level changes due to aging are present.

Control Samples at More Than One Level.
Where multiple products have a wide range of levels on a measurement or where two families of products are produced—a type that runs high in the data range and a type that runs low in the data range—then two separate measurement control procedures, such as Twin metric with control supplies at the two levels, may be advisable.

USING CONTROL SUPPLIES

Control Samples as Computational References.   For some test procedures there is large variability from one test time to another, but these large systematic errors at any one test time affect equally all samples processed at the same time. The best approach to such problems is tighter control of the test method operating conditions and procedures to reduce the time-to-time variability that inflates the long-term measurement variance component. In situations where a practical route has not yet been found to reduce the time-to-time variability, it is common to calibrate all the routine samples run at a given time by simultaneously analyzing some control samples. Then the reported test result is determined by referencing the raw test results computationally to the control sample results from the same test time. In the simplest instance the referencing is done by simple differencing:

$$\text{Reported test result} = \text{OV}_{\text{PS}} - \text{OV}_{\text{CS}}$$

where OV_{PS} = process sample observed value and OV_{CS} = control sample observed value.

The consequence of this approach is that the short-term measurement variance component for the reported test result is double that for the process sample observed value. This comes about because the variance of a difference is the sum of the variances, assuming the observed values are statistically independent with respect to short-term sources of variability. Under the assumption that the routine samples and the control samples have the same variance, the variance of their difference is double the variance of one observation. Hence, the use of a control sample as a computational reference is beneficial only if the reduction in the long-term measurement variance is substantially greater that twice the value of the short-term measurement variance. The short-term measurement variance inflation can be made less than a doubling by using, as computational references, the average of several simultaneously analyzed control samples.

Sometimes an observed value is referenced to a control by ratio rather than difference. Propagation of error theory shows that the inflation of the short-term measurement variance component due to a ratio is quantitatively similar to the inflation due to a differencing operation, so the same guideline is appropriate.

Multiple Measurement Process Configurations.   When any one of many measurement process configurations, such as multiple instruments or multiple operators, may be used in routine testing of the same product property, it is necessary that all such measurement process configurations be maintained at the same value of X_0. To maintain the same value of X_0, it is desirable to use the same controls for all. This enables expeditious detection of biases among instruments or operators. For example, where there are multiple instruments, Twin Metric schemes could be maintained for each instrument, the average of all instruments, or differences between each instrument and the average of all instruments. Obviously, not all of these should be used for any one application.

Confirming the Effectiveness of a Measurement Adjustment or Calibration.   When a measurement Twin Metric or CUSUM signal is received and proper action is taken, it is advisable to carry out additional testing with controls to confirm that the action has in fact returned the measurement process to the aim point. Such a confirmation step is particularly advisable when the adjustment or calibration of the measurement is known to be inaccurate or has a history of poor behavior.

TESTING PRODUCT WHEN MEASUREMENT PROCESS IS OFF-AIM

When the measurement process is detected to be off-aim and reaction to this knowledge returns the measurement process to the aim point quickly, no special steps need be considered in dealing with the product or the production process. If the measurement process is not returned promptly to the

aim point, the measurement process output should not be reported or used to control the production process or to characterize the product. Simply stated, when the measurement process is off-aim too long, then the product is not being produced under standard operating procedures and should be given special marketing treatment.

A backup measurement method (often less automated, slower, and more costly per test result) may be available for emergency use. This backup method must itself be periodically validated to maintain its accuracy for when it is needed.

VALIDATING NEW MEASUREMENT METHODS

If we cannot measure a problem adequately, we cannot correct it either. For this reason, periodic adoption of new/better measurement methods is a principal route to quality improvement.

Whenever it is proposed to substitute a new measurement method for an existing method to measure the same characteristic of the product, it is necessary to establish that the new method is adequate for the needs. It is not enough to demonstrate that the new method is cheaper, faster, less labor intensive, and the like. It must have three performance characteristics:

- The slope (sensitivity) of the average response of the measurement process must be sufficiently large versus the property measured to provide the needed average responsiveness.
- The variability of the measurement process must be small enough in comparison to the slope of the average response so that an adequate signal-to-noise ratio is obtained.
- The measurement process, with its documented test protocol and its procedures for periodic calibration, must be demonstrated to be stable and reliable in actual use.

The first two performance characteristics can only be demonstrated by a designed experiment. (See Section 47, Design and Analysis of Experiments.)

The third performance characteristic can be demonstrated by an extended simultaneous overlap period during which both the old and the new methods are used, allowing the measurement variability sources for the new measurement method (i.e., SPROCM and/or VST, VLT) to be estimated under conditions of actual use. During the time when data are collected for purposes of estimating the value of X_0 and SPROCM for the new method, the old test method should remain in place for purposes of process control and product characterization.

The relationship between the old and new methods may often be demonstrated by scatter plots and calculations. However, it must be understood that the observed numerical correlation coefficient between two measurement methods will be lower than the correlation between the true average responses due to the measurement variances for both methods (Hald 1952, p. 615). Moreover, the new measurement method may not measure precisely the same product characteristic as the old method. This is a vexing problem for many processed material products. This points up a fourth important performance characteristic that any measurement method applied to final product must have:

- Measurements from the new method must correlate with customer use requirements.

Here again, experimental design methods are the tools to establish adequacy of the measurement method.

ESTIMATING AND MAINTAINING VARIANCE COMPONENTS FOR THE PRODUCT AND MEASUREMENTS

Previously in this section the "package" form of product unit was defined, and with it, the five variance components that are needed. The tool called "analysis of variance" (ANOVA) is the statistical

method for separating the total observed variability in a measured product property into sources of variation, and for estimating the magnitude of variation that can be attributed to each source. (See Section 47, Design and Analysis of Experiments.)

Analysis of variance should be used in many ways, including

- To analyze "routine production process data" that are obtained to monitor the process average and variability, and to provide information to periodically update the quality system design.

- To analyze on-going "maintenance data" that are obtained to maintain current estimates of the measurement process and within-package variance components. When the maintenance data are combined with the routine production process data, all five variance components can be estimated separately and updated regularly.

Analysis of Variance Using Production Process Data.

One-way analysis of variance, also known as "among and within groups ANOVA," is a statistical method for isolating two sources of variation in a measured product property and for estimating the magnitude of variation that can be attributed to each of the two sources. (See Section 47, Design and Analysis of Experiments.) This discussion is intended to highlight the relevant concepts of ANOVA and to illustrate the calculations required when the product unit is a package. In practice, the ANOVA computations should be computerized as part of the software system.

Guideline for Obtaining Variance Components Data.

The variance components estimates should be based on data that:

- Provide at least 60 degrees of freedom for the estimate of each component
- Cover at least 60 production days
- Cover at least 90 calendar days

When both routine production data and maintenance data are being collected regularly (e.g., daily), this guideline is straightforward to implement. There are strong reasons for this guideline, both theoretical and practical.

In theoretical terms, the guideline is important to ensure enough data so that variance component estimates are adequately close to their true values. The theoretical effect of degrees of freedom in the precision of estimating a simple variance (single variance component) for a random sample is shown in Table 27.1.

Thus, 60 to 90 degrees of freedom are required to get a variance estimate that will be within 25 to 30 percent of the true value with reasonable confidence. Small variance component estimates derived from ANOVA calculations may have somewhat greater statistical variability. This level of accuracy is necessary and is sufficient for the various uses of the variance components.

TABLE 27.1   Confidence Limits on Estimate of Variance.

Degrees of freedom	90% Confidence limits on the ratio: estimated variance/true variance
4	0.18, 2.4
10	0.39, 1.8
60	0.72, 1.32
90	0.77, 1.25

Source: Donald W. Marquardt (1991). *Product Quality Management,* DuPont Engineering, Wilmington DE.

In practical terms, the guideline is also important. From experience with a wide variety of applications, it has been found that adequate stability of process and measurement variances can only be obtained when sampling covers the elapsed time periods prescribed in the guideline.

Variance Component Estimates from Production Process Data.   The two mean squares calculated in the one-way ANOVA are not themselves the variance components (i.e., VLL, VPP, VWP, VST, and VLT). The within-lot mean square is only influenced by sources of variability occurring within a lot. The lot-to-lot sum of squares, on the other hand, is influenced not only by lot-to-lot sources of variability but within-lot sources as well.

Call the within-lot variance component VPPU, for the package product unit case, where the U stands for "uncorrected." VPPU is the source from which VPP is calculated, but it must be "corrected" for the effects of other within-lot variance components. Call the lot-to-lot variance component VLLU. If three packages were sampled per lot, the lot-to-lot mean square is an estimate of:

$$VPPU + 3 \times VLLU$$

The one-way ANOVA table can now be completed as in Section 47, Design and Analysis of Experiments, and expressions for expected mean squares can be used to solve for estimates of VPPU and VLLU.

These expressions for the expected mean squares are exact for the true (population) values of the mean squares and variance components. The estimates of the variance components are obtained by substituting the estimates for the population values, and solving for VPPU and VLLU. The expected mean square expressions in Figure 27.12 show that VPPU = MSWL directly; then VLLU = (MSLL − VPPU)/a.

Neither VPPU nor VLLU is an estimate of any of the five desired package product unit variance components, VLL, VPP, VWP, VST, or VLT. Both VPPU and VLLU are estimates of combinations of the variance components. As mentioned earlier, VPPU includes all sources of variability occurring within the lot, namely, VPP, VWP, and VST, while VLLU includes all sources of variability occurring external to lots, namely, VLL and VLT. In fact:

VPPU estimates VPP + VWP + VST

VLLU estimates VLL + VLT

Estimating VWP, VST, and VLT From the Maintenance Sampling Plan.   It is important to estimate and update all variance components on a regular basis, using data accumulated during on-going operation of the system. The routine production process data normally are used for production process control and sometimes for product release, in addition to their use in estimating and updating variance components. As described earlier, estimates of

$$VPPU = VPP + VWP + VST$$

$$VLLU = VLL + VLT$$

come from the routine production process data.

Source	Sum of squares	Degrees of freedom	Mean square	Expected mean square
Lot-to-lot	SSLL	DFLL	MSLL	VPPU + $a \times$ VLLU
Within-lot	SSWL	DFWL	MSWL	VPPU
Total	SSTOT	DFTOT	MSTOT	
Note: a is the number of packages sampled per lot.				

FIGURE 27.12   ANOVA table with expected mean squares. [*From Marquardt* (*1991*).]

To be able to estimate all five variance components, extra production samples—the "maintenance samples"—are required at regular time intervals. Typically, a group of maintenance samples is submitted to the measurement facility daily whenever the process is making the product. The maintenance data are used to estimate and, periodically, to update ("maintain") the values of VWP, VST, and VLT.

Maintenance Sampling for Measurement Components of Variance.

The minimum adequate extra sampling for maintenance of VWP, VLT, and VST requires a group of four samples to be submitted routinely at scheduled intervals (e.g., daily) to be measured for each sampled property, a so-called ABCD plan. The four maintenance samples for the ABCD plan are designated A, B, C, and D. A fixed sampling strategy should be used in selecting the A, B, C, and D samples. For example:

- Sample A might always be taken from near the "top" or "outside" of the package.
- If so, then sample B should always be taken in a fixed adjacent relationship to A, for example, immediately "after" or "below."
- If A is taken near the "top" or "outside," then C should be near the "bottom" or "inside."
- Sample D should always be taken immediately "after" or "below" sample C.

A and C are tested "today"; B and D are tested at a later time, for example, "tomorrow."

The lag between the times of testing the (A, C) and the (B, D) samples ideally should be long enough for all long-term sources of measurement variability to come into play. Sometimes a 1-day lag is not enough, and VLT may be underestimated if a longer lag time is not used.

Note: Care should be taken in defining what is meant by a "test time." If the routine production process samples are taken and tested daily, then the test time for maintenance sampling should be 1 day as well; if the routine samples are tested during each shift, especially if the process is controlled and product is released by shift, the maintenance sampling test time could be a shift. In any case, A and C are tested right away (within the test time definition) and B and D are tested later (often, the next shift or tomorrow).

One degree of freedom is sacrificed to remove any fixed effects when estimating each of VWP, VST, and VLT according to the procedure outlined in the following paragraphs.

Contrast Method of Variance Components Estimation.

The data from the ABCD plan can be analyzed by general ANOVA procedures similar to those outlined in Section 47. The simple computing procedure recommended here for the special ABCD structure, the "contrast method," gives results identical to the general ANOVA, uses convenient numerical procedures, and supplies useful diagnostic information.

For the ith maintenance set, $i = 1, 2, \ldots, R,$ where R is the number of maintenance sets of data, compute three quantities (contrasts):

$$WP_i = (-A_i - B_i + C_i + D_i)/2$$

$$LT_i = (-A_i + B_i - C_i + D_i)/2$$

$$ST_i = (+A_i - B_i - C_i + D_i)/2$$

When the samples are taken in the recommended fixed sampling pattern, it becomes possible to:

- Test for the existence, or monitor the magnitude, of a consistent average slope within packages (top to bottom or outside to inside, as the case may be)
- Test for the existence, or monitor the magnitude, of a consistent average degradation or bias between the samples analyzed "today" and those analyzed "tomorrow"
- Test for the existence, or monitor the magnitude, of a consistent average change of slope (interaction) within a package

The presence of consistent profiles or biases of these types will not inflate the variance component estimates. However, such consistent profiles or biases represent possibly serious deficiencies in the product or the measurement processes. Technical programs should be initiated to eliminate the biases if their magnitudes are large enough to be important in practice.

The next step in the contrast method determination of the variance components is to compute the following three averages:

$$\overline{WP} = \frac{1}{R} \sum_{i=1}^{R} WP_i$$

$$\overline{LT} = \frac{1}{R} \sum_{i=1}^{R} LT_i$$

$$\overline{ST} = \frac{1}{R} \sum_{i=1}^{R} ST_i$$

Next, compute the three mean squares:

$$MSWP = \frac{1}{R-1} \sum_{i=1}^{R} (WP_i - \overline{WP})^2$$

$$MSLT = \frac{1}{R-1} \sum_{i=1}^{R} (LT_i - \overline{LT})^2$$

$$MSST = \frac{1}{R-1} \sum_{i=1}^{R} (ST_i - \overline{ST})^2$$

Finally, the variance components are calculated as:

$$VWP = \frac{MSWP - MSST}{2}$$

$$VLT = \frac{MSLT - MSST}{2}$$

$$VST = MSST$$

and each has $R-1$ degrees of freedom.

The ABCD ANOVA calculations correspond exactly to those for a two-way crossed ANOVA, where both the within-package and long-term factors are crossed with each other and only one replicate is included in the data. The expected mean squares apply to this two-way crossed ANOVA model. The short-term "factor" is really the interaction plus short-term measurement. In much collective experience, this factor effect has never been statistically significant.

Estimating and Maintaining VLL and VPP.   Estimates of VLLU and VPPU and estimates of VWP, VST, and VLT are combined as follows:

$$VPP = VPPU - VWP - VST$$

$$VLL = VLLU - VLT$$

This completes the calculations of all five package product unit variance components.

In practice, the variance component updating procedures (including calculating initial estimates of all components) should be done by computer. The data are entered into the computer database lot

by lot (daily, by shift, or whatever) as they become available. The ANOVA software, both routine ANOVA and maintenance ANOVA, should contain diagnostic procedures to warn of any outlying test results, outlying averages, flinching, or unusual patterns in the data. Useful diagnostic procedures include sample sequence plots and histograms, CUSUM sequence plots, and sequence plots of lot averages and of maintenance contrasts.

If routine production process data have missing observations, the routine ANOVA formulas must be modified. It may be best simply to discard incomplete routine or maintenance data sets, so long as at least 60 complete sets are available in both cases for analysis. The causes of the missing data should be investigated periodically, using techniques such as Pareto analysis of the circumstances when data are missing.

The procedure that has been described here for collecting and analyzing routine production data and maintenance data will produce values of VLL, VPP, VWP, VST, and VLT that estimate the variability encountered with the way the plant processes and the measurement facilities are being operated.

PRODUCT CHARACTERIZATION

Having determined quantitatively the five variance components as described in the foregoing paragraphs, it is straightforward to calculate the implied conformance of product made. If the process is operating on-aim, first calculate

SPROD = true product standard deviation, the standard deviation of the true product property
from product unit to product unit

$$= \frac{VLL = + \ VPP}{2}$$

Then calculate

$$Z = \frac{\text{UTL (High)} - \text{UTL(Low)}}{2 \ (\text{SPROD})}$$

The UTLs are the unit tolerance limits (Figure 27.8). Then find the conformance of product made using a two-sided table of the cumulative normal distribution.

Some representative table values are presented in Table 27.2.

For example, if the UTLs are 2.5 multiples of SPROD above and below X_0, then the Z value is 2.5 and the conformance of product made is 98.8 percent.

If the process is operating off-aim, two values of Z must be calculated, one for each tail of the distribution.

$$Z_1 = \frac{\text{ProcessAverage} - \text{UTL(Low)}}{\text{SPROD}}$$

$$Z_2 = \frac{\text{UTL(High)} - \text{ProcessAverage}}{\text{SPROD}}$$

Then find the conformance corresponding to each of Z_1 and Z_2 using a one-sided table of the cumulative normal distribution. Some representative values are presented in Table 27.3.

Then the conformance of product made is obtained by adding the two conformances and subtracting 100. The conformance of product made decreases steadily as the process average moves off-aim.

For example, suppose the actual process average is one multiple of SPROD above X_0. If the UTLs are 2.5 multiples of SPROD above and below X_0 then the value of Z_1 is 3.5 and the value of Z_2 is 1.5. The conformance of product made is then $99.98 + 93.32 - 100 = 93.30\%$.

If an effective process control scheme is in place, it is unlikely that the process average would be off-aim as much as one multiple of SPROD for the entire period of producing a shipment of product

TABLE 27.2 Percent Conforming Product for Representative Z Values—On-Aim Process

Z	Conformance, percent
1.00	68.3
1.50	86.6
2.00	95.5
2.50	98.8
2.58	99.0
3.00	99.7

Source: Donald W. Marquardt (1991). *Product Quality Management,* DuPont Engineering, Wilmington DE.

TABLE 27.3 Percent Conforming Product for Representative Z Values—Off-Aim Process

Z	Conformance, percent
1.0	84.13
1.5	93.32
2.0	97.72
2.5	99.38
3.0	99.86
3.5	99.98

Source: Donald W. Marquardt (1991). *Product Quality Management,* DuPont Engineering, Wilmington DE.

for a customer. However, it also is unlikely that the process average would be precisely on-aim for the entire period. Thus, for this hypothetical example, the effective conformance of product made will likely be somewhere between 98.8 and 93.3 percent on a true-product-value basis.

It is well to remind ourselves at this point that only critical properties are candidates for treatment on a true-product-value basis. Often, with such properties the measurement variance (VST + VLT) is a substantial fraction of the total variance (VLL + VPP + VWP + VST + VLT). Then the interval UTL(high) − UTL(low) will be substantially smaller than the typical range of routine measurements from the process. Statistical process control becomes more difficult, and any attempt to improve conformance by releasing only product that is within "release limits" becomes inherently ineffective. This is a quite common circumstance in the process industries for such critical properties.

The prevalence of this circumstance is one reason why the most effective statistical control procedures, such as Twin Metric or CUSUM, are worthwhile in the process industries.

USE OF THE VARIANCE COMPONENTS FOR IMPROVEMENT OF THE QUALITY MANAGEMENT SYSTEM

Variance components are to be developed and maintained only for properties that are "critical," that is, properties that require careful control and are most in need of improvement.

The five variance components are invaluable information for purposes of quality management system improvement. A simple Pareto analysis, that is, ranking of the five variance components from largest to smallest is a first step. Suppose the VPP component is the largest, being, say, half of the total of the five variance components. It is then clear that the biggest quality management problem

is with the product itself; in particular, the predominant source of product variability is among pack-ages within a lot. That knowledge immediately directs improvement attention to those features of the production process that can contribute to variability within a lot. On the other hand, suppose VST is the largest, being half or more of the total of the five variance components. This indicates that the biggest quality management problem is with the measurement system, and comes from the short-term sources of measurement variability. Improvement attention should then be directed to those aspects of the measurement process that can contribute to short-term variability in the measurement.

In the absence of such quantitative information about the magnitude of key sources of variability, many companies have worked for years on the wrong part of the system and have failed to achieve the improvement they sought. Periodic updates of the variance components provide quantitative evidence of the degree of success of improvement efforts.

USE OF THE VARIANCE COMPONENTS FOR ROUTINE SAMPLE DESIGN

The MSSD (mean square successive difference) method was recommended in a foregoing paragraph as the means to estimate the standard deviation, SPROC, for process control purposes. The MSSD method is recommended for SPC on both critical and noncritical properties.

For those few properties on which variance components are developed and maintained, the vari-ance components provide guidance in designing the structure of the Twin Metric or CUSUM sam-pling plan. For that purpose the following formula can be used to take account of the expected relationship between the sampling plan structure and the value of SPROC, where

$$NPP = \text{total number of packages sampled per lot}$$

$$NWP = \text{total number of distinct samples per lot}$$

$$NST = \text{total number of test results per lot}$$

$$NLT = \text{total number of test times per lot}$$

For example, if there is one observation for each of four packages sampled in each lot, and these are submitted to the laboratory for analysis in two groups at different times, the numbers are NPP=4, NWP=4, NST=4, and NLT=2.

The goal is to make SPROC as small as practically feasible. The routine SPC sampling plan is described by the denominators in the formula. The formula shows that, for most purposes, one obser-vation per package is optimum unless VST is by far the largest variance component. Similarly, NLT is often set to 1 unless VLT is a large variance component. In situations where a formal product release system is deemed necessary, the variance components are essential to effective release system design and evaluation. (See Li and Owen 1979; NBS 1959; Owen and Boddie 1976; Owen and Wiesen 1959.)

QUALITY MANAGEMENT SYSTEM UPDATES

Intent, Definition, and Timing of an Update.   The quality management system will reli-ably produce the claimed product quality levels if all functions of the system are properly designed, and carried out as designed. To guarantee continued compliance with the quality management sys-tem design, all system elements must be updated on a periodic basis. The activities necessary to accomplish the update serve as part of an internal audit of the system. It is important to document the administrative procedures and the organizational responsibilities to ensure that the necessary preparations are completed correctly on a timely basis.

The activities that take place during the update often identify specific data problems, quality man-agement system design problems, or the like. Fixing any of these can lead to an improvement in the

system or its utilization, and lead to actual product improvements. Used in this manner, the update is an excellent source of ideas for continual improvement.

An update refers to:

- Assembly of data
- Calculation of variance components, SPROCs, etc., using the most recent data
- Calculations of system performance criteria (conformance, yield, and cost) for the period since the last update
- Calculations of predicted system performance criteria
- Recording of this information
- Discussions among Production, Marketing, and other appropriate personnel to decide whether any changes are needed in any component of the quality management system
- Documentation of the decisions taken

In preparation for an update, Production personnel analyze the accumulated data since the last update. For critical properties of high-volume products, the variance components and other statistics should be updated, say, quarterly. Updates for lower-volume products may only be practicable at longer intervals.

AUDITS

Every process in a quality management system should be audited periodically to ensure the objectivity and integrity of system performance. (See Section 11.) In many situations, such internal quality audits serve an additional role as precursors to external audits for external quality assurance requirements.

When audits and their resulting reports are wisely administered, audits are perceived by all participants as a mutually helpful vehicle to improve the quality system and the product quality.

Preparation of an audit plan should include a detailed review of everything that has been agreed to be done in implementing the quality management system.

Obviously, not everything can be audited at frequent intervals. The audit plans should establish audit priorities and audit schedules that reflect the priorities. High-priority items will be audited frequently, low-priority items infrequently.

Lower-Level and Higher-Level Audits. At each organizational level the audit team should consist of persons who collectively have knowledge of the activities being audited and their proper procedures. To ensure objectivity, at each audit level the team should not be composed entirely of local personnel. The nonlocal personnel can include: higher-level management; technical personnel or supervision from the corresponding organization at another site; technical personnel or supervision from a distinct, but related, organization at the same site; and personnel from staff specialties such as Research and Development, Statistics, Marketing, and Quality Management Systems.

Numerical Audits and Procedures Audits. In discussing periodic system updates, it was noted that the activities necessary to accomplish an update serve as key parts of the numerical aspect of an internal audit of the quality management system.

When developing routine system updates, the integrity of the numerical data should be questioned by graphical examination of data. In particular, the histograms of maintenance data and of routine product data should be inspected to detect flinching, outliers, or other anomalies. Time plots of these data are also informative, especially for revealing any long-term trends, cycles, or other patterns. The accuracy of data entry, storage, and manipulation should be spot-checked.

Procedures audits must include on-site observations of actual quality procedures. The objective is to assist the audited site in complying with quality management principles. Inspection details will differ from situation to situation, but should include:

- Verification that original data are accurately and promptly entered into the database system (computer or manual) with no form of flinching (Marquardt 1994).
- Verification that Twin Metric or CUSUM signals are followed by prompt and effective action.
- Verification that product release decisions are being made and followed properly.
- Verification that process materials acceptance decisions are being made and followed correctly.
- Verification that designs for Twin Metric or CUSUM and for product release are updated correctly and whenever required.
- Verification that standard operating conditions and standard operating procedures are being followed.
- Verification that standard procedures are properly documented and current versions (only) are readily available to those who need them.
- Verification that accurate records are kept.
- Verification that Production operators, inspectors, laboratory technicians, and others are following proper procedures, including:

  Production equipment checkout and control

  Process instrumentation calibration

  Sample taking

  Sample preparation and handling

  Laboratory instrument calibration

  Laboratory control sample validation and handling

  Product packaging and handling

  Product labeling

- Verification that action has been taken to correct quality system deficiencies identified in previous audits.

A written report should be prepared after each audit, and follow-up procedures should be established to verify that any quality management system deficiencies uncovered by the audit are corrected.

SECTION 28
QUALITY IN A HIGH-TECH INDUSTRY

M. K. Detrano

INTRODUCTION

In order to understand the role of quality in a high-tech industry, it is important first to define what both "quality" and "high tech" mean in this section. The term "quality" is interpreted very broadly and can be thought of as a synonym for "business excellence", i.e., that attribute of business systems and processes which contributes to successful and sustainable business results, encompassing a balance among employee, customer, shareholder, and other stakeholder (community, environment, etc.) values.

The term "high tech" is used to refer to any business that produces a product that has "high tech" attributes, uses processes that rely on "high tech" methods of production, or addresses a marketplace that has "high tech" product or service needs. What, then, are these "high tech" product, process, or market needs attributes? From a product point of view, "high tech" can be defined as *a product that is propelled by a powerful technology learning curve and that has a complex architecture with high feature density, speed, and/or bandwidth requirements.*

While products from the electronics and communications industries are obvious examples of high tech, the definition can be interpreted more expansively, especially when examining process and marketplace attributes. For instance, high tech processes have many of these challenges:

- Rapid time to market with shorter development and life cycles

- Very well-educated, technically excellent, multicultural work force

- A growing body of de facto global standards

- A significant reliance on "qualified" suppliers and complex manufacturing systems

The preceding characteristics represent internal aspects of high tech. The external or marketplace needs have these attributes:

- A customer base that may have little or no experience with the product or technology
- A marketplace that is willing to accept innovative solutions to problems they may not yet know they have

There are probably no aspects of total quality management (TQM) principles in "any tech" industries that do not pertain to high-tech industries as well. Therefore, no attempt will be made in this section to outline all TQM activities pertaining to industry. Only selected aspects of quality management principles that are particularly relevant to high-tech industries will be discussed.

Finally, the discussion will roughly track the 1997 U.S. Malcolm Baldrige National Quality Award Criteria, highlighting topics as they pertain to each of the following Baldrige categories:

- Category 1: Leadership
- Category 2: Strategic Planning
- Category 3: Customer and Market Focus
- Category 4: Information and Analysis
- Category 5: Human Resource Development and Management
- Category 6: Process Management
- Category 7: Business Results

This is in keeping with the intent to define "quality" as "business excellence." As the understanding of the impact of quality continues to mature and expand, it is appropriate to broadly address all areas of business excellence. This is especially true in high-tech industries, where there is a growing intolerance for mediocrity in terms of time to market, quality of products and services, competitive value, and flawless execution.

BALDRIGE CATEGORY 1: LEADERSHIP

Speed is clearly a major differentiator in a high-tech industry. This has important implications on the leadership and management systems.

Speed manifests itself in various important ways. These include

- The organization's and the leader's ability to learn
- The process and length of time it takes to reach organizational alignment
- How long it takes to channel technical breakthroughs into innovative products
- How quickly informed decisions are made

Each of these areas will be addressed in turn below.

Ability to Learn.   First, good leaders are not only able to learn but they are also *willing to be seen learning.* They are in a continuous learning mode with shorter and shorter cycles. They create an environment open to learning and change, and they expect the people in their organizations to behave similarly. This enables both the leaders and the work force to continually and quickly develop the better answers that are demanded in their high-tech world.

Organizational Alignment.   Second, the leaders must set direction but not overmanage. Constancy of purpose with repetitive attention to clearly articulated goals is important. The use of a policy deployment (or similar) process with mutually negotiated goals, metrics, cascaded objectives, and frequent review sessions is very beneficial. Such a process can reach all levels in the organization quickly and is helpful in a high-tech environment because technical innovation frequently can

create apparently conflicting goals. In addition, it helps leaders conduct a systematic analysis for near- and longer-term goals. It helps communicate the critical few breakthrough projects needed to make the organization successful. And it helps employees know what is important and how they personally connect to the organization's goals.

Figure 28.1 provides a sample format for the structure of an organizational policy deployment matrix. Typically, these are layered downward through the organization, with a referencing scheme (numerical or otherwise) that allows lower levels, including individuals, to relate their goals to higher-level ones. Each organization, in turn, uses the matrix/matrices of the organizations above it *and beside it* as guidance and insight into the development of its own matrix, negotiating with higher-level organizations as necessary. The essence of the matrix-development task, therefore, is to develop a set of goals and objectives that have these characteristics:

- They specifically address the scope and area of responsibility of that particular organization.
- They are aligned with the overall business goals and objectives.
- They are limited to a reasonable number of clearly understood and mutually agreed-to projects and/or metrics.
- They are synergistic but not conflicting with neighboring organizations.

Each individual employee, with the supervisor's input, now develops his or her own set of personal goals from these organizational matrices. These employee goals, representing a mutually negotiated agreement between the employee and his or her supervisor, should have the same four key characteristics as outlined for organizations above. *In some cases, the identical "individual" goals are applied uniformly to a team of employees, where the team has agreed to work as a unit, i.e., they succeed or fail together.* Figure 28.2*a* presents a possible standard template for an individual employee goal based on the higher-level matrix. Figure 28.2*b* uses this template to derive a sample goal from the higher-level organizational goals shown in the example in Figure 28.1.

An important point to note is that policy deployment can be used to define and track incremental business goals as well as breakthrough goals. It is helpful to keep the number of breakthrough goals very small, e.g., two to three, because too many large projects will dilute the benefit of concentrated effort. Having a clear understanding of which goals are breakthrough versus those which are incremental will help ensure that appropriate effort, staff, reporting timeframes, expectations, and rewards are instituted commensurate with the type of goal.

The use of the traditional plan-do-check-act model here helps to show the importance of linking strategic planning to policy deployment. The entire goal-setting and cascading portion of the organization's policy deployment process should be completed before the beginning of the fiscal year and should be integrated with the strategic planning process for that year. This can be thought of as the "plan-do" steps, i.e., "plan" through the development of the strategic plan and the more tactical policy deployment matrices, and then "do" through the cascading of the policy deployment matrices throughout the organizations. The review portion of the policy deployment process, the "check" and "act" steps, should be arranged so that every organizational metric is reviewed daily, monthly, and/or quarterly, i.e., checked, as appropriate. Figure 28.3 is a sample of a monthly metric reporting sheet. Trending data are required and corrective action, i.e., the "act" portion, instituted against root causes in cases where the trends are in the wrong direction or behave outside expected control limits. (See Baldrige Category 2: Strategic Planning, below, and Section 13 for a broader discussion of strategic planning.)

These monthly metric reports, or a condensed version of them, can be "made visible" to all employees as a continuous reminder of priorities and goals, i.e., constancy of purpose. A simple example of a visibility method is the use of video monitors mounted in high-traffic hallways. Information is refreshed daily and has a simple choreography designed to catch the eye. Such a display can summarize policy deployment metric status as well as community announcement activities, e.g., new employee arrivals, upcoming ISO audits, etc.

One note of caution is necessary regarding the reporting portion of policy deployment. Most often policy deployment fails because the entire process is allowed to degenerate into the creation of a stack of arcane monthly reports that no one looks at, responds to, or is held accountable for. This could be indicative of a number of root causes:

Corporate goal	Subproject	Project owner	Metric	Metric reporter	Target (current year)	Long-term target
1.0 Increase customer satisfaction	1.1 Institute rigorous survey method	J. Smith	1.1a Monthly survey results	K. Andersen	10 months	1 every month
			1.1b Quarterly survey analysis	B. Baker	3 of 4 quarters	Every quarter
	1.2 Create customer response team	R.Johnson	1.2a Percent customer complaints resolved	V. Jones	60%	95%
	1.3 Achieve ISO registration	D. White	1.3a Successful external audit	O. Thompson	During 3rd quarter	N.A. (Need long-term goal for ISO)
2.0 Enhance employee engagement	2.1 Pilot self-directed team concept	E. Edwards	2.1a Choose and train pilot group	E. Edwards	End of 1st quarter	N.A.
			2.1b Percent favorable response to questionnaire	P. Brown	80%	95%
3.0 Create additional share owner value	3.1 Decrease accounts receivable	W. Green	3.1a Percent product DOA	O. Director	75%	99%
		R. Johnson	1.2a See above			
	3.2 Reduce COGS	C. I. Owe	3.2a Manufacturing cost reduction	T. Bender	10%	35%

FIGURE 28.1 Policy deployment matrix.

28.4

GOAL DEPLOYMENT TEMPLATE

Goal: (State what the goal is in one sentence.)

Goal Reference Number: (In order to keep the numbers consistent, use a reference number that refers back to the policy deployment matrix.)

Plans/Steps/Process to Accomplish Goal: (Outline briefly what are the steps that are needed to accomplish this goal. Note: This is not a replacement for a detailed work plan but a vehicle to clarify expected work effort.)

Possible Barriers to Overcome: (Identify any issues or situations that could impede progress. Note: This helps to visualize areas for special attention for both the employee and his/her support manager.)

Probability of Meeting Goal (High, Medium, Low): (Identify probability of success. Note: Most goals have a high probability of success. However, if the goal is a "stretch" goal that is perceived to be very difficult, a medium or low probability may be more realistic. This does not mean that the employee will not work hard to accomplish it, but it does give the employee the sense of support from his/her manager that the manager acknowledges the difficulty of the goal. In this case, there should be an accompanying discussion in the "Steps" and "Barriers" paragraphs above about ways to increase the probability of success.)

To Whom Is Goal Deployed: (Note: This is normally the employee. It also frequently includes other people that the employee is expected to influence or work closely with.)

Metric(s) to Measure Progress:

   Name: (Identify some metric that is measurable that will show progress or completion.)
   Source: (Identifying the source of the metric helps eliminate vague metrics.)
   Target: (Helps to realistically assess the usefulness of the goal and the metric.)

Goal Owner: (Person responsible for the goal. It may be the employee, the employee's manager, etc.)

Signatures for Concurrence:

Employee: **Date:**

Goal Owner: **Date:**

Manager/Support Person: **Date:**

FIGURE 28.2a   Goal deployment template description.

EMPLOYEE GOAL DEPLOYMENT

Goal: Become a productive team member for the new customer response program.

Goal Reference Number: 1.1

Plans/Steps/Process to Accomplish Goal: Take training to become certified in product knowledge. Complete workshop on "Talking with Unhappy Customers." Develop spreadsheet to help analyze customer call statistics.

Possible Barriers to Overcome: Training material may not be available in time. May need to find more informal ways to learn about products. (My manager can help negotiate training schedules, etc. on behalf of the new team.)

Probability of Meeting Goal (High, Medium, Low): High

To Whom Is Goal Deployed: I. M. Worker

Metric(s) to Measure Progress:
   Name: Course completion rate
   Source: Training records
   Target: 2 courses, one each quarter, completed by end of 2Q.

   Name: Spreadsheet usage
   Source: Monthly reports
   Target: All team reports produced by this software from 3Q on.

Goal Owner: I. M. Worker

Signatures for Concurrence:

Employee: *I. M. Worker*   **Date:**

Goal Owner: (*Same*)   **Date:**

Manager/Support Person: *U. R. Boss*   **Date:**

FIGURE 28.2b   Employment goal deployment sample.

Metric: *% Customer Complaints Resolved*   **Sponsor:** *R. Johnson*

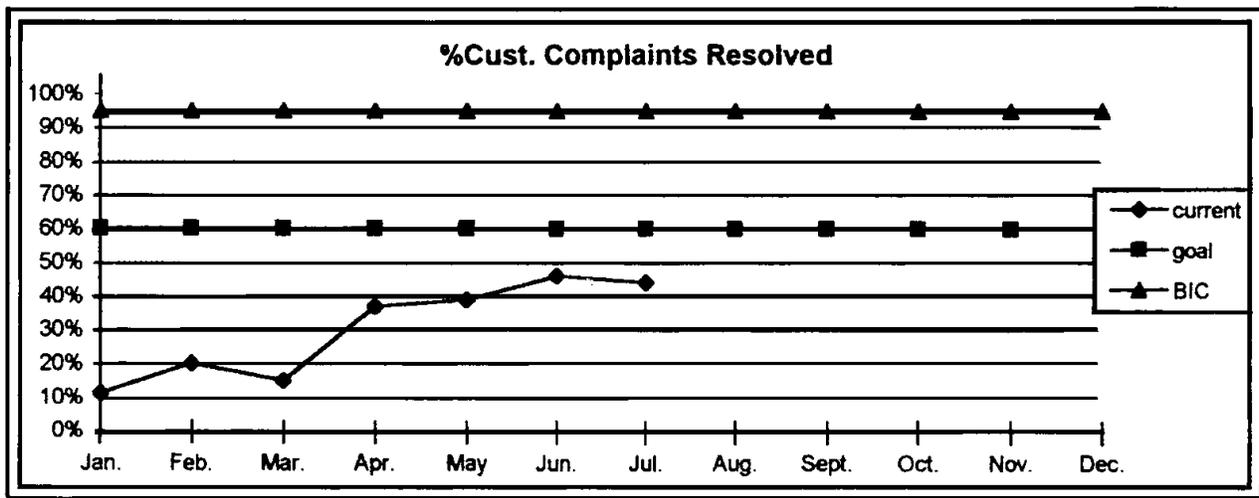
Cascade Reference Number: *1.2a*

Policy Deploy.Objectives: **Level 1:** *To Increase Customer Satisfaction*

Level 2: *To Create Customer Response Team*

Level 3:

QI Story	**Step 1:**	*Need systematic way to respond to customer complaints.*
-or-	**Step 2:**	*Data of current situation shows no repeatable "system".*
Improvement	**Step 3:**	*Root cause analysis shows need to formalize responsibility, et al.*
Plan	**Step 4:**	*Currently instituting needed countermeasures.*
	Step 5:	*Some early results are beginning to show improvement.*
	Step 6:	*Will formalize new approach next year if continued successful.*
	Step 7:	*Will start next level of work toward BIC of 95%.*

Trend Chart: (Show this year's goal and B-I-C or competitive benchmark.)


Person Tracking This Data: *V. Jones*

Explanation of Spikes/Dips: *Begun to implement Q.I. Story Countermeasures in March. Results beginning to show improvement in April. Final Countermeasures will be in place by August.*

FIGURE 28.3   Monthly metric report.

- Wrong choice of metrics

- Lack of a suitable venue for review and action

- Waning attention to the need for constancy of purpose

The first two causes can be addressed through the use of problem-solving techniques. The third cause, however, may be a symptom of waning leadership attention. It requires direct leadership intervention.

Finally, at the individual employee level, performance evaluation against goals is a major tool in the overall human resources performance management process. (See Baldrige Category 5: Human Resource Development and Management.) Individual goals should be reviewed at least quarterly and updated as necessary because individual assignments and goals are likely to change more frequently than overall organizational goals.

Product Innovation.   A third leadership challenge is to channel technical excellence into innovative products rapidly. Policy deployment, coupled with a systematic approach to ensuring that customer needs are well understood by the R&D community, can help this. (See Baldrige Category 3: Customer and Market Focus, Reaching the R&D Work Force.) A dual-reporting organization that allows a program manager (one who manages a new product or service) to operate as the link between research and development (R&D) and the customer, while offloading administrative overhead to a functional manager, has shown success in some areas. This can be augmented by a strong focus on teams and teamwork for that product or service, including team members from business, marketing, and sales. All team members must be fully conversant in the technology. Lack of understanding on anyone's part will slow down or misguide that information flow between technology capability and customer needs. (See more in Baldrige Category 5: Human Resource Development and Management.)

Decision Making.   Lastly, the leadership and management system must be able to make informed decisions quickly, particularly where new products are concerned. A well-followed and well-cared-for "gate process" has the potential to move product decisions along expeditiously. While the basic purpose of a gate process (see process flow in Figure 28.4) is to ensure that the right things are done at the right time via checklists at each gate review (everything from funding approvals to documentation available at time of product ship), it has the added benefit of creating a rhythm for moving the product along through its various stages or "gates." If the process is followed, with aggressive target dates set for passage through each gate, it is expected that new products will be introduced sooner, more smoothly, and with a better sense of cost of development, while at the same time weeding out false starts early.

BALDRIGE CATEGORY 2: STRATEGIC PLANNING

This area touches on two aspects of strategic planning: (1) a comprehensive and thorough plan-development process that includes feedback loops and (2) a deployment and execution process. If either of these areas is incomplete or performed outside the normal flow of business, the effort will fall short of its potential. It is important to note that the planning process needs to include an update-cycle capability. In high-tech industries, the rate of change demands continuous evaluation and improvement.

Plan Development.   The process that develops the plan must include many constituencies, but in a high-tech industry it is essential to include technology (i.e., where the technology is going, what breakthroughs are needed, and how fast the technology will change) as a major component. To accomplish this, real diversity of ideas is needed. In high-tech businesses, not all strategy ideas are "found" at the top. Therefore, it is important to include the "diversities" of the organization regardless of hierarchy. [A *Harvard Business Review* article (Hamel 1996), addresses this issue in detail.]

Each project, before it is approved to move to the next stage, i.e., through a "Gate", must undergo a "Gate Review". (Note: this requires that a detailed project schedule has been defined, including the projected dates for each Gate Review at the time of initiation of the project.)

A "Gate Review" is a formal meeting, conducted by a moderator with the assistance of a scribe, that systematically reviews a checklist of items that are required in order to allow the project to move through the gate. The review is conducted by a set of "gatekeepers", i.e., a cross-functional group of people representing each organization that has responsibility for some part of the project. Consensus is usually required.

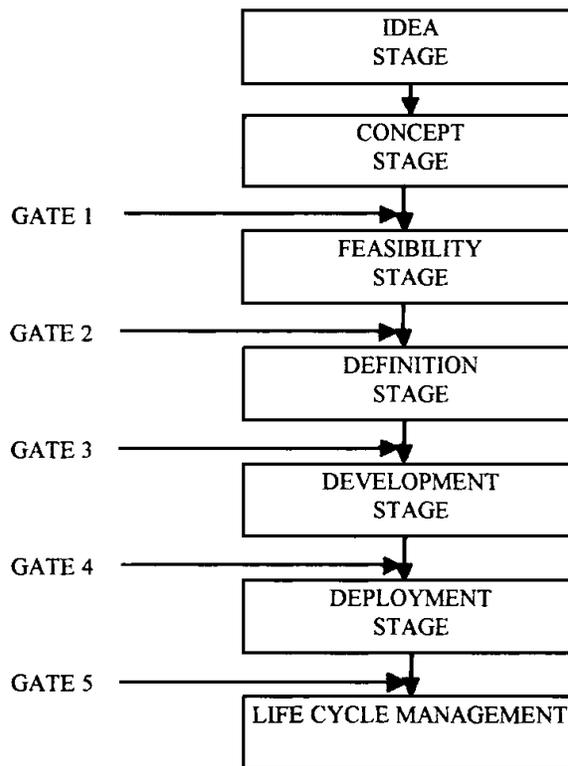
The "Gate Process" has a formal process owner who works with the organization to define the five checklists and other process details, keeps track of gate review statistics (projects, schedules, etc.), and applies process improvement suggestions, as needed.


FIGURE 28.4   Gate process.

A second impact of high tech, and an outgrowth of this diversity, is the need to ensure that R&D breakthrough project plans and foundational technology work that is clearly linked to the goals of the business are included in the strategic plan.

A third consideration for plan development in a high-tech business is integration of contingency planning. When speed to market is important and the product is based on new technology, the product-development process, as well as the product delivery and customer expectation management processes, must account for the risk implied from the unknown.

This leads to the last, albeit most important, consideration: that of input from the customer, together with input from the market and the sales channels. This feedback loop is essential. As more and more high-tech business becomes "customized," the ability to see, hear, and accommodate the "customer of one," i.e., the individual needs of every customer, is critical. Also, when designing a new product concept, it is important to understand the impact on the customer/market that was created by a previous product. This is due to the ability of new high-tech products to actually define new markets or cannibalize old ones. A comprehensive "voice of the customer" system can fulfill this need for systematic and comprehensive customer input. (See more on this topic in Baldrige Category 3: Customer and Market Focus.)

Deployment and Execution.   The deployment and execution phase of strategic planning can be linked directly to and accomplished by policy deployment and human resources performance management practices. The objectives set out in the policy deployment matrix can be captured directly from the strategic plan. As discussed earlier, regular reviews of progress toward these objectives is essential to maintaining the relevancy of the strategic plan, i.e., constancy of purpose.

BALDRIGE CATEGORY 3: CUSTOMER AND MARKET FOCUS

Customers are just as important in a high-tech environment as in any other environment. However, since there is a temptation in high-tech industries to focus more on the technology of the product or the process, some aspects of customer satisfaction should be highlighted. These include

- Achieving balance between a customer and a product focus
- Systematic surveying
- Reaching the R&D work force
- Managing customer expectations

Note that the term "voice of the customer" is used informally several times. It implies a recognition that input from the customer comes in many forms and through many different channels and that these sources should be analyzed and integrated systematically.

Balancing Product and Customer Focus.   In high-tech industries, there is an obvious need to focus on technology leadership. However, attention to the voice of the customer is a critical balance if the new product is to fit a useful application. Being mindful that the introduction of new technology can create discontinuities in the market, it is vital, therefore, to listen both to existing customers/markets and to those who would become users of the newer technology. (Wireless telephony that allows someone to carry a phone with them wherever they go rather than being tethered to fixed locations is an obvious example of this discontinuity. Computing technology that moved from mainframes and timeshare to PCs and client/server is another.)

While much emphasis is placed on the chain of traceability from customer requirements through product delivery, it may be useful for high-tech companies to initiate this chain even before the customer is necessarily aware of what is desired or wanted. Gale (1994) discusses the concept of product attributes and their seven-stage life cycle, from "basic" attributes, i.e., required with no competitive edge, to "latent," i.e., not yet visible or apparent in the marketplace. Table 28.1 describes each of these seven stages.

When searching for and listening to the voice of the customer, high-tech businesses that are mindful of this hierarchy can now probe for clues about new product possibilities based on what customers portray as "unique," "desired," or "latent" attributes, i.e., needs they have that are not yet fulfilled and hence are new product opportunities.

TABLE 28.1   Stages of the Attribute Life Cycle

Stage	Description
1. Latent	Not yet visible or apparent
2. Desired	Known but not currently supplied
3. Unique	Only the pioneer scores well
4. Pacing	One supplier is already ahead
5. Key	Differences in performance determine competitiveness
6. Fading	"Catch-up" moves begin to take away the top performer's edge
7. Basic	All suppliers perform well—no competitive edge

Source: Gale (1994).

Systematic Surveying.   Speed and the acceleration of change in a high-tech industry also influence when and to whom to listen in the customer/market environment. Systematic surveying processes, showing trends in the market and the competition, are particularly useful if executed at regular intervals that keep tempo with market and technology changes. Surveys and surveying techniques that crosscut the management hierarchy of the customer base, including key decision makers, technology directors, and line technicians, fill in a more complete picture of how the customer needs are being perceived and met. Next, feedback to the customer to clarify what was heard and what should be expected helps to manage the risk of wasting ill-affordable time on bad assumptions. Finally, an aggressive action plan to assimilate and act on what was heard reassures customers that their time was used productively.

Reaching the R&D Work Force.   High-tech industries need to have a wide, heavily used, and effective channel by which the voice of the customer can be clearly heard throughout the ranks of the technical community. While this may be difficult to create because of the distance in the value chain from R&D to the customer (customer to sales to marketing to product management to product planning to design to development to research), user group programs, technical seminars, formalized customer-visit processes, and creative partnering are examples of such channels. High-tech leaders who demonstrate equally high respect for the customer and the technical community and recognize the necessity to bring these groups together lay a good foundation for effective channel implementation.

Customer Expectations.   Customer focus is *bidirectional*. Since uncertainties and unfamiliarities are intrinsic to new technology, it is just as important for the company to *speak* to its customer/market as it is expected to *listen* to its customers. Educating the customer/market about the new technology and helping to align expectations regarding the capabilities of the new technology are responsibilities that a high-tech company or industry must assume.

BALDRIGE CATEGORY 4: INFORMATION AND ANALYSIS

Topics to be addressed here fall into four broad areas:

- Finding and using the right metrics
- Using information technology
- The role of benchmarking
- The methods and benefits of overall organizational assessment

Metrics.   It is not easy to find the right metrics. Relating back to policy deployment, any metric that is chosen for tracking should pertain to the objectives on the policy deployment matrix in some way and should support the greater good intended by the highest-level matrix. An example is useful here. Suppose one of the highest-level goals of an organization is to increase customer satisfaction. Further suppose that root-cause analysis of customer feedback data indicates that one of the issues for many of the customers is that installation time is too long. In response, a tools group within a product support division in the organization decides to invent tools to ease the installation burden for existing products. (Product re-engineering is surely one of the objectives for the design group, but that is longer term.) A metric for the tools group, therefore, might have to do with the speed with which they develop tools. This metric of development speed would pertain to the higher-level metrics of customer satisfaction and installation time and, at the same time, support the intended greater good. If, on the other hand, the tools group chose the metric "number of tools built," it could potentially build many tools that were not very useful even though their metric performance would be good. This attention to avoiding local optimization is what is meant by supporting the greater good. One therefore can see that while a metric might be far too detailed and obscure at the highest levels, it can nevertheless be a valid metric at lower levels if it can affect directly the performance of a higher-level metric.

In addressing an additional point that metrics also need to be truly measurable and quantifiable, some metrics must be broken down into constituent parts to be measurable. For example, in an R&D community, technical excellence, while very important, is in itself quite vague. It could, however, actually be decomposed into individual excellence, team excellence, and technical leadership excellence. Now how does an organization measure something like individual excellence? Individual excellence could be further broken down into attributes that address hiring, continuing education, and retention. Specific measures for these attributes can now be enumerated, such as hiring statistics from target schools and markets, attrition rates, participation in training programs, and so on.

Product-development indicators are especially important for high-tech products. One category of product-development indicator covers the overall development process, such as the frequency with which new products are being introduced or how effective vis-à-vis revenue is to the development process. A second category that is especially important for high-tech products pertains to the product at different stages of its development cycle, such as a metric having to do with testing and performance uncertainty. For instance, in many cases, hardware test data results are heavily dependent on the resolution of available test instrumentation, which, in an area of high technology, may approach the tolerances of the product. Hence empirical and testing data from field trials, prototyping, etc. are essential from the *earliest stages* because of the higher degree of uncertainty.

In summary, every level or function in the organization will likely have its own set of metrics, some of which are common across the organization and others of which relate directly to locally derived objectives. Identifying the right metrics, especially to ensure traceability to the customer, may take analysis of the task and insight into what behavior or outcome is sought. Typical metrics categories might include revenue, customer value, cycle time, productivity, cost (including cost of quality), reliability, defect rate, on-time delivery, technical excellence, product-development indicators, and manufacturing statistics.

Information Technology.   Due to the combination of a global work force and a need for speed, the technology of the information systems is important. The systems must be integrated and able to gather, process, distribute, and share data quickly. This helps to close the geographic gap, make the employees more knowledgeable, and enhance the sense of awareness of the current situation. All these aspects help to bring a global work force together faster. The example of a hardware-development process illustrates the point here. Traditionally, the R&D group would design a circuit board, for example, and then create a working model, test it, and finally send it to the factory for manufacture. In turn, the factory engineers would redesign aspects of the circuit board to better accommodate supplier and production issues that had not been fully considered by the R&D staff. Today, a highly integrated design database coupled with a "concurrent" engineering process, i.e., R&D and factory working from the same design database at essentially the same time, can bring the two work groups together from the very beginning of the design phase even if not colocated. Significant interval reductions can be achieved, as well as side benefits such as better overall design and a stronger sense of teamwork.

Benchmarking.   Benchmarking of product attributes is sometimes very difficult because new product performance characteristics are generally a closely held and well-controlled body of knowledge. However, high-tech companies can benchmark process capabilities. Benchmarking can help an organization to quickly study, assimilate, and improve processes based on the experience of others. High-tech companies in particular that are driven by speed can benefit from this because it helps them avoid the loss of time due to a more traditional trial-and-error method.

The areas for benchmarking include almost any process that is part of the day-to-day business. An obvious example of this is the 6σ improvement process that has been adopted by many companies interested in defect reduction (Harry n.d.).

Management System Assessment.   Finally, a systematic management assessment process is essential to maintaining leading-edge performance. Because of the rate of innovation and change in a high-tech industry, it is important to guard against the tendency to fall behind if the organization is not growing, learning, and improving continuously. An efficient method of regular and periodic assessment with improvement planning built into the policy deployment process is a good countermeasure.

There are many different models against which an organization may audit itself for this purpose. The U.S. Malcolm Baldrige National Quality Award and the European Quality Award are two such models.

These models can be modified and used outside the intended formal award structure to bring the assessment process directly into the management and governance structure of the business. For a high-tech company whose survival depends on speed and quality, an integrated assessment process can serve as a constant barometer of its health. In this environment, the assessment process can be streamlined in time (e.g., on a regular basis, the leadership team can perform a self-assessment under the guidance of a trained examiner) and/or focused on a specific area (e.g., the R&D community might perform an assessment focusing on its ability to innovate.) Figure 28.5 is an example of an assessment process that falls between the formality of a national quality award application process and a simple leadership brainstorming session. It serves to suggest the existence of useful alternatives.

BALDRIGE CATEGORY 5: HUMAN RESOURCE DEVELOPMENT AND MANAGEMENT

The most obvious challenge in a high-tech business is to ensure that the organization has motivated and correctly trained people when and where it needs them in the global business environment. This applies not only to the R&D work force but also to the factory, business, sales, and customer service employee base. This requires lead time and is an important consideration in the strategic planning process and the policy deployment process.

In addition, highly trained technical work forces create the need for HR-related processes that specifically address the following needs:

- Nourishment of a feeder pool through trade school, university, and research partnerships
- Expectation of obsolescence and how to avoid it through a constant learning mentality
- Motivation to excel and incentive to innovate
- Tolerance for failure and risk-taking
- Retention of a scarce resource

Innovative processes that bring together technical expertise, corporate education, and HR can produce insights into core competency skills. They also can design and provide the best and quickest ways to acquire, develop, and maintain these needed skills.

Step 1: Using Baldrige criteria, the coach prepares a set of questions. The coach then conducts an initial round of sessions with focus group(s) (a group of subject matter experts from the organization, preferably the leadership team). Done in two adjacent half-day sessions, using a timekeeper:
  - Each question is displayed on a Vugraph. 2 minutes to read.
  - 5–10 minute brainstorm, "What are we doing?"
  - 5 minutes to highlight strengths.

Step 2: The coach prepares summaries of focus group results for each question.

Step 3: The coach reconvenes original focus group(s) to
  - Review and validate the findings
  - Score the question
  - Identify gaps based on the findings
  - Propose possible countermeasures

The coach guides and helps calibrate scoring. An average score is developed.

Step 4: The coach prepares a summary by question, identifying strengths, gaps, and score for each question.

Step 5: [Optional] The coach leads an independent assessment team through the focus group findings. They develop an independent score, compare it to the focus group score, and resolve differences.

Step 6: Coach prepares executive summary and shares results with leadership team.

FIGURE 28.5 Simplified Baldrige assessment process.

In addition, to quickly and efficiently tap the potential of the large, skilled, distributed work force, it is important to avoid creating "linear systems." (Linear systems here generally imply processes that serialize events between and across groups of people.) The use of "parallel processes", e.g., policy deployment or concurrent engineering, and distributed information networks, serves to facilitate parallel yet coordinated activity. Here again, as mentioned in Baldrige Category 1: Leadership, a management approach that sets clear direction, expectations, and accountability but does not serialize or micromanage, i.e., one that has "loose hands on the reins," is essential to the success of parallel systems. One would not like to envision an organization where its manager inserts himself or herself into every decision, thereby throttling back decision frequency to a point that is commensurate with the "bandwidth" of the manager!

No amount of process, leadership direction, training strategies, and so on will succeed, however, if the employee body is not motivated to contribute to the success of the business. One technique that tends to couple approaches for motivation, resource retention, and business goal alignment is the use of a broad recognition system. Assuming that business values and goals have been communicated clearly through leadership initiatives and policy deployment processes, a follow-up system that formally and informally rewards behaviors aligned with those values and goals can be motivational in itself. For a highly technical work force in which recognition traditionally has been realized through intellectual and frequently individual achievement, a recognition program can highlight the value of team participation, speed, and innovation. Regardless of the monetary value of a recognition "event" (anything from a simple thank-you note to an expensive gift or free vacation), such an overall program serves to reinforce across the work force the power and the value of its individual and team contributions.

An even more powerful approach starts with the selection of the employees through a testing system that measures individual tendencies with respect to the core values of the business. Simply stated: Those who have the values that align with the organization's values are invited to join the team. For instance, if the need for collaboration among team members is identified as an essential element for success, then potential employees are interviewed to ascertain their affinity for collaboration before they are hired or invited to join the team. *Only those who demonstrate the desired attitudes, in addition to having the needed technical skills, are acceptable for that position.* A prerequisite to this approach is the existence of a set of principles or core values against which to measure candidates.

While this approach is probably part of every hiring practice to some degree, a thorough and systematic application uniformly across the organization can quickly set up an environment that has a very high probability of operating according to its stated principles and core values. For a high-tech company, the values of teamwork, collaboration, the need to be respectful of others, the drive to demand respect for every individual, a predisposition to excitement about new things, and the need to achieve and celebrate are the types of values that can positively influence the productivity of an organization. The other two essential ingredients in this formula are that there is a "structure" that supports and nurtures this environment—e.g., a separate location, perhaps, or no privileged parking (other than customers)—and that everyone *lives* the principles. If a transgression is sensed, any employee can and will speak to the transgressor, regardless of level. A related requirement that aligns with this approach is the use of process. Any process that has been adopted is rigorously followed with substance and conviction.

BALDRIGE CATEGORY 6: PROCESS MANAGEMENT

In the past, "process" has been considered anathema by many in the technical community. In practice, however, processes, whether formal or informal, are the repositories of organizational learning. The better the management of process (not to imply unnecessary complexity or overhead), the better is the ability to systematically produce quality results repeatedly and, hopefully, faster and faster. Therefore, a discussion of the management of process in a high-tech business is an important first step before addressing the issue of engaging the technical community in process.

The Management of Process.   To meet the high-tech challenges of speed, global work force demands, and other issues, processes need to be well documented, effective, speedy, tolerant of very

little variation in output, easy to use, easy to change, and integrated with each other. In addition, processes need a supportive environment around them, including tools, owners, coaches, and related "care and feeding," such as management support and recognition programs. ISO 9000 registration, when accompanied by a healthy corrective action process, invites consideration of the preceding aspects and has helped organizations introduce process discipline into their activities.

ISO 9000 requires that processes are monitored for trends that indicate that sloppiness is creeping in. (*Sloppiness* here means things like missing quality records, processes not being followed, and dwindling leadership involvement.) When and if this is detected, root-cause analysis and corrective action are performed. If, however, the "corrective action" clause is not invoked frequently in order to maintain processes that are continually refined, the tendency is to tolerate or, worse, circumvent a system of processes that have become stagnant and obstructive.

It has been said that "if you do anything the same way twice, you are not learning to do it better." The point here is an interesting one. This idea, which on the surface may appear to be in conflict with the requirement of repeatability, is actually quite aligned with it, as can be seen in the simple process management flowchart in Table 28.2.

Note that "cycle" in the flowchart is loosely defined to imply some time period of homogeneous work, e.g., a software release, a major contract development, or a yearly performance review cycle. In some sense, the shorter the cycle and the more meaningful the improvement, the better the organization is at learning, innovating, and changing. Care needs to be taken, however, not to introduce a feeling of chaos. Further, quantum changes in technology could render parts or all of a process obsolete, or competition could demand significantly better performance. In these cases, aggressive process re-engineering is required.

In addition to ISO 9000 and the specifics of process management, supporting tools and environments that help build a healthy process management system include the following:

- *Leadership's constancy of purpose:*   Continually reinforcing and rewarding process improvement. Leaders themselves should "own" breakthrough process changes.

- *Policy deployment:*   This is a useful process to gather attention and promote momentum for breakthrough process re-engineering efforts.

- *Quality improvement story* (Qualtec 1991):   This is a useful seven-step tool for tackling process-improvement activities. See Table 28.3 for a simplified chart of the seven steps.

Engagement of the Technical Work Force.   And now to the question of engaging the technical community in process. The scientific method is in itself a process but is not labeled as such. In software, there is a growing body of evidence that careful application of process can substantially improve productivity and quality. Well-known processes such as quality function deployment (QFD, a.k.a. "house of quality") clearly provide R&D with a credible (to them) understanding of customer needs. These observations explicitly demonstrate to the technical world the benefits of process as a daily approach to product development. Leadership reinforcement, together with a responsive corrective action system, signals to this community that process is the acceptable approach. Process audit practices such as the Capers Jones CHECKPOINT software measurement method (Jones 1991) and the Software Engineering Institute's Capability Maturity Model (Paulk 1995), in addition to ISO audits, are

TABLE 28.2   Simplified Process Management Flowchart

Step	Action	Effect
Step 1	Define and deploy the process.	Stabilize the process and define the baseline.
Step 2	Use it for a cycle.	Measure it and gain experience with how the process operates.
Step 3	Change it via the corrective action process.	Improve the process per the experience gained by using it.
Step 4	Deploy the changes.	Systematically track the state of the process.
Step 5	Go to step 2.	Create an opportunity to improve the process again.

TABLE 28.3   Quality Improvement Story Simplified Flowchart

Step	Description
Step 1: Reason for improvement	Identify a theme (problem area) and reason for working on it. Identify team and schedule.
Step 2: Current situation	Select a problem (problem statement), set a target, and collect data on all aspects of the problem.
Step 3: Analysis	Identify and verify the root causes of the problem via cause and effect analysis.
Step 4: Countermeasures	Plan and implement countermeasures to the selected root causes of the problem.
Step 5: Results	Confirm that the problem and its root causes have been decreased and that the target has been met.
Step 6: Standardization	Systematically prevent the problem and its root causes from reoccurring. Replicate solutions, as appropriate, in other areas.
Step 7: Future plans	Plan how to tackle remaining problems. Evaluate Team's effectiveness.

Source: Qualtec Quality Services, Inc. (1991).

practices that help maintain alignment with process improvement. Finally, when connected to the customer, process has the added benefit of ensuring that customer input is systematically made available to the technical community, something generally sought but not always available.

Regarding this connection to the customer, a strong relationship between the sales/marketing organizations and the R&D organization provides a foundation for productive customer-R&D interactions, i.e., forums where R&D people discuss technology visions with customer groups and receive feedback on the visions. For more in-depth product understanding, process tools such as QFD can provide systematic support to the development process from the point of view of product definition. ISO 9000 then plays a strong role because of the discipline it implies in the development and manufacturing environment for the creation and deployment of the product with traceability to the customer.

Fundamentally and in summary, all this comes back to the organization's ability to accept and improve processes. The true measure of process-management capability then becomes the *speed at which small process improvements or major breakthroughs can be transferred into the mainstream operation* without losing efficiency, integration, and other aspects of the processes.

BALDRIGE CATEGORY 7: BUSINESS RESULTS

Results are really the ultimate metrics that show how well or how poorly a process or set of processes is producing sustained performance. It is important that the metrics represent not just financial results but a balance among shareholder, employee, customer, and other stakeholder values. For high-tech businesses, indicators of innovation, work force effectiveness, product quality, supplier quality, process management (especially speed), and customer satisfaction are essential. The major question to answer, then, is, "Are results meeting the goals defined by the strategy and policy deployment processes, and are the goals aggressive enough, i.e., best in class, breakthrough, or incremental, to sustain the desired trajectory?"

SUMMARY

Quality in a high-tech business has to do with a well-balanced mix of customer focus, process management and improvement, and engagement and alignment of skilled employees in support of clearly understood and cascaded goals. Particular tools and methods help to achieve the desired results. The major tools and methods that have been highlighted here include

- Policy deployment
- Process management and ISO 9000 certification
- Management system assessment against Baldrige criteria
- Customer interaction programs
- Employee engagement processes, e.g., training, recognition, etc.

The leadership of the business or industry, through its behavior, defines the approaches that will be used for each of these components. The customers of the business or industry ultimately decide the effectiveness of those approaches.

SECTION 29
AUTOMOTIVE INDUSTRY[1]

Yoshio Ishizaka

INTRODUCTION

The word "quality" has taken on new meaning in the automotive industry over the past two decades. No longer is quality simply a statistical scorecard on freedom from defects or the measurement of fit and finish. Today, quality has a much broader meaning that involves a customer's inner feelings about a product and the company that offers it.

The new definition of quality takes in the basics of performance, comfort, environmental suitability, and affordability, but it adds certain elements of what is known as "production quality", related to the maker's ability to perform consistently better, and "ownership quality", which deals with customer satisfaction.

---

[1] In the Fourth Edition, material for this section on the automotive industry was supplied by J. Douglas Ekings. In the Third Edition, material for the section on the automotive industry was supplied by Soichiro Toyoda.

Two other significant shifts have occurred in recent years to raise the level of quality and quality consciousness in the automotive industry. One is the industry's move to *anticipating* customer requirements rather than responding to them, as in the past. Increasingly, automakers have employed sophisticated demographic and other studies to learn more about tomorrow's consumer, whereas in the past the industry relied on comments from customers as information was gathered for product development.

The other important change is the increase in closeness between automakers and their key suppliers. In the past, suppliers tended to be treated as vendors and were selected mainly on the basis of price and delivery capabilities. Today, the industry's key component suppliers are nearly full partners with the major companies they supply, with both automaker and supplier reaching into one another's designs, plans, and quality-improvement mechanisms. This increased confidence, trust, and reliance serve to form shared-destiny relationships that are crucial to the improvement of quality in the automotive industry.

Historical Perspective of Automotive Quality.

The automotive industry has grown from the days of hand craftsmanship into a complex infrastructure of the globally competitive automotive giants of today. Figure 29.1 reveals five eras in the growth of the automotive industry.

The earliest automobiles were built largely by hand, with each bearing as much quality as was put into it by a single craftsperson or a small group of them. Assembly was careful, time-consuming, and costly. The resulting quality was high, but expensive and inconsistent. Only the wealthy could afford a motorcar.

Henry Ford is widely regarded as the father of mass-production quality. He designed reliable cars that could be built rapidly, consistently, and inexpensively by people with less than master skills. Ford's vehicles met the consumer satisfaction requirements of the day, and America took to the road as ordinary families became able to afford automobiles.

Alfred Sloan advanced the concept of mass production but noted that consumers were raising the standard for customer satisfaction. He recognized that quality had begun to mean that a product had to meet customer expectations, not just a manufacturer's standards. Thus he created a great variety of motor vehicles, and his General Motors Corporation grew by offering cars for every purse and purpose.

Later came the rise of consumerism, followed by environmentalism, as will be explained.

Quality in the Automobile Business.

There are three dimensions to quality in the automotive industry: quality in product, quality in production, and quality in ownership.

Quality in product is the product's overall ability to perform required functions. In the case of an automobile, this means certain performance capabilities, such as the ability to accelerate to 60 mi/h in a certain time; comfort and entertainment features, such as a quiet, smooth ride, controlled climate, and ergonomically designed components such as audio equipment; environmental acceptability, which means the vehicle is fuel-efficient, clean, and safe; and affordability, or meeting the customer's ability to pay.

Quality in production is the ability to produce consistent quality as designed while still meeting volume and cost targets. Within this important dimension are four functions. The first is production of a quality product, measured by defects per hundred. The second ensures operational quality, which

1. Traditional quality	Craftsman
2. Mass-production quality	Henry Ford
3. Customer satisfaction	Alfred Sloan
4. Rise of consumerism	Safety
5. Green movement	Conservation and clean air

FIGURE 29.1   Quality, historical perspective

is the plant's ability to introduce new models, remain flexible, and still maintain consistency. Efficiency is third and is the key to producing even higher quality as volume increases. The fourth production function is cost. The plant must be able to produce an affordably priced product at a profit.

Quality in ownership is the overall ability to satisfy customers throughout their ownership life cycle. This is a critical dimension of quality, but it is the one least understood. Ownership itself is the first function. In it, our progress is measured from the sales experience through each phase of initial ownership including trade-in and repurchase for all subsequent owners. It involves the quality of the purchase experience, the everyday use of the vehicle, service, repairs, and trade-in. Cost of ownership is another function, taking in everything from down payment and monthly payments through operating expenses, maintenance costs, and insurance, finally coming down to resale value. The third function involves the intangibles—the psychological value of this ownership experience. It is centered in pride of ownership, the owner's self-image, and other special feelings created by this relationship with a vehicle.

Industry Structure.   The automotive industry has undergone a concentration that accelerated greatly in the postwar years. Today, the world has 65 international automakers, of which 22 compete in the United States. Under the pressure of cost and currency differentials and government urgings to balance trade, numerous international companies have opened manufacturing and assembly plants in the United States over the past two decades. Today, the United States is home to 61 passenger-vehicle assembly plants.

Design and Production.   The cost of designing and manufacturing motor vehicles is very high, owing to the complexity of the vehicles, the rigid quality and safety standards involved in making them, plus the rigorous testing required and the frequency of design change. Thus design and manufacture are carried out in a very few very large companies. Increasingly in recent years, portions of the product design function have been shared by major automobile makers with their supplier companies. This sharing has added a dimension to the responsibility for quality assurance.

Marketing.   Most manufacturers design and produce a variety of models in order to attract customers of varying means and tastes. Vehicles are sold through nationwide networks of franchised dealerships, some of which offer more than one manufacturer's products. Vehicle dealerships, most of which also offer used vehicles and service and repair facilities, numbered 22,650 in the United States as of January 1, 1998.

The External Climate.   External factors began to affect the industry more and more in the postwar years. These include growing consumer activism, safety issues, product liability, government regulation, and the rise of environmental concerns.

Consumerism.   As the automobile industry's annual-model cycle matured in the 1950s and 1960s, the opportunity for product improvement often was overlooked in the race to create change for its own sake—change more likely to involve fashion than function. Consumers began to resist this trend, demanding that vehicles meet quality standards not only at the time of delivery but throughout their lives and even at the time of trade-in. In this era of consumerism, automotive quality began to be measured over time.

Safety.   Along with consumerism came new standards for safety. Many years after safety glass became standard in American automobiles, a great rush of safety-related improvements came to market, including advanced passive-restraint devices, antilock brakes, energy-absorbing steering columns, crumple zones, child safety seating, and stronger side-impact protection, among many others. Dealing as they do with the preservation of human life and limb, these improvements further raised the standard of quality required in automotive design and production.

Improvements that aimed to promote visibility, accident avoidance, and survivability in crashes were accompanied by some intended to ease the job of collision repair and to lower its cost. Certain

safety improvements, notably passenger seat belts and other restraint devices, have proven to be successful in reducing injuries, and their installation is now mandated by federal law in the United States.

Product Liability.   Manufacturers have been required to consider product liability, which has grown to become a serious concern, especially in the United States. It plays a significant role in product design and manufacturing. As consumers become more aware of manufacturers' legal obligations and the legal system encourages legal action when faulty product is the suspected cause of personal injury, automobile companies have had to become more cautious not only in product design and manufacturing but also in documentation communicated to consumers in association with their products.

Government Regulation.   Government regulation has had a profound effect on the automobile industry. In the United States, the National Highway Traffic Safety Administration (NHTSA) regulates federal safety requirements that can affect design, cost, and consumer expectations of vehicles. Government regulations also mandate certain fuel-efficiency standards for motor vehicles sold in the United States. Although it is difficult to estimate the cost of compliance, increasing NHTSA mandates and other controls have tended to increase manufacturers' costs and vehicle prices significantly.

Environmental Issues.   Two factors combined to create the green movement: One was the development of uncertainties in the world's fuel supplies; the other was worldwide recognition of the problem of air pollution. Following the oil crises of the midseventies and early eighties and the rise of air pollution to unhealthful levels in many of America's largest cities, the industry no longer could overlook fuel efficiency and exhaust emissions in its measurement of quality. All manufacturers of motor vehicles sold in the United States now operate under federal laws mandating increases in fuel efficiency and decreases in emissions.

Concept of Quality Assurance.

The concept of quality goes beyond just meeting customer expectations and fitness for use, as has been explained. This concept extends to serviceability, costs, and emotional issues and remains until the eventual disposal of the vehicle at the end of its useful life. Toyota employs a system, illustrated in Figure 29.2, that also is characteristic of those in most automobile manufacturing companies.

This system for quality assurance was developed in Toyota Motor Corporation along with the company's renowned Toyota production system, to which it is closely tied. As standardization of product and process became the keys to consistent, high-quality production, certain communication disciplines became the keys to quality assurance. These were centered in the steady feedback of information from audits, inspections, testing, and analysis throughout the process of creating and producing vehicles.

Flexible manufacturing based on consumer preferences became the norm. Prior to this, the industry built huge banks of vehicles not to customer requests but on a push system of factory capacities. These changes, and inventory reductions that accompanied the lean-production, just-in-time philosophy, have radically altered production activity.

Lean Production.

Several aspects of the Toyota production system combine to create what is known as "lean production", a concept now widely emulated by American automobile makers. Lean production involves the removal of waste from every step in the production chain—waste of energy, motion, time, and resources. It is based on the pull-through method of inventory control that Toyota's Taiichi Ohno devised in the 1950s, now known as "just-in-time".

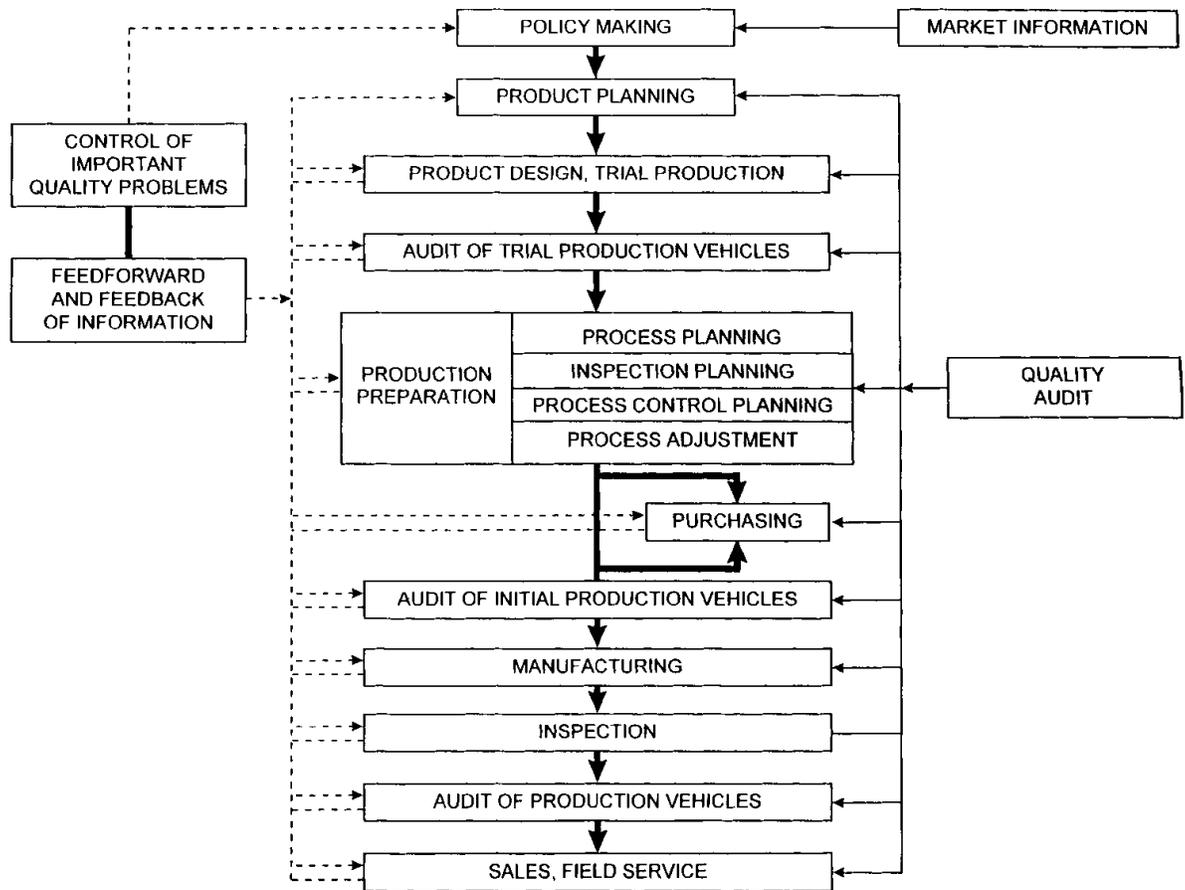
Through training and partnering with suppliers, extensive cost reductions have been experienced by both manufacturers and suppliers as they order, build, and ship materials and vehicles on a pull-through or customer-demand system. With inventory reduction, hidden quality problems surface quickly and must be addressed immediately. This is often referred to as "lowering the water level," which will expose rocks (or problems) previously unknown or concealed. In this way, lean production yields important quality-assurance benefits.


FIGURE 29.2   Toyota concept of quality. (*Toyoda, Soichiro. Automotive Industry 3d ed.*)

PRODUCT PLANNING

As increased consumer awareness and demands added fuel to the competition between growing automobile companies, product planning needed to follow the improvements in mass-production systems. As production systems improved and frequent major or minor model changes were required for competitiveness, the time required for new model planning and launch had to decrease. Thus the concepts of chief engineer, product platforms, and simultaneous engineering became the norm for all companies.

In Toyota, the chief engineer concept meant one person led a team of experts from various disciplines to plan and launch a vehicle in an efficient and effective manner. As the leader, the chief engineer must organize human resources and facilitate discussions to solve complex issues and ultimately is responsible for the success of the vehicle. To design and produce vehicles efficiently, the chief engineer is encouraged to use common parts and to look at class distinction in regard to vehicle content. Focus is also placed on engineering capability and assembly simplicity.

In the United States, many companies employ a platform concept that has radically improved both the quality and efficiency of the development process. Further steps are being taken to streamline timing and personnel efficiency to improve competitiveness.

The once-normal 36-month lead time for product planning and launch is no longer acceptable. Using the chief engineer and platform concepts, Chrysler and Toyota have achieved 23- to 28-month launches. The new target at Toyota is 18 months—half the historically acceptable norm. Shortened lead times also support customer-satisfaction improvements because they permit the timely response to economic circumstances and customer preferences that can change over periods of less than 3 years.

Figure 29.3 shows a typical approach to new model planning based on the 3-year term that was once normal in the industry.

Time-Phased Planning.   The initial step in long-range planning is market research. To illustrate consumer buying trends, Figures 29.4a and 29.4b show research for customer vehicle purchase patterns. New model proposals set parameters to further define vehicles for the detailed planning phase. Parameters include the vehicle type, such as sedan, coupe, or station wagon; vehicle specifications for function, performance, reliability, service, and maintenance; timing for development; and cost and finance items, including selling price and profit.

Critical Quality Problems.   An important step in the new model proposal is defining critical quality problems that must be addressed. This step is illustrated in Figure 29.5. The design group must provide data to support this activity and track its timely completion.

Design Planning.   The design planning phase includes development of detailed specifications of components and their interface with major body/frame dimensions that are concurrently being developed. Drawings are developed, and consideration is given to historical data on like-vehicle development/manufacturing to "design in" foolproofing or elimination of such concerns.

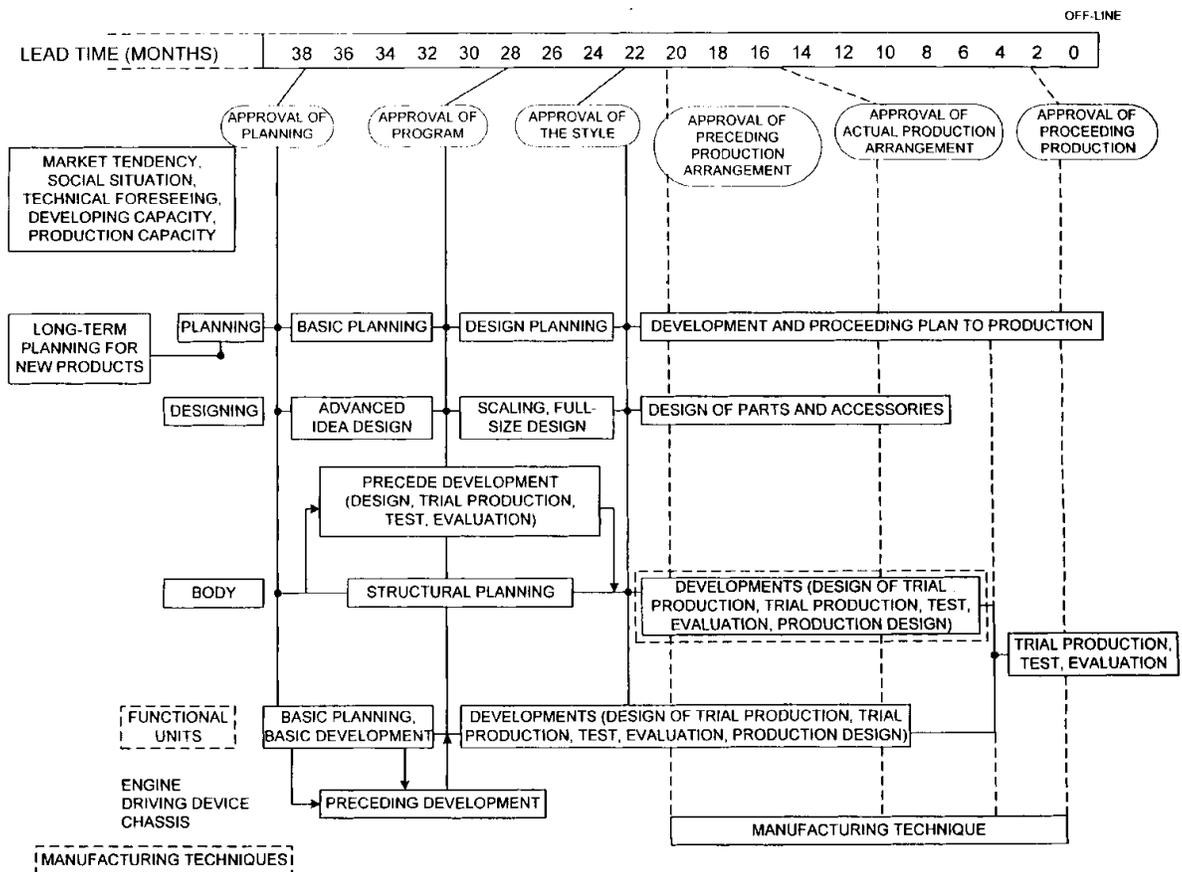
Design Review.   The design review phase is a critical step in the design process. A cross-functional team representing all disciplines reviews the design in detail. The team verifies and identifies safety and critical characteristics to ensure that specifications are clearly defined and that


FIGURE 29.3   Product planning activity timing. (*Toyoda, Soichiro. Automotive Industry.*)

	Replaced Vehicle				Additional	First	
	Same Class		Different Class				
Type	Bought New	Bought Used	Bought New	Bought Used	Vehicle	Vehicle	Total
Van	30	10	32	13	14	1	100
SUV	20	5	43	17	14	2	100
Pickup	36	15	17	16	15	2	100
Small	23	11	21	23	17	5	100
Medium	30	8	30	15	13	3	100
Large	34	6	38	10	10	2	100
Luxury	48	7	28	4	12	2	100

Note: Owing to rounding errors, numbers in row may fail to total 100.

FIGURE 29.4*b* Customer patterns of vehicle purchase (in percent). (*1996 Toyota New Buyer Survey.*)

all supporting functions comply with specifications. Marketing and practical aspects are also evaluated. Consensus must be reached to ensure that all activities and input are in line with the overall plan guidelines. The effort required to identify and address issues early in the design phase can save tremendous costs and delays later in the program.

Laboratory Testing. Laboratory testing during the design and prototype phase is important for all new products, materials, new or changed tooling, or new suppliers. With supplier participation in such testing, critical characteristics pertaining to function, durability, environmental conditions, simulated driving conditions, and crashworthiness can be measured prior to part finalization.

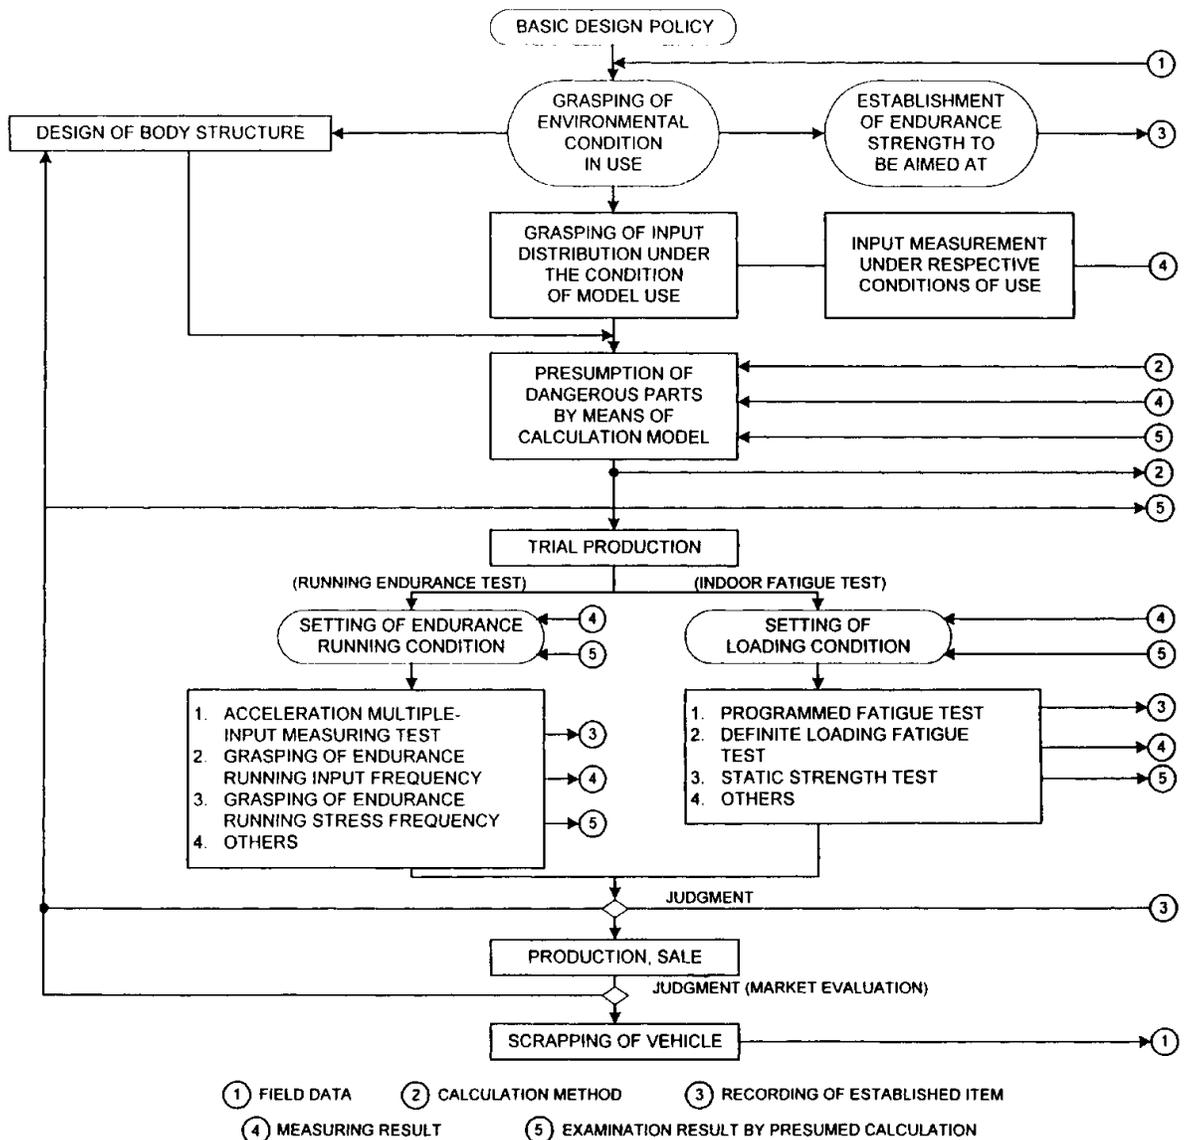
Evaluation under Actual Conditions. Prototype parts can be tested on current vehicles, either under test-track or actual road conditions, to obtain data that do not depend solely on laboratory


FIGURE 29.5   Idea model for body strength. (*Toyoda, Soichiro. Automotive Industry.*)

tests. This activity is important to warranty or long-term durability design activities. By incorporating this activity into customer-fleet or employee-fleet use, companies can collect extensive data on real-time use that may include extremely severe conditions and use, as with taxi or delivery-vehicle fleets. This testing may occur prior to release of the production part to all customers or in preparation for a product enhancement in the future.

Safety Evaluation.   Individual components and completed vehicles are tested exhaustively to ensure the greatest possible protection for occupants. Various means are used to test components in the laboratory. Vehicle testing will be done to measure the effects of head-on, barrier-impact, rollover, and side-impact crashes, as well as the latest testing that includes variations of head-on impact at differing angles. Much of this information is used to enable insurance companies to calculate the cost of repair of a damaged vehicle and to establish facts on which to base safety-oriented advertisements.

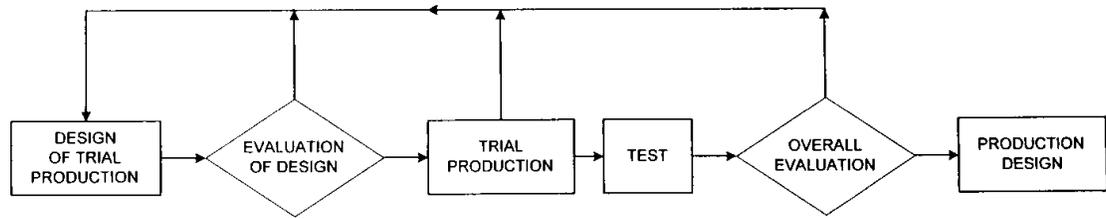
Overall Evaluation.   Constant feedback and communication are critical to the success of the design review, laboratory, and usage testing activities. Figure 29.6 depicts the steps of the feedback process that supports such activity. In this process, the more communication, the better.


FIGURE 29.6   Design evaluation communication system. (*Toyoda, Soichiro. Automotive Industry.*)

Preparation for Production.   As in the planning phase, production personnel are represented on the cross-functional team to support preparation for production. This phase directly supports the vehicle launch activity. Production personnel will help coordinate pilot production either at a separate facility or at the production line. As pilots are run, information is gathered to assist with the ramp-up to full scale. The participants may be the people who will train production-line workers. Others who will later be assigned as trainers may participate as well. The point of this activity is verification of issues such as the production process, tooling, and quality-control parameters.

Organization for New Model Planning.   The organization supporting this activity varies not only by company but by model and complexity. The larger the company and more complex the change, the larger is the group and the number of departments. Normally, coordination of such activities can be provided by

1. Planners assigned full time to specific models
2. Task forces or committees with assigned representatives to facilitate communication
3. Formalized plans written to encompass all groups and required support
4. Process and procedures such as sign-offs

SUPPLIER MANAGEMENT

Supplier support and supplier partnerships become increasingly important in a lean-production environment. (See Section 21: Supplier Relations.) Gone is the day of the adversarial relationship between automobile manufacturers and suppliers. While the Japanese companies have practiced supplier partnerships for years, Chrysler and Ford are fast approaching the same practices. By developing trust between manufacturer and supplier, many mutual benefits can be achieved.

Supplier Relations.   The component-supplier community can be immensely helpful to the automobile manufacturer in providing design expertise. If the manufacturer provides performance specifications to the supplier, leaving the component company to proceed with design, costs to the automaker can be sharply reduced. To support this activity, the manufacturer must allow supplier representation in the early phase of vehicle development—a big step in the partnering philosophy. This also requires agreements to allow suppliers to invest in development costs with some assurance of being awarded the business. The other element of trust involves suppliers opening their books and sharing costing information to support the manufacturer's objectives.

This is not a short-term activity, and it requires a great deal of interface between the management teams of both the supplier and the manufacturer to develop the required trust and support. This cooperation is essential for long-term competitiveness in the automotive arena.

Partnerships have long been a strength of the Toyota system. Through its close relationship with Toyota, a supplier can become stronger and more efficient. Various Toyota groups share the Toyota production system (TPS) expertise with their suppliers. Toyota groups in the United States have been receiving TPS training from the experts at Toyota Motor Corporation in Japan, and the sharing of

this knowledge with suppliers has proven beneficial, since Toyota has experienced outstanding sup-plier improvements. As an example, the following facts show one company's improvement experi-ence after 2 years of working with Toyota on TPS implementation:

Finished goods inventory reduction	82%
Work-in-process reduction	59%
Plantwide productivity increases	32%
Quality index improvements	58%
Production lead-time reduction	74%

The overall improvement depends on the supplier's system at the beginning of the project, but experience has shown that results like those in the preceding example are not uncommon. This activ-ity takes a great deal of time and requires a large commitment on the supplier's part. Actual monetary investments are normally small; training, research, and reorganizing efforts can involve substantial investments of time. All suppliers have benefited many times over from these investments.

Often taken for granted by manufacturers is the openness of two-way communications between supplier and manufacturer. In many cases, however, the supplier will not share thoughts in order to appear not to question the customer's decisions. In order for the partnership to work properly, the customer must depend on suppliers for honest feedback on design, processes, and any other issues that may affect the output of their partnership. For their part, suppliers are entitled to a fair hearing of their honest feedback.

Supplier Base Reduction.   If suppliers are to believe that they will be rewarded for the com-mitment of resources to a customer's product development, they must be able to see an opportunity to capture a significant share of the customer's business. Often this means that the number of suppliers must be reduced. By reducing the number of suppliers, the manufacturer's staffing and support also can be reduced, thus lowering costs. The supplier list can be reduced in a number of ways.

1. *Tiering.* Using large, tier-one suppliers to supply completed assemblies, rather than just their components, improves production efficiency, material handling costs, and supplier interface expenses. The tier-one supplier establishes relationships with the other component suppliers and becomes the final design, development, and assembly point for the completed assembly.

2. *Exclusive contracts.* As partnerships grow, it becomes normal for some suppliers to develop spe-cific parts, as long as they uphold their portion of the partnership. Communication lines, devel-opment expertise, and overall system understanding are critical to these relationships. In some cases, supplier representatives have offices and full-time employees located in the manufacturer's facility to support that activity.

3. *Outsourcing.* In many cases it can be more expensive and cumbersome for automobile manufac-turers to continue producing various components in-house than to rely on external suppliers. If a manufacturer has aging facilities, outdated production methods, or dwindling expertise, it may make sense to join forces with a supplier who is an expert in production of a required component.

Supplier Selection.   As new products, processes, and increased volumes begin to demand the addition of supply resources, certain criteria must be established for their selection. Supplier surveys may be performed by individual departments or, preferably, by a cross-functional team representing all disciplines to ensure that all aspects of the company's capability are considered. Many factors may be considered, such as

1. Previous experience with the supplier
2. Affiliated company experience (parent, sister, joint venture, etc.)
3. Reputation or recommendations of other companies

Quality Assurance by the Supplier.   As with other supplier activities, communication is critical for both supplier and manufacturer to understand the supplier quality assurance activities. This begins with early supplier involvement in the development process. Once the product is agreed on, designed, developed, and prototyped, four basic steps are key to ensuring customer satisfaction with the product.

1. *Product approval*
   a. Verification of understanding *and agreement on specifications.* The supplier must understand the manufacturer's expectations and be able to deliver timely production quantities consistently on that level. The supplier also must understand the broader system and know how each component fits into it.
   b. Initial sample approval. Samples provided for testing must come from production lots, not from laboratory or prototype production, if production capability is to be measured properly. All systems require first-production-piece verification. The additional requirements for sample size, test requirements, and reporting format may vary, but the intent is that the supplier must use this process to verify that expectations for continuous mass production can be met. On completion of this activity, the supplier will submit the part and information to the manufacturer for review. If all criteria and expectations are met, the supplier is given formal, written approval for production to begin. Should a concern arise, it must be addressed immediately to ensure that the part meets expectations and that timing is not delayed.
   c. Comparison of test methods. The approval process should include a check of the compatibility of test methods. The supplier should include the test data with the test certificate attached to samples, including any information about accelerated life testing and destructive testing. The supplier should be given the automobile company's test results in order to discover and correct any differences in testing techniques.
2. *Process review.* A common practice with new suppliers is to audit the production process prior to awarding business. Process reviews of current suppliers also are conducted periodically. During the audits, discussions are held on improvements based on a comparison with other suppliers and the experience of the auditor. Also, suppliers may have process improvements or changes that require approval or on-site review by the manufacturer. On-site supplier visits can be useful, since continuous improvement activities will strengthen the process, partnership, and product quality. It cannot be stressed enough that manufacturers should view this as an opportunity and a small investment in the future of the relationship. This activity also strengthens both companies and builds trust through face-to-face meetings. Should the supplier experience difficulty or need assistance with a process, the door should be open to contact the manufacturer and ask for help. Within the manufacturer's ranks, experts should be available to be dispatched to support the supplier. The supplier also may seek the assistance of outside consultants known to the manufacturer to be capable of supporting both process and management improvement activity.
3. *Feedback.* Communications between the automobile company and the supplier must be open, whatever the topic. The supplier should expect honest, fact-based feedback from the manufacturer. The better the information provided, the quicker and more responsive will be the supplier's reaction. This is a true test of both partners' ability to give detailed information and respond quickly with a detailed, concrete action plan. No production system is ever completely foolproof, so when a concern does arise, responsiveness and support are of the utmost importance.
4. *Continuous improvement, or kaizen.* The supplier's work force should be made to understand that simply maintaining the present level of quality is not enough and that constant effort must be applied in the pursuit of improvement. The manufacturer's quality assurance group can help spearhead continuous improvement throughout the supplier firm by making available trainers and training materials; fostering quality-improvement competition between work shifts, departments, and teams; meeting with supplier teams to discuss quality issues; and recognizing continuous improvement by means of on-site supplier award presentations. If managements of both the manufacturer and the supplier regularly demonstrate their wholehearted support of *kaizen* in these ways, associates are more likely to buy into team problem solving, quality circles, and other techniques for ensuring continuous improvement.

Controls on the Supplier.   Automobile companies exercise control over suppliers in several ways. Some of these, such as the process of supplier selection, joint quality planning, and supplier quality assurance, take place before production. Others take effect after deliveries begin.

Acceptance Inspection.   Initial quantities of components from mass-produced lots are subjected to random sampling for the first 1 to 3 months of production. If defects are found, sampling quantities are increased and action taken as needed. If random sampling indicates quality within agreed standards, sampling is reduced and finally ceases, with the automaker relying thereafter on the supplier's test certificates and periodic quality audits. At this point in the relationship, dual sampling is avoided, and the supplier takes on greater responsibility for both product quality and its proof.

Supplier Quality Audits.   An annual review of a supplier's facilities is normally conducted to ensure that the supplier is adhering to federal requirements and quality control plans in system testing and document control activities. By contract, suppliers must notify manufacturers of process changes, so documentation and the actual process can be reviewed during the visit. The on-site visit will include many subjects, some of which are listed in Figure 29.7.

Supplier Ratings.   A rating system encompassing various supplier activities can be used for quality-improvement activities and awards. The system may compare the supplier against expectations, previous performance, and other suppliers. As an example, a summary page from the Toyota quality alliance rating system, administered by Toyota Motor Sales USA, Inc., is shown in Figures 29.8*a* and 29.8*b*.

MANUFACTURING

Development of Manufacturing Methods.   Over the years, substantial growth in motor vehicle production volume led to the automation of numerous production-line activities, with the result that the economics of production became more favorable. A corollary benefit—greater quality—was created when automated machines and associated transfer devices demanded improved uniformity of input components to maintain continuous production. Thus automation yielded not only greater productivity and better economic use of human resources but also improved quality.

This benefit continues to follow the increasing use of computers to guide design and manufacturing processes, since computers make possible far greater reproducibility and consistency—essential to quality assurance—than is possible with purely mechanical means.

Production Preparation.   Automobile companies maintain departments that carry out the preparatory steps through which the production force can maintain the desired level of quality: facilities and process planning, and trial mass production.

Organization	Incoming inspection procedure
Quality control policies	Process deviations
Product identification	Supplier performance records
Lot ID and traceability	Cosmetic acceptance standards
Test procedures	Defective material handling
Test results	Supplier defect notification
Process flow diagrams	Drawing control
Engineering change procedures	Specification documents
Inspection standards	Specification deviations

FIGURE 29.7   Supplier audit subjects. (*Note:* This is not al all-inclusive list.)

Product quality
   Quality Assurance   20
   Warranty   15
Operational quality
   Deliver   15
   Mispack/damage claims   5
   Purchasing   20
Product support
   Marketing   12
   Program management   5
   Technical development   8
Total points   100

(a)

Category	Group	Department
Product quality		
1. Quality assurance	U.S. products	Supplier development
2. Warranty	Service/U.S. products	Warranty administration
Operational quality		
1. Delivery	Parts	Parts supply
2. Mispack/damage claims	Parts	Parts invoicing
3. Purchasing	U.S. products	Procurement
Product support		
1. Marketing	parts	Parts marketing
2. Program management	U.S. products	Program management
3. Technical development	U.S. products	Parts and accessory engineering

Note: Suppliers should direct all inquiries regarding any portion of the evaluation to their respective buyers.

(b)

FIGURE 29.8   (*a*) Supplier evaluation scoring categories. (*b*) TMS responsibility by scoring category. (*Toyota Quality Alliance Rating System, Toyota Motor Sales, USA, Inc.*)

Facilities and Process Planning.   The process-planning step specifies operations to be performed, the tools and machines to be used, and other aspects of production technique. Included in this step is an examination of the quality capability of the process to see if it meets the tolerances and dependability specified in the design. For the production of components related to basic vehicle functions or safety, the most stable and foolproofed production and inspection systems should be used.

Trial Mass Production.   When all is in readiness for production, trial mass production is carried out to confirm that quality standards continue to be met as volume production proceeds. The variability or dispersion of the product at all stages, from manufacture of parts through final assembly and testing as automobiles, is measured closely. Dispersion data can be used to identify any processes requiring improved uniformity. Trial mass production also helps to identify any required changes in tooling.

Process Control.   The control of manufacturing processes becomes simpler with each addition of computerization in the workplace. Relying as it does on rapid feedback of information, process control is well served by computer processing of quality data. Some production functions rely on older, conventional processes subject to human variability and provide little feedback. In these, worker training and motivation become ever more important as production volumes increase.

The concept of process capability is in widespread use throughout the automotive industry. Because process capability can vary with process conditions, it can be useful to maintain a record of process capability and to investigate any significant variances, especially deterioration.

Operator process control and product acceptance empowerment also became popular in recent years. Equipped with information on quality standards, machine operators are being empowered to take greater control in regulating the process to meet standards. Operators also are being empowered

to accept or reject product under the operator self-inspection concept. The operator decides whether the process should continue or stop and whether the product meets quality specifications.

Automatic process regulation takes the place of human judgment in many applications, relying on automatic measurement and feedback for regulation of processes without human intervention. Maintenance of such systems does require periodic human intervention, and inspections of the process capability lead to necessary repairs, adjustments, and replacements.

Process Improvement.   Historically, industry has relied on engineers and supervisors to contribute changes to industrial processes. Worker contributions were limited to suggestion-box ideas and received relatively little recognition.

During the 1960s, Japanese industries launched extensive educational programs for workers at all levels on ways to control and improve processes. At Toyota Motor Corporation, such programs began in 1961 and included such matters as quality control, Pareto diagrams, characteristic factor diagrams, histograms, control charts, and correlation diagrams. Quality circles were initiated to foster improvement in intradepartmental processes, with remarkable results. A later campaign to eliminate defects and claims due to process deficiencies and operator error also was responsible for great improvements in quality.

Kanban.   *Kanban* is one of the primary tools of the just-in-time system that is used to facilitate an even flow of production and an even distribution of work among the various stages of manufacturing and transportation. With thousands of items such as engine components, drive train parts, sheet metal pieces, seats, and other interior parts, *kanban* maintains an orderly and efficient flow of goods, material, and information throughout the entire manufacturing process.

Kanban is usually a printed card in a clear plastic cover that contains specific information such as part description, part number, and quantity or lot size. This card is affixed to the various containers, bins, and racks that hold the parts. These *kanban* cards are used to withdraw additional parts from the preceding process to replace the ones that are used. It is the concept of "sell one, buy one." In so doing, only the right parts are used, in the right quantities and at the right time. You might look at it as a waste-free means of producing and conveying materials.

INSPECTION

In-line and final inspectors have been an important part of automobile manufacturing for many years. The inspection operators review material, component, and assembly quality to ensure conformance to standards. Data provided by the inspection functions can facilitate product and process improvements to foolproof product quality. The information is used primarily for immediate operator feedback and machine adjustments. This information is used for reports to management for comparison and tracking purposes to support cost justification for machine, product, or process improvements. Management support can be directed to areas requiring improvement based on inspection feedback. This focus can greatly assist management, and the overall process will benefit. To a considerable extent, the role of inspector in some automobile companies has been taken by production-line operators as a part of the operator process control and product acceptance empowerment mentioned earlier.

Classification of Defects by Seriousness.   The automobile industry has developed a widely accepted classification system, with three major groupings for all defects.

A. Safety or critical functions that can endanger operators or passengers or render the vehicle functionally inoperative, such as brake function, electrical operations, or steering.

B. Operations that affect primary functions of the vehicle or major appearance items that most customers would not accept, such as inoperative locking mechanisms; faded, chipped, or peeling paint; or noisy operation of engine or brakes.

C. A third category includes items that do not affect vehicle functions or appearance items not leading to customer complaints, such as crooked labels or stripes, underbody rust, or an inoperative glove box light.

Concerning customer satisfaction, *A* defects will be returned for repair, *B* defects normally will be returned, and *C* defects are almost never returned if they are the only issue found. This severity rating helps automobile companies focus on major issues.

Organization for Inspection.   Incoming, in-process, and final inspections are the three types commonly used in automobile plants. Inspection methods are usually developed by each group to support customer satisfaction by focusing inspections based on product, process, and operator concerns. In many cases, formalized procedures requiring documentation must be tracked [e.g., Federal Motor Vehicle Safety Standard (FMVSS) requirements, or other safety items]. Many of these issues can be machine-verified, but issues that cannot be verified are 100 percent checked by inspection personnel. Other inspectors may do random audits of machine processes to verify that machine results and readings are accurate.

- *Incoming* checks are performed on raw materials or purchased components. Different testing requirements based on different raw materials must be developed based on hardness, strength, clarity, and otherfactors.
- *In-process* checks include items such as dimensional checks (stampings, machining, molding); equipment temperature, pressure, and timing (casting, forging, molding); fit verifications; and functional verifications. Major functional components such as axles, transmissions, and engines may be operated prior to final assembly to save repair time and costs should a defect be found.
- *Final vehicle inspection* is performed after all components are assembled and the vehicle is complete. Many functional checks, adjustments, and verifications are required. Based on vehicle complexity, some additional functional issues may need to be verified. A few of these are

  Water test: Ensures leak-free vehicles

  Front wheel alignment: Verifies toe, caster, and camber to ensure best handling and long tire wear

  Brake function: Ensuring no leaks and that all components functioning

  Headlight aim

  Complete functional check

Prior to shipping, a complete appearance check is done to ensure that no damage, paint, or fit concerns reach the customer. Although most inspections are redundant or additional overhead activities, they are generally accepted as a requirement by automobile manufacturers to promote customer satisfaction.

FIELD SERVICE

Of concern to all automotive manufacturers are the sale and service of vehicles they produce. Since most vehicles are sold through independently owned dealers, manufacturers do not have direct control of this activity.

Role of the Dealer.   It is the obligation of the dealer to deliver the vehicle in good, clean condition, with emphasis on satisfying the customer during the sale and beyond. Manufacturers spend a great deal of time, effort, and money to develop procedures to support dealer sales and service. Recognizing that these activities may be the only experience the customer has with the manufacturer other than vehicle performance, automobile companies provide extensive training for sales and

delivery activities. This assists dealers to improve initial reaction and retain the customer for future sales. Training provided by the manufacturers for technical service of the vehicles is even more extensive than sales training. Certification programs have been developed for service technicians to create levels and competition among technicians. Manufacturers support sales and technician training with the hope and expectation of increased customer satisfaction as dealership personnel become better and stronger assets.

Vehicle Service System.   During the warranty period, dealers are almost guaranteed that customers will return to the dealership for maintenance and warranty repairs, if required. Most of these charges are paid directly to the dealer by the manufacturer. Dealerships must satisfy customer needs during the warranty period in the hope that the customer will return to them for maintenance and repairs beyond the warranty period. By satisfying customers and creating ongoing business, the service area can be an excellent profit center for the dealership.

As the automobile manufacturers increase the warranty period and coverage of their vehicles, dealerships are guaranteed more service activity that can lead to increased after-warranty service. Figure 29.9 shows the initial maintenance log for a typical manufacturer. Dealerships have many sources of parts to use after the warranty period, but during the warranty, manufacturers require the use of original equipment (OE) parts. All manufacturers have extensive parts distribution systems to support dealer requirements for these parts in a timely manner. Toyota, for example, established its North American Parts Logistics Division to improve local parts sourcing and to serve as a parts distribution network supplying all North American Toyota dealers, export markets, and certain General Motors vehicles.

Once the warranty period has expired, the parts-purchasing option is open to the dealership. Since the OE parts have satisfied the dealer's needs and are competitively priced, the manufacturer urges the dealer to continue to use them. This supports the manufacturer by ensuring that

1. High-quality parts are used.
2. Specifications including fit and functions are correct.
3. Manufacturer's distribution systems are supported for ongoing activity.

The use of factory parts also will help support high customer satisfaction.

Feedback of Information on Field Quality.   The performance of vehicles and parts in the field is information essential to the manufacturer. Not only is this information pertinent to continuous-improvement activity on current parts and future designs, it is vital to ensuring customer satisfaction. Safety concerns are normally monitored by government regulatory agencies such as NHTSA in the United States, and the manufacturer must communicate to the agency all pertinent activities to support the issue. On nonsafety issues, customer satisfaction is a major concern, and the way the recall campaign is handled can be critical to satisfying customers. Figure 29.10 shows a typical feedback system for manufacturers.

Field Service Beyond the Warranty Period.   As repairs to customer vehicles are made during the warranty period, extensive information is required to support dealer payment. This information is extremely helpful for improvements to parts, decisions to launch a recall campaign to repair or replace defective parts, or setting realistic parts performance expectations based on actual field data. Figure 29.11 shows many of the inputs required to complete a warranty claim. The information is very similar for all manufacturers.

Manufacturers require that many of the parts being replaced be returned for teardown and analysis. Root-cause analysis using the "plan-do-check-action" (PDCA) model (Figure 29.12) can be performed by the responsible engineer and/or supplier using these returned parts. This information is much more useful than a written description of the technician's opinion.

Fleet Feedback.   Vehicles in customer or automaker-employee fleets also are sources of information. With customer fleets, high mileage or hard use may accelerate the feedback obtained.

5,000 Miles or 4 Months*

☐ Replace engine oil and oil filter

Additional Maintenance Items for Special Operating Conditions:
Please refer to page 30 of this supplement to determine if your vehicle requires the additional maintenance items.

Inspect the Following:
☐ Air filter   ☐ Ball joints and dust covers
☐ Brake: linings, discs/drums   ☐ Drive shaft boots (re-torque flange bolts)
☐ Steering linkages   ☐ Body/chassis nuts and bolts

FIGURE 29.10   Feedback.

FIGURE 29.11   Warranty input information.

With employee vehicles, prototype or improved parts can be tested to verify effectiveness of the changes.

Customer Complaints.   All manufacturers have toll-free telephone service for customers to gain information and assistance or to voice complaints. In many cases, this information can be used to support product or process improvements. Also, quick reactions by the appropriate individuals can ensure the maintenance of high customer satisfaction. The overall goals of this activity are improved product quality and increased customer satisfaction.

QUALITY AUDIT

As an additional check prior to shipping vehicles to customers, manufacturers do random-sample vehicle audits. Although many audits take place in-plant, analysis of the final assembled vehicle can verify product and process quality throughout the entire production system. The final vehicle audit is broken up into various areas.

Specification.   This includes torque tests of various fasteners, verifying component correctness, function tests for setting within specified ranges such as parking brake or shift adjustments, air-conditioning function, and a leak test.

Customer Acceptance.   This includes fit, finish, and function.

Road Test.   Driving vehicles measures noise, vibration, harshness (NVH) issues and functional or dynamic problems such as front end or wheel balance.

Water Test.   Ensures that all sealing areas are complete. Issues found in these areas are immediately referred to root-cause analysis and countermeasure development. The final vehicle audit

ACTION Phase

receives a high priority within the manufacturing facility, since the vehicles selected were approved throughout the system and are ready to be sent to the customer.

Additional in-system checks may be performed by the personnel of production, tooling, and other departments to verify that their areas are meeting requirements. All have the same goals of defect-free quality and increased customer satisfaction.

THE OUTLOOK FOR AUTOMOTIVE QUALITY

Steady Gains.   The world's automotive industry met the challenge of converting from handcraft to mass production and went on to produce tremendous improvements in product quality. Better processes, materials, equipment, and worker training yielded great gains in consistency as production lines moved faster and faster in mass production's early years. The industry also responded well

to the growth of consumerism and environmental awareness with substantial improvements in product quality and safety and in the reduction of emissions and effluents both from vehicles and from the plants that produce them.

Next Steps.   In the final years of the twentieth century and into the next, the industry will consolidate and reinforce these gains in product quality, reliability, and environmental acceptability. Further quality gains will come from team production methods, from the use of robotics, and from just-in-time production control and the other techniques that in Toyota are known as the "Toyota production system". Supplier relationships, already very close in many parts of the industry, will grow closer still, with manufacturers and suppliers sharing even more of their product plans, production methods, and quality disciplines.

The growth of intelligent transportation systems, which will have intelligent vehicles traveling intelligent highways, will bring about new quality concerns and opportunities. Distance sensors, "smart" cruise control, onboard navigation systems, built-in diagnostic devices and other electronic equipment will add complexities to the measurement of quality and require new approaches to in-plant process control and quality assurance methods. Many of the suppliers of these components may be companies not now involved with automakers and unfamiliar with automobile industry quality initiatives.

The New Battleground.   The primary quality battleground, however, will shift from the production plant to the retail sale. More and more surveys, studies, and focus-group comments show that automobile buyers associate quality not only with the product but also with the purchase and service experiences that accompany it—the components of customer satisfaction.

Success in the retail battleground may be the automobile industry's greatest challenge, for it is here that the automobile manufacturer exercises the least control over any aspect of the design/production/distribution/sale process. Although the manufacturer influences this part of the process, the conversion of prospects into customers rests with independent dealers.

If the automaker is to meet the buyer's needs, it needs to know much more about changes in buyer demographics and about the changing ways motor vehicles fit into new lifestyles. Manufacturers must consider the new and greater pressures on the buyer's time and financial resources, changes in commuting habits, the growth of entrepreneurship, and the work-at-home phenomenon, among other factors.

Some opportunities are available to the automobile manufacturer interested in improving the sale and service experience, however. Dealer training may be the greatest of these opportunities, since manufacturers can do much to raise the level of knowledge and professionalism among dealers' sales and service employees. Most manufacturers have programs in place for this kind of training. All are likely to be accelerated as competition drives the need for more and better customer relations.

Another area for improvement is emphasis on "lean distribution", the field equivalent of lean production. Manufacturers will be working on ways to improve their responsiveness to vehicle orders, which would have the combined effects of pleasing customers with prompt delivery as it shrinks costly dealer inventories.

Finally, manufacturers will be able to improve the quality of the vehicle-purchase experience through customer education and communication, mainly by way of the Internet. Growing numbers of automobile buyers are gathering information about motor vehicles electronically from their homes as they begin the search. This puts customer and manufacturer into direct, two-way communication in ways never before available. New capabilities lent by Internet communications range from simple matters such as showing the automobile buyer how a certain vehicle would look in his or her choice of colors and appearance options to detailed answers to highly technical questions about performance, materials, warranty details, and other matters.

The automotive industry is being challenged to change from quality considerations based on product to those which include all aspects of the ownership experience. How we meet this challenge will test each of us about responsiveness, adaptability, and genuine customer-service attitudes.

SECTION 30

TRAVEL AND HOSPITALITY INDUSTRIES[1]

Patrick Mene

[1]In the Fourth Edition, material for the section on the service industries was supplied by Charles D. Zimmerman III and John W. Enell.

MISSION OF THE TRAVEL AND HOSPITALITY INDUSTRIES

While the travel and hospitality industries are different from each other, they are strongly related. The differences are apparent in their respective missions. The travel industry provides travel advice to travel planners as well as transportation and travel-related services for travelers. The hospitality industry provides food, lodging, meeting places, and hospitality-related services to travelers.

The two industries are related by their interdependence—the hospitality industry depends on the travel industry to deliver its customers; the travel industry depends on destinations, including resorts and conference sites, to justify its existence as a travel provider. For this reason, companies in the two industries are also frequently related through joint marketing. (For example, it is common for conference registration material to make provision for special ticket prices with a preferred air carrier and discounted rooms rates with a preferred hotel at or near the conference site.)

In this section, quality as practiced in the travel and hospitality industries is presented primarily through the experience of airline and hotel companies, respectively. There are also some examples from the experience of other participants in the industries, such as travel planners and cruise lines.

The section covers these broad areas:

- The definitions of *quality*.
- Quality challenges and barriers.
- A brief history of the industry, including the way in which societal and legislative changes affected the approach to managing for quality. The emphasis is on the years since 1950.
- The quality management processes—quality planning, quality control, and quality improvement—as practiced in these industries.
- The importance and management of supplier quality.
- Benchmarks—the industries' best performances.
- A prognosis of quality in these industries.

DEFINITION OF QUALITY IN TRAVEL AND HOSPITALITY PRODUCTS

Within these industries, quality has long been defined in terms of product features or product grade. Three basic grades—luxury grade, deluxe grade, and economy grade—are frequent in a product line and serve to illustrate the approach. These three grades are based on the number and kinds of features, benefits, and advantages expected by the customer. Product grade also establishes the expected level of user satisfaction. Luxury is the highest level, and economy the lowest. Although the grade names for a given product may be different and the grade structure may contain more or fewer divisions, customers are generally made aware, through advertising, sales prospectuses, and the like, that a grade structure does exist. This grade structure may be signaled through brand name or class of service within a brand. Table 30.1 depicts the three product grades in several dimensions.

TYPICAL QUALITY CHALLENGES IN THE TRAVEL AND HOSPITALITY INDUSTRIES

Importance of Nonfunctional Expectations.   Most customers of airlines, hotels, and cruise ships have expectations that extend beyond functional requirements of the product or service being used, especially when the travel is for long periods or a special occasion. Their ultimate desire

TABLE 30.1   Product Grades

Grade	Luxury	Deluxe	Economy
Features (what the product promises to the user)	Beautiful, pristine, comfortable surroundings	Attractive, clean, comfortable surroundings	Pleasant, clean, comfortable surroundings
	Highly personal service	Courteous service	Courteous service Attractive price levels
	Timely delivery	Timely delivery	Timely delivery
	Immediate and complete problem resolution	Problem resolution	Problem resolution
Ultimate benefit (what the product does for the user)	A positive, memorable experience	Freedom from a negative experience	Lowest cost
Personal advantage (what the user can do because of the product)	Be more productive, comfortable, and prestigious	Be productive and comfortable	Justify the cost to themselves or to others

is a "memorable experience" that makes them feel well (Cleveland 1988). The characteristics of the experience are accumulated matters of a psychological nature—the look and feel of the surroundings, the warmth of the greeting, the feeling of comfort and importance. These sensory matters create personal advantages for customers that have a major effect on their loyalty and willingness to pay premium prices.

The sense of feeling can be easily damaged by an indifferent attitude, an unclean carpet, a distracting noise, an insincere smile, or any inappropriate appearance such as an unsightly "out of order" sign. The damage is compounded because humans have a tendency to judge what they cannot see by what they can see. In the words of Tom Peters, "Coffee stains on the airliner food tray suggest poor engine maintenance." The magnitude of the damage multiplies rapidly because the news (of the offensive sensory qualities) spreads quickly.

The importance of nonfunctional requirements is explained by Rapaille, a cultural anthropologist who makes customer loyalty a subject of his research. In Rapaille's view, the decision-making process customers go through when selecting any product or service is based on emotion or what he terms the "logic of emotion." For a brief summary of his theories, see Bernowski (1996). For a data-based approach to nonfunction requirements, see below, under Quality Improvement: Services, Special Jobs, and Events, for the example from KLM Royal Dutch Airline.

Overdesign.   While customers often harbor unrealistic expectations, developers and operators of high-grade products often set nonfunctional standards to levels beyond those sensed by the customers, adding cost rather than value. One example is the former practice of a leading New York restaurant. Their menus were printed on an imported paper known as "elephant hide" that had the appearance of parchment paper with an ultrasmooth feeling to the touch. While the cost of the paper was more than double typical graphic products, the tactile perception of it by the diner was very ordinary. This product merely added cost, not value.

Knowledge of Travel Planners.   The purchase of travel and hospitality products takes place from a variety of intermediate travel planners (although some purchases are made directly by the traveler). These travel planners include administrative support people in an organization, travel agents, and meeting planners. Airlines, hotels, and cruise ships are faced with the challenge of establishing the superiority of their product (however minor it may be) not only to the traveler but also to all the intermediate planners throughout the travel planning chain. Each of these intermediaries

varies in ability to evaluate quality and influence travelers. The following summarizes the knowledge and economic strength of these planners. (This part of this section will not attempt to address the entire complex distribution system of the industries.)

Meeting planners can be viewed as the "vital few" of travel planners. They usually represent a small number of organizations that hold many, often large meetings at various destinations throughout the year. Their economic strength cannot be ignored. Their technical knowledge is very high for several reasons: (1) industry training and certification, (2) extensive experience planning and managing repeat events, and (3) collection and analysis of event data.

Corporate travel planners have the same economic strength as meeting planners. Their role is to develop travel policies (usually with the advice of a travel organization expert). It is noteworthy that travel and entertainment expenditures are typically the third largest in an organization, preceded by payroll and data-processing costs. Some quality experts and travel planners regard corporate travel policies that solely attempt to minimize travel expenditures as antagonistic to employee productivity. They contend that travel which is selected on price alone causes delays, complexity, stress, and fatigue. The ultimate effect on the traveling employee is reduced productivity.

Travel agents have been gaining economic strength since the Airline Deregulation Act of 1978 (see below under Government Influence). Most independent travel agents have become members of various franchise or industry association brands, generally known as consortiums, to compete with leading global brands. Like meeting planners, travel agents, owing to their extensive travel experience, have the capability to evaluate quality.

As of 1995, the travel agent industry, especially in the United States, faced several threats. With the introduction of the Internet (i.e., the computer information highway), travel customers have direct access to travel products and instantaneous verification of travel arrangements. In addition, most major U.S. carriers have begun to limit travel agent commissions on domestic flight tickets sold. The extension of this policy to international flights is also under study. To compensate for this changing environment, large travel companies have begun bundled prices for their corporate customers in the form of fee-based arrangements.

Administrative support people in an organization typically plan travel for people in the organization. This may include the inbound visitor or the outbound travel of a senior leader. Collectively, these intermediaries are significant. Their technical knowledge is limited because they do not routinely evaluate product quality.

In all cases, airlines, hotels, and cruise ships provide product information and personable salespersons to assist the travel planner in evaluating product quality and demonstrating the noticeable differences to their travelers. Where product superiority is minimal, marketing skills can make a remarkable difference in sales income. For more on this topic, see the example in Section 7 on Consumer Preference and Share of Market.

Product Perishability.   Airline seats, hotel guest rooms, and cruise ship cabins are the most perishable product of travel and hospitality enterprises, more so than food. (One-half an apple not sold today can be used tomorrow, but an airline seat or a guest room not sold today is lost forever.) Inventory management practices must be planned and managed carefully to avoid costly spoilage.

The decor of cabins and guest rooms also will progressively age over time and ultimately will perish unless scheduled process checks and corrective action are conducted (i.e., scheduled housekeeping and maintenance).

Limited Awareness of Process Management.   Traditionally, companies in the industries have brought most of their objectives and resources to bear on attracting and retaining customers by emphasizing the features and benefits of the products offered. There has been little awareness of the processes necessary to create and deliver these features and benefits. In fact, for years, the prevailing mindset has denied that the concept of "process" had application in the industry. ("That's manufacturing. We're different.") Consequently, processes were typically some combination of inefficient, obsolete, excessively bureaucratic, or even nonexistent. To have no concept of process is to deprive an organization of a powerful arsenal of process-related logic and tools to prevent or correct

quality and related productivity problems. Without such preventive or corrective action, a whole class of chronic, severe problems can plague the complex organizational processes that cut across multiple departments. Accepted as fate—"the way things are"—these attitudes have caused organizations to accommodate them. This accommodation is typically a many-level management hierarchy in which it is not unusual to have organizational units with a ratio of workers to managers as small as 7 to 1. This ratio imposes substantial salary costs as well as a mindset that is further damaging to quality and human relations. This bureaucratic approach fosters a social system where easily replaced unskilled workers in narrowly defined jobs merely carry out the plans of managers. This low-quality work life transforms itself into low-quality products of cross-departmental processes as well as high organizational costs. For more on this subject, see Section 6, Process Management.

DYNAMIC NATURE OF THE INDUSTRIES

Typically, 30 percent of travel orders placed by customers will change or be canceled. This high rate of change causes scheduling and information problems as well as extra work and costs. This information-dominant condition provides strong justification for (1) building flexibility into the reservation and production systems and (2) a control system that places the emphasis on the accuracy and up-to-dateness of information provided to all concerned. These industry challenges have a major effect on sales income and costs. The effects of these challenges are summarized by grade in Table 30.2.

BARRIERS TO PROBLEM ANALYSIS

Multiple Types of Processes.   Airline and hotel products employ three basic types of processes: (1) continuous production, (2) special job, and (3) service delivery. Each of these processes exists for different reasons and has distinguishing features. They are not mutually exclusive.

TABLE 30.2   Typical Quality Challenges

	Grade		
Challenge	Luxury	Deluxe	Economy
Psychological features and benefits are inadequate.	S	S	S
Appearance standards are set to levels beyond those sensed by the customer.	C	C	C
Product superiority is not established with travel planners.	S	S	S
Airline seats, guest rooms, and cabins perish when not sold.	C	C	C
Furnishings and decor "wear out."	C-S	C-S	C-S
Processes are ineffective, inefficient, obsolete, bureaucratic, or nonexistent.	C-S	C-S	C-S
Process planning and control depends on an elaborate management hierarchy.	C-S	C-S	C-S
Unskilled workers in narrowly defined jobs merely carry out the plans of managers.	C-S	C-S	C-S
Information about customer orders undergoes frequent change.	C	C	C

Key: Challenge has a major effect on C= costs; S = sales income.

1. *Continuous production* processes exist when the product has a standard design that must be produced repeatedly. These processes share many similarities with production and assembly work. Some examples are

- Fulfilling airline or hotel reservation requests
- Providing airline seat assignment
- Assigning hotel guest rooms
- Cleaning and resupplying of aircraft
- Cleaning and resupplying of hotel guest rooms
- Preparing airline or hotel food
- Handling airline baggage
- Providing hotel valet parking

Although this type of work usually provides tangible products (e.g., reservation information cards, restocked guest rooms or a plate of food), service delivery processes are involved as well.

2. *Special job* processes exist when there are multiple designs for a product requiring something new or different from each production run. Some examples are

- Generating a cruise ship itinerary
- Providing a chartered aircraft flight
- Staging a meeting, convention, or banquet

This type of process relies heavily on communicating essential information to all concerned, and the production run is typically short. Again, service delivery processes are involved.

3. *A service delivery* process exists when the supplier meets the customer to conduct a transaction face to face. It typically involves delivery of one or more of the following: (a) personal effort to add comfort or well-being, (b) information to solve a problem, and (c) tangible products. Some examples in the airline and hotel industry are

- Welcoming a traveler
- Providing directions
- Relieving a traveler of baggage
- Serving a beverage or a meal
- Providing forgotten items

It is important to note that service delivery processes may be embedded in both the continuous production and the special job processes. It is useful to understand service delivery as a continuum. At one end is the *individualized service* of a bank machine. This mechanized process can identify an individual by bank card number and process the *individual request*. At the other end of the continuum is the warm, comfortable, *personal service* one would provide at home to guests. Since service delivery is central to hospitality organizations, especially high-grade ones, the service delivery processes are highly personalized and carefully planned and managed.

The Logistics Are Complex.   Service delivery is involved with virtually all work in a travel/hospitality enterprise. Since service is consumed promptly by the customer (at the time of delivery), three logistical problems exist when analyzing trouble:

1. Analysis can easily interfere with customer satisfaction.

2. It is not feasible to stop delivery to identify a problem cause.

3. The information collected is usually in the form of recollections, not real-time observations.

The time elapsed in service delivery is usually so short that most problems (such as providing incorrect directions to a traveler) are not even detected until the service delivery is complete.

Short-Term Economic Pressure.   Airlines and hotels are capital-intensive enterprises whose performance is closely monitored by external financial analysts. Financial performance reviews of these investments are conducted on at least a quarterly basis. Accordingly, exhibiting positive quarterly financial results is often more of a priority than discovering the causes of good results and generating competitiveness. In the words of one well-known consultant, "an imbalance exists between counting the golden eggs and making the goose healthier." Table 30.3 summarizes process characteristics and barriers to problem analysis.

THE RISE OF CURRENT QUALITY PRACTICES

Much has been done within specific organizations to create a historical perspective of the industries (Abbey 1995, Forsyeth 1995). An explanation of this work follows.

Few National Carriers or Hotel Companies.   Throughout the 1930s and 1940s, there were few national carriers or hotel companies in the United States. Airline carriers had a tiny share of the travel market and were primarily regional; most hotels were small and independently owned. Airlines and hotels were located in population and trade centers, and sea travel was international aboard transatlantic ocean liners.

No Standardization of Product.   Although there were airlines and hotels with common ownership, even the most prominent of them lacked standard policies, procedures, product design, or referral networks.

Changes in Society.   Beginning in the 1950s, however, society began to experience dramatic change in demographics and in habits and practices relating to travel and lodging.

1. *Population growth.* Following World War II, the rate of household formation jumped, and the population began growing significantly (at a rate of 1.35 percent compounded annually), especially in the South and the Mountain and Pacific regions.
2. *Population shift.* In addition to this growth, the population began shifting; the Sunbelt (especially Florida and Texas) and the western states (Colorado, Arizona, and California in particular) experienced a tremendous influx of people.
3. *Greater life expectancy.* The population grew also because life expectancy increased, a reflection of advances in medicine and public health measures.
4. *Improved incomes.* Individual real incomes improved in the postwar economy, and two-income families became more common. After the belt-tightening war years, families suddenly had more money to spend on travel and leisure.

TABLE 30.3   Airline and Hotel Processes and Barriers to Analysis of Chronic Trouble

Process type	Product design	Production/delivery run length	Barrier
Continuous production	Standard design	Long	Hundreds of functional and sensory variables to control
Special job or event	Multiple designs	Short	Most analysis cannot be put to use on the current job
Service delivery	Customer-employee interface	Brief	Measurement can only be conducted after the delivery (i.e., the data are retrospective recollections)

5. *Increased leisure time.* Leisure time increased in the early postwar years, when the 40-hour work week became commonplace and additional legal holidays were given to workers. Job market factors such as part-time work and job sharing contributed to the increased amount of leisure time available to workers.

6. *Proliferation of convention centers.* The 1950s and 1960s experienced a booming U.S. economy. As businesses and business and fraternal organizations grew, people needed facilities for conventions and meetings. Some cities had civic centers or auditoriums that could accommodate groups. As business expanded into the suburbs or outgrew the limited facilities of the smaller city-based convention centers, there was a surge in the demand (and supply) of convention-related travel and hospitality products. This demand occurred in cities and in regional and resort destinations.

7. *Expansion of the highway system.* Construction of the Interstate highway system began in 1956. Soon, the 42,000-mile system became an important factor in the number of Americans traveling, both for business and for leisure. Vehicle registrations grew dramatically, and Americans took to the roads in great numbers.

8. *Increased air travel and growth in airport infrastructure.* Air travel became a commonplace part of the American business and leisure scene. By the early 1980s, more than 700 airports were certified for passenger service, including 23 large hub airports (in Chicago, New York City, Dallas, Atlanta, and so on). The large hubs were destinations in their own right, as well as connection points for an increasing number of domestic and international flights. In addition, 35 medium hubs served regional areas such as the Southwest or Northeast, and 62 small hubs provided statewide connections for a growing number of business and leisure travelers.

9. *Expanded connoisseurship.* Consumers became increasingly informed, astute, and discriminating in making travel and hospitality decisions. Travelers were increasingly unwilling to accept limited comforts, whatever the product grade.

10. *Decline of international sea travel.* Rising costs and the increasing attractiveness of air travel caused international sea travel to decline and finally to virtually disappear.

INDUSTRY RESPONSES TO SOCIETAL CHANGES

Consolidations: National Alliances and Hotel Chains.   The industries evolved rapidly to meet the challenges posed by a changing society. Independent and regional airline and hotel enterprises began to seek affiliations to compete more effectively. The basic motivation of joining a national alliance was the added prestige (i.e., the ability to trade on the quality reputation of the alliance) as well as the increased purchasing power.

Common Management.   Not until the 1950s did national carriers or hotel companies adopt common management to coordinate all commercial activities. During this period of coordination among the affiliated business units of an airline or hotel company, each consolidated organization developed its own policies, procedures, product designs, amenities, and referral networks.

To meet the demands of road travelers in the 1950s, the lodging industry responded with the development of chain properties. Holiday Inn, Ramada Inn, and Howard Johnson's were among the lodging pioneers along interstate highways. Hilton Hotels chose to capitalize on the expanded demands for convention centers by developing or purchasing facilities that were fit for large conventions.

By the 1960s, giant air carriers attempted to capitalize on their quality reputations by extending their product lines to include hotels. United Airlines, TWA, and American Airlines each developed or acquired a lodging brand. While this approach eventually was abandoned in the United States, the airlines of other countries later adopted it. Some examples are

Airline	Lodging product
Air France	Meridien
Japan Airlines	Nikko
KLM Royal Dutch Airlines	Golden Tulip
SwissAir	Swissotel

The growth of affiliations and information technology created the conditions for the first toll-free reservation systems in the 1960s. These automated systems provided instantaneous verification of travel and lodging arrangements.

In retrospect, early quality efforts were characterized by standardization of product design to distinguish products from those of competitors, a response to the requirements of management. It would be some time before managers would recognize that response to customer requirements was an even more effective competitive strategy and vital to long-term business health.

GOVERNMENT INFLUENCE

Two acts of legislation have greatly shaped the economic and competitive situation of today's hospitality/travel industries in the United States: The Airline Deregulation Act of 1978 and the Economic Recovery Act of 1981.

Airline Deregulation Act of 1978.   With the first legislation, airlines ceased to be regulated as public utilities. The gradual removal of economic controls was designed to encourage competition and improve service quality among U.S. air carriers. Some effects have been predictable and some surprising.

Predictable effects
1. *Passenger traffic increased.* In 1977, U.S. airlines carried 240 million passengers. By 1994, the number totaled 605 million.
2. *The price of air travel decreased.* As of 1995, about 90 percent of all air passengers paid at a discount from standard fare. Passenger traffic on low-fare airlines grew from 3 percent of the total in 1980 to 12 percent of the market in 1993, a trend that continues with no end in sight.
3. *Competition grew.* Immediately following deregulation, a flurry of new airlines entered the market. Although most of these new entrants failed or were merged into other carriers, the competition is still very stiff.
4. *Large carriers have abandoned small communities.* Major airlines are leaving the service of smaller cities to commuter carriers that feed traffic to their hubs for connecting service. In 1977, commuter airlines carried 9.2 million passengers. By 1994, the number had risen to 56.5 million.

Surprising effects
1. While traffic growth has been favorable for large, full-service airlines, most of the growth experienced by the top three airlines happened soon after deregulation was initiated in 1978. Demand for full-service airlines seems to have flattened, owing to adverse economic conditions and the attractiveness of low-fare airlines.
2. Chapter 11 reorganization has affected pricing. Since deregulation, there have been 117 bankruptcy filings in the airline industry, including 18 major U.S. carriers. Carriers operating under Chapter 11 are protected from creditors. This enables them to offer discounted fares, forcing competitors to match their prices at unprofitable levels.
3. The airline industry is evolving into two major segments; one segment will feature convenient schedules; and the other, attractive pricing.

Economic Recovery Act of 1981.   To stimulate capital investments in the United States, Congress allowed for investment tax credits as well as shorter depreciation and amortization schedules. As a result, hotels were built without regard for market demand. This condition changed with the Tax Reform Act of 1986. There remains an average surplus of hotel rooms amounting to 40 percent (as of 1995), a surplus that is expected to persist until the turn of the twenty-first century.

QUALITY PLANNING IN THE TRAVEL AND HOSPITALITY INDUSTRIES

How to Think About Quality Planning in the Travel and Hospitality Industries.

The launch of a new aircraft, a new hotel, or a new cruise ship is a capital-intensive, high-risk under-taking. Inadequate quality planning creates unnecessary costs, possibly even catastrophe.

Long airport check-in lines, uncomfortable surroundings in a hotel, runways crumbling at a new airport, food poisoning, and a ship that overturns at sea are all potential results of inadequate quality planning. [For further examples, see Juran Institute Quality Minute Video Education Series (1994)].

A well-documented example of the cost of poor quality planning occurred in a major resort hotel in the United States. This property featured a magnificent outdoor pool and sunbathing area, accommodating several hundred guests. Among the most popular products served there was the frozen yogurt and the yogurt-based cream drinks made by machine at the poolside service area. A chronic problem was the unreliability of the yogurt machine. The failures were frequent, causing lost sales, rework, added steps, accidents, employee fatigue and turnover, and customer dissatis-faction. Management of the property decided that the purchase of a new yogurt machine would remedy the trouble. The choice of a $12,000 unit was influenced by a $5000 discount on the pur-chase price.

Management was surprised when the workers at the pool area complained about the new equip-ment. Some managers resented the protest, even claiming the work force was "insatiable." An inves-tigation by the hotel purchasing agent uncovered the following facts:

1. The capacity of the new machine was inadequate for production needs.
2. The work force was not trained in an important particular: to store the yogurt mix between 30 and 45°F. The use of improperly stored mix rendered the unit inoperable.
3. The workers were substituting expensive ingredients.
4. Procuring the substitute ingredients caused extra work paid at the overtime rate.
5. Customers of the pool bar were dissatisfied with the sporadic unavailability of yogurt during the summer.

In the words of one worker, "Twelve thousand dollars was spent; things are worse; yet management thinks they saved $5000." Worker input was a vital missing element in the original planning and in the replanning of yogurt production. Sound quality planning can produce processes and products that are robust against failure and avoid attendant costs of failure.

Quality Planning Facilities and Equipment.

Aircraft, hotels, and ships are built to order by capable suppliers not made by the purchaser. Planning for such an investment typically involves a well-organized joint planning effort. It requires assembling a team of experts from several disci-plines: marketing, finance, architecture, engineering, construction, operations, and so on. The team usually draws architectural and other discipline expertise from outside firms that specialize in the discipline. The planning team draws marketing and operational expertise from inside the purchaser's organization. The team's mission is to identify and incorporate the necessary product features and to identify and avert potential sources of failure in the finished facility. In addition to providing their market and operational knowledge, the representatives of the purchaser's organization play two addi-tional roles that are vital to the success of the completed project. One role is to keep before the team the economic constraints of the project; the second is to provide a consistent management process within which the team can effectively carry out the project.

The process of planning a new hotel facility will illustrate some proven approaches. Typically, the team uses one of two basic approaches to develop a new facility: (1) "last model built" or (2) bench-marking "the best."

The last model built approach uses the last hotel as a starting point for the next step in an evolu-tionary continuous improvement. The benchmarking approach is used when the hotel company is

seeking a fresh approach to facility design. The team of professionals identifies the best-in-industry facilities or even best-in-class outside the industry. The airline industry has benchmarked hotels for equipment, cruise ships have engaged hotel interior architects, and hotels have benchmarked cruise ships for facility design and equipment. British Airways engaged an industrial design firm known for its work on expensive boats to redesign its first class cabins (Goldsmith l995). From these benchmarking experiences, the team of professionals identifies the most important facility features of its new product, whether they be functional or sensory qualities. For further discussion, see Section 12, Benchmarking.

It is typical of the industries to use existing products or competitive products as a source of inspiration to answer the question: Which product features best respond to customer needs? This approach is in contrast to the approach of home appliance makers, for example, who are more likely to use extensive market research into customer needs as a basis for new product design. The last model built approach fosters consistency of product design as well as a low degree of difficulty in planning and execution. Conversely, this approach not only invites carryover failures, it also can lead to product obsolescence. The benchmarking approach can generate breakthrough improvements, yet it is more difficult to manage the new and untried.

Some travel products and travel-product specifications became so closely identified with quality levels that their names and terms became descriptors in everyday language. *Ritzy* is synonymous with elegance and refinement, based on the luxury hotels of César Ritz. The term *posh* is an acronym for port outbound starboard home, which specifies cabins that are free from the glare of the sun on both legs of a round-trip ocean liner journey between the East Coast of the United States and Europe.

Once the basic concept is developed, the performance evaluation of the new facility or equipment is measured in a series of thorough reviews and tests. These critical examinations are centered on validating four characteristics: (1) life safety, (2) appearance, (3) feasibility, and (4) reliability (i.e., time-oriented performance.)

The life-safety validation is typically carried out under the supervision of the appropriate regulatory agency. Matters of appearance are validated by the expert sensory evaluation of architects, whereas economic feasibility is monitored by the expert financial analyst. Validating reliability is a more complex issue than the preceding items. Since facilities and equipment in the industries are purchased products, reliability largely depends on (1) supplier reliability data (today, most suppliers use their internal reliability data as marketing evidence regarding product performance and (2) interviewing customers who use the product.

Another form of design assurance is the construction of product models. Airlines, hotels, and cruise lines build and test cabins and guest rooms. Some are laboratory simulations, whereas others are small-scale tests in existing facilities. The Hong Kong and Shanghai Hotel Company, owners and operators of the Peninsula Group of hotels (located predominately in the Far East), use "home testing" for small, untried equipment. New or untried guest room equipment must be installed in the home of an upper manager for 1 year's practical use prior to implementation. This approach overcomes the pressure to use the latest technology as well as gaining insights into the intended versus real use of equipment by customers.

Since the ultimate test of new facilities is customer use, most enterprises in the industries conduct some form of postproject evaluation of the new product. These evaluations usually include some form of postcustomer reaction and cost analysis.

Unfortunately, in my experience, the industries have not yet seen the value of continuously assessing and improving the product development process itself. This form of 1-day review by upper managers (made popular by Japanese manufacturers) would benefit the entire organization. This audit in some organizations receives the personal attention of the president of the enterprise. Not surprising, this review is often termed the *presidential audit.* This examination makes new products more salable, eliminates waste, reduces capital costs, and improves the return on investment.

Once new facilities clear the design validation phase, preparations for regular operations begin. Since construction and installation schedules and costs can gain the upper hand, it is important that the startup process be reliable. Accordingly, most enterprises use readiness systems such as countdowns or checklists (as practiced in hospital operating rooms and spacecraft launches) to get new products off to a good start.

Products in the hospitality and travel industries are subject to cyclic demand patterns. New products are typically launched in advance of a peak demand period, allowing time to identify and correct deficiencies before the peak occurs.

As mentioned earlier in this section, the management of facilities/equipment inventory (e.g., aircraft seats, hotel guest rooms, and cruise ship cabins) is a complex subject. The complexity is caused by two compounding factors: (1) the inventory is more perishable than food and when lost is lost forever, and (2) 30 percent of travel plans either change or are canceled. Today, inventory management in the industries is very scientific. The object is clear: Sell every item (i.e., seat, guest room, cabin) *today* at the best possible price. The airline industry has been at the frontier of this special form of inventory management. It was the first to use automated inventory management systems to provide decision support in controlling inventory flow and price levels. It would be no exaggeration to say that improving the yield of facilities and equipment has a major effect on the profitability of an enterprise in the hospitality and travel industries.

Quality Planning for Service.   Unlike facilities/equipment planning, which is dominated by consulting specialists, planning for new service is monopolized by managers of the enterprise. Most frequently, their qualification for this role is their experience in customer service. (The training and experience of industrial engineers, much valued in planning of services within industrial companies, is not seen as relevant to service planning within the hospitality and travel industries, with the exception of a few major airlines.)

At the Ritz-Carlton Hotel Company, a Malcolm Baldrige National Quality Award recipient, upper managers are personally involved in planning service for each new hotel. The foundation of their approach is the "Gold Standards" (see Figure 30.1). These standard specifications and processes guide the activities and decisions of the entire organization, especially in the ambiguous situations commonly encountered in personal service delivery. When new hotel development occurs, experienced managers migrate to the new location to select scientifically a work force that shares the organization's values. This scientific selection process, developed by a supplier-partner, uses an empirical-based instrument to "screen in" promising managers and workers. The screening instrument compares the candidate's character traits (i.e., spontaneous behaviors) to those of consistent superior performers of the Ritz-Carlton.

During the 7 days prior to initial customer occupancy of the hotel, upper managers play an active role. In the first hour of employment, the President/C.O.O. assertively instills and models the "Gold Standards" for all new recruits. These new recruits then spend the next 2 days in classroom sessions with trainers. During these sessions, the new recruits gain a better understanding of the "Gold Standards." In essence, every new recruit of the Ritz-Carlton Hotel Company must master the employee-customer interface process shown in Figure 30.2. This process requires and allows anyone in the entire work force to (1) break away from routine duties when the customer is dissatisfied or requires something that is not in the standard array of products or (2) provide immediate positive action, (3) document the incident for future analysis, and (4) "snap back" to routine duties. The preceding relationship-management process training is a strictly enforced prerequisite for new recruits (at any level of the organization) before they can begin functional training or have any customer contact.

British Airways provides another example of personal involvement of upper managers in service-delivery planning. After World War II, this national airline of England made a practice of hiring former military personnel. As a result, the culture and organization of the airline was decidedly militaristic. Their core beliefs centered around a traditional hierarchy, conformance to regulations, and safety. Despite the airline's core technical competencies, its losses required substantial subsidies from the government.

The company surveyed 45,000 customers for opinions and attitudes regarding the airline's products. The findings were not entirely surprising: "Your people, while technically competent, are cold, aloof, uncaring and bureaucratic." These findings set in motion cultural and organizational countermeasures that have improved the financial performance of the airline dramatically (Geojiales 1995).

Quality Planning for Special Jobs.   Once aircraft, hotels, or cruise ships are in regular operations, special jobs occur that require special planning and coordination. These jobs may take

---

THREE STEPS OF SERVICE

1
A warm and sincere greeting. Use the guest name, if and when possible.

2
Anticipation and compliance with guest needs.

3
Fond farewell. Give them a warm good-bye and use their names, if and when possible.

"We Are Ladies and Gentlemen Serving Ladies and Gentlemen"

THE RITZ-CARLTON®

CREDO

The Ritz-Carlton Hotel is a place where the genuine care and comfort of our guests is our highest mission.

We pledge to provide the finest personal service and facilities for our guests who will always enjoy a warm, relaxed yet refined ambience.

The Ritz-Carlton experience enlivens the senses, instills well-being, and fulfills even the unexpressed wishes and needs of our guests.

THE RITZ-CARLTON® BASICS

1 The Credo will be known, owned and energized by all employees.

2 Our motto is: "We are Ladies and Gentlemen serving Ladies and Gentlemen". Practice teamwork and "lateral service" to create a positive work environment.

3 The three steps of service shall be practiced by all employees.

4 All employees will successfully complete Training Certification to ensure they understand how to perform to The Ritz-Carlton standards in their position.

5 Each employee will understand their work area and Hotel goals as established in each strategic plan.

6 All employees will know the needs of their internal and external customers (guests and employees) so that we may deliver the products and services they expect. Use guest preference pads to record specific needs.

7 Each employee will continuously identify defects (Mr. BIV) throughout the Hotel.

8 Any employee who receives a customer complaint "owns" the complaint.

9 Instant guest pacification will be ensured by all. React quickly to correct the problem immediately. Follow-up with a telephone call within twenty minutes to verify the problem has been resolved to the customer's satisfaction. Do everything you possibly can to never lose a guest.

10 Guest incident action forms are used to record and communicate every incident of guest dissatisfaction. Every employee is empowered to resolve the problem and to prevent a repeat occurrence.

11 Uncompromising levels of cleanliness are the responsibility of every employee.

12 "Smile - We are on stage." Always maintain positive eye contact. Use the proper vocabulary with our guests. (Use words like - "Good Morning," "Certainly," "I'll be happy to" and "My pleasure").

13 Be an ambassador of your Hotel in and outside of the work place. Always talk positively. No negative comments.

14 Escort guests rather than pointing out directions to another area of the Hotel.

15 Be knowledgeable of Hotel information (hours of operation, etc.) to answer guest inquiries. Always recommend the Hotel's retail and food and beverage outlets prior to outside facilities.

16 Use proper telephone etiquette. Answer within three rings and with a "smile." When necessary, ask the caller, "May I place you on hold." Do not screen calls. Eliminate call transfers when possible.

17 Uniforms are to be immaculate; Wear proper and safe footwear (clean and polished), and your correct name tag. Take pride and care in your personal appearance (adhering to all grooming standards).

18 Ensure all employees know their roles during emergency situations and are aware of fire and life safety response processes.

19 Notify your supervisor immediately of hazards, injuries, equipment or assistance that you need. Practice energy conservation and proper maintenance and repair of Hotel property and equipment.

20 Protecting the assets of a Ritz-Carlton Hotel is the responsibility of every employee.

FIGURE 30.1 The Ritz-Carlton Hotel Company "Gold Standards."

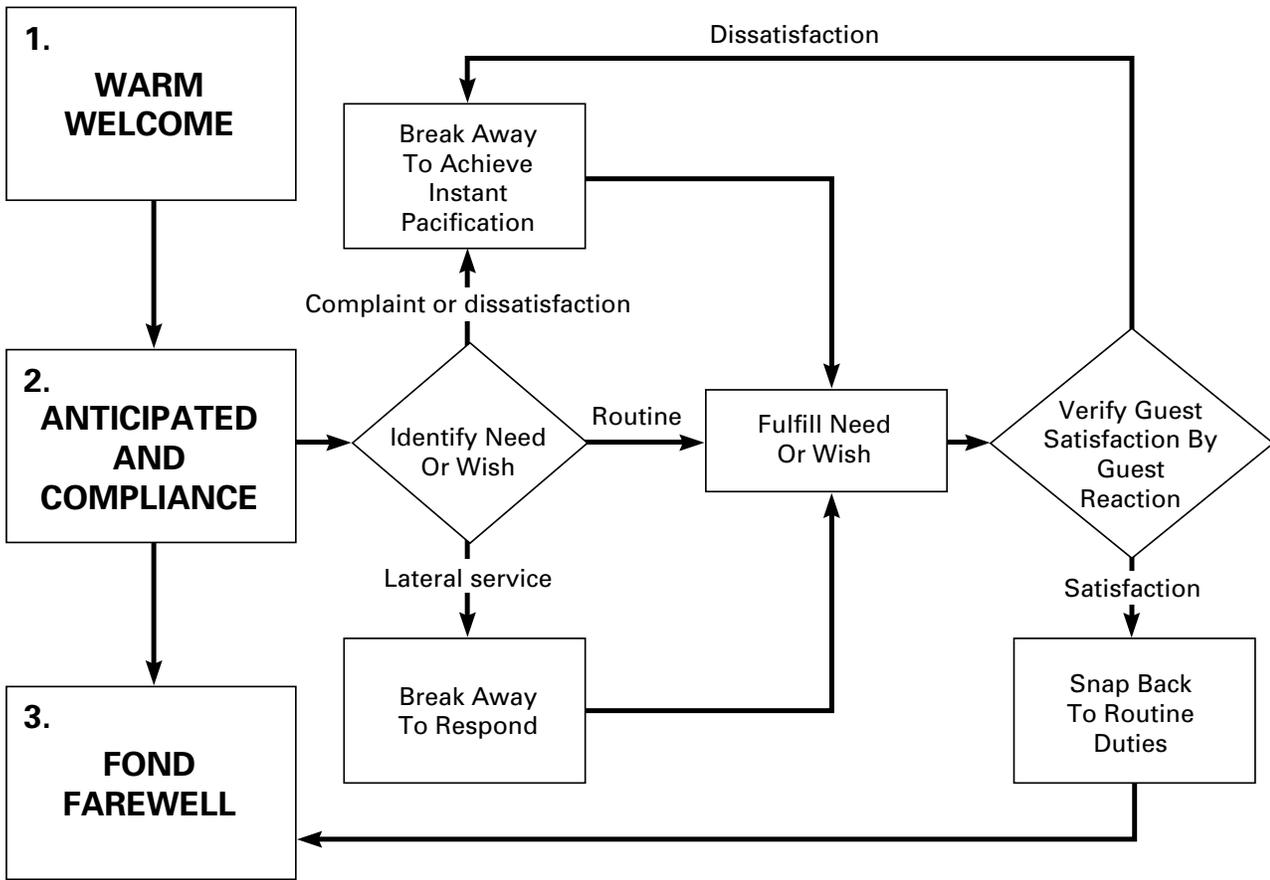
the form of chartered air travel, a special cruise itinerary, or a special event such as a convention or banquet. Such jobs usually involve the requirements of multiple customers traveling and/or convening together. These special jobs often account for 50 percent or more of an enterprise's revenue. Virtually every organization in the industries has a planner for special jobs or events who knows the capabilities of the organization as well as the economics of special jobs or events. This internal planner determines the requirements of the customer, usually through personal interview and historical


FIGURE 30.2   The Ritz-Carlton Hotel Company "Three Steps of Service."

information. The planner then creates and circulates documents to all concerned for execution of the job. It appears easy! However, even for a knowledgeable and experienced internal event planner, the entire process is filled with potential difficulties for many reasons. The event planner, although a high-level coordinator in the organization, has no hierarchical authority. The work usually passes through multiple divisions and/or departments and is subject to the preexisting difficulties between and within these work jurisdictions. The internal planner can easily underplan or overplan the job or event.

A case of overplanning occurred in a special job where the planner established a 150-point checklist for one aspect of the job. Not only did this list require many detailed inspections and tests, the minimal results of this extra attention to the job output were undetectable by the customers. Taken to the extreme, overplanning a special event or job increases the cost of planning, the attention to trivia, documentation, and the control effort in general.

Conversely, underplanning increases the likelihood the job or event fails to respond to the requirements of the customer and the work becomes more costly than necessary. An example of underplanning resulted in costly litigation. A hotel failed to determine the seating requirements of a special event. The operating forces, functioning without specifications, were left to decide the number of seats per table. Their decision was different from the seating plan of the host organization. The effect of the underplanning damaged the reputation and aim of both the customer and the hotel while adding extra costs to both.

The amount of event communication can rise to enormous proportions, fostering inaccurate and missing information. Furthermore, problems of a job or event usually receive only immediate action, not longer-term corrective action. As a result, the entire event or job can be filled with mistakes, rework, breakdowns, delays, inefficiencies, variations, rebates, and massive inspection efforts. To eliminate or reduce these problems and their extra costs, upper management must create a seamless

interface between the planners and those who execute the plan. This organization should develop event specifications so that internal event planners understand the minimum information needed to define and produce an event as well as special event details to prevent defects and extra costs. Only the people who perform the work can provide this vital information to the internal planner of the event or job.

The seamless organization also must have standing and special meetings to review event or job plans. The main purpose of the standard meeting is to provide redundant verification of circulated document information. The special meeting is designed to focus on a single event or job to identify potential failures. The special review meeting is especially important when the job or event is new and untried. When potential failures are identified, the organization works to correct the problem before it reaches the customer and notifies the customer of the situation.

On the surface, alerting the external customer may appear to be an unnecessary, even harmful disclosure. However, research has demonstrated that special event planners expect to be informed on all matters of progress (Power 1994).

Finally, when problems do occur, the organization must first work to solve the problems event by event, because most problems have their origins in the planning of the event itself. In doing so, the organization can prevent a recurrence in repeat jobs or like jobs.

Ritz-Carlton has developed a simple but powerful aid to event planning. The setup sequence (Figure 30.3) and the operations sequence (Figure 30.4) provide a clear conceptual framework that applies to all special events. The *setup sequence,* borrowed from the logistics of the industrial job shop, shows the four categories of elements that constitute a special event, an abbreviation of the generic planning steps for the elements in each category, and the planning goal for each element by category. The grand goal of planning for any special event is a state of readiness, achieved when the goal for each individual planning element is achieved.

The *operations sequence* presents in simple terms the key interfaces between the hotel organization and the major external suppliers and the responsibilities of the major contributors in executing the plan for a special event. The operations sequence also provides a graphic (and perhaps comforting) reminder that much of the work of managing a "special" event consists of coordinating tasks that are part of the hotel's everyday routine, such as laundry, billing, housekeeping, and the like.

At Ritz-Carlton, managers who have had to master the planning and execution of the special event through repetitive involvement have welcomed the introduction of the setup and operations sequences. Managers find these tools useful in discussing an event plan with others, training inexperienced planners to plan and execute events effectively, and reducing the length of time it takes for inexperienced planners to achieve full productivity in event planning and execution. As they have come to appreciate the power of these tools as applied to special events, the managers also have begun to apply the concepts to all work flow generally. Furthermore, these tools provide an ice-breaking example of cross-disciplinary learning. Managers acknowledge that these graphic tools, inspired by the experience of the industrial manufacturing job shop, are very useful in application to hospitality issues. Such acknowledgment opens the door to discovery of other useful concepts from other disciplines outside the hospitality industry. (For a full discussion of special job or event quality, see Section 24, Job Shop Industries.)

Another application of special event or job planning can be useful to restaurants. In this case, each occupied table should be considered a special job. In order to fully understand what's new or different about each table's order and execute the order without failure, the dining room function and the kitchen function must be horizontally integrated. They must agree on the following things:

- The minimum information needed to define and produce a food order

- The additional information needed to prevent errors on a food order (e.g., degree of doneness on meat orders, the seat location for each item to be delivered, etc.)

- A system to coordinate the final food preparation of each order with the start of food delivery

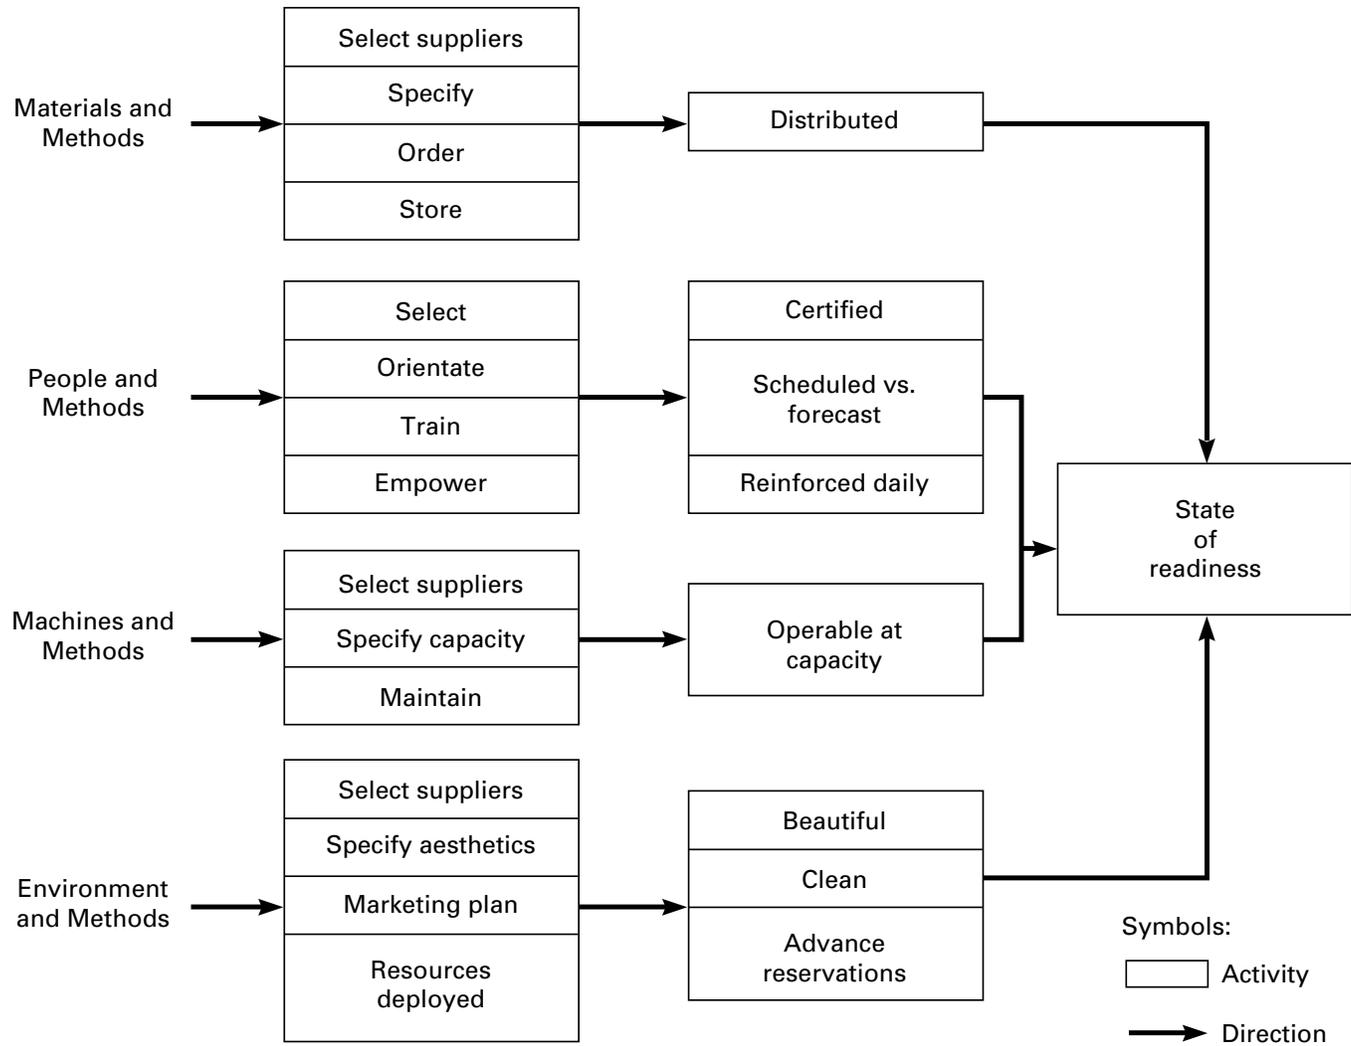
Restaurants have made great strides in reconciling freshly prepared food and timely delivery. This success is a result of high-quality planning, not high levels of personnel or automation. Today, most restaurant kitchens use some variation of the quality plan shown in Figure 30.5.


FIGURE 30.3   Setup sequence for special event. (*Courtesy of The Ritz-Carlton Hotel Company.*)

The Role of *Savoir Faire* in Travel and Hospitality Planning.   It simply is not feasible to detect the perferences of every customer. Accordingly, many decisions about ambiance, protocol, and general appropriateness are left to the travel or hospitality organization. For this very reason, most high-grade products in the industries employ leaders who have an ability to say or do the right thing in any social situation. This knack (which is often called *savoir faire* from the French "to know what to do") is learned behavior, usually acquired through emulation of a role model early in one's career.

CONTROLLING QUALITY IN TRAVEL AND HOSPITALITY INDUSTRIES

Although the cardinal rules of controlling quality generally apply to the travel and hospitality industries (Juran 1988), it would be fair to say quality performance in these industries does not receive the same degree of control as other internal measures such as schedules or finance. The appropriate controls to be used are most easily determined by understanding the characteristics of the processes employed in the industries.

Worker-dominant processes: When the process is dominated by people (such as service delivery), the control system relies heavily on the talent, skill, and knack of the individual worker.

Material-dominant processes: When the process is dominated by materials (such as uniform purchases or some forms of food production), the control system depends on supplier relations and inspection of delivered lots to identify the unacceptable.

Time-dominant processes: When the process changes with time (such as unsold cabins or guest rooms losing value, machines or decor exhibiting wear and tear), the control system relies on frequent process checks.

Information-dominant processes: When the process undergoes frequent information changes (such as travel reservations, staging a special event or job), the control system addresses the accuracy and the up-to-dateness of the information. (For more on information-dominant processes, see above under Quality Planning for Special Jobs.)

Setup-dominant processes: When the process is dominated by a setup (such as arrangements for a special event or banquet or the placement of baggage-delivery equipment), the control system relies on verification of the setup (i.e., the design).

Facilities and Equipment Quality Control.   When facilities and equipment have reached operating conditions, quality is monitored with emphasis on four dimensions: (1) life safety, (2) continuity of electrical/mechanical service, (3) inventory management yield, and (4) appearance of

Dining Room Team	<u>Designate</u> a worker who assembles food orders in the kitchen, then delivers them to the appropriate table

FIGURE 30.5   Quality food delivery plan.

surroundings. Since many of the things measured change with time (e.g., unsold cabins and guest room age), frequent appraisals may be necessary. These appraisals usually take the form of scheduled process checks. Table 30.4 is a matrix of facilities/equipment quality control.

For the matter of aircraft maintenance, fundamental improvements have been developed. The airlines have abandoned scheduled overhauls in favor of reliability-centered maintenance (also called *on-condition maintenance,* since 89 percent of the failure patterns were not age-related). This subject is addressed in Section 7, Quality and Income, and Section 25, Customer Service. For more on the topic of sensory inspections, see Section 23, Inspection and Test.

Service Quality Control.   The activities to control service delivery in the travel and hospitality industries should be centered on controlling the behavior, skills, and knack of the workers. For example, service employees should be empathetic and have a high degree of skill in resolving problems. (Unempathetic workers will not carry out customer-oriented policies and procedures adequately.) If there is no process to (1) control or screen out unempathetic candidates and (2) develop the necessary skills and knack to carry out the services required by customers, significant inspection and corrective action will be necessary. The inspection usually takes the form of management review, both daily inspection and performance appraisal systems. This approach has inherent shortcomings.

Regarding inspection, experience has demonstrated that inspection activities detect only 80 percent of the deficiencies, release the worker from the responsibility for quality, are an added cost, and often blame the workers for problems that are beyond their control. A more enlightened approach is to verify the designs of the service delivery and then put the work force in a state of self-inspection or self-control. This alternative works to recruit people who share the organization's values of courtesy, timely delivery, and problem resolution. Through daily reinforcement of these values, the worker spontaneously controls his or her attitude, makes final conformance assessments before service delivery, and extends himself or herself to solve the problems of customers. Periodically, the workers and managers evaluate the customers' assessment of service delivery to identify chronic, severe trouble. Progressive organizations also educate their work force about quality logic, tools, and processes to prevent or correct difficulties.

Generally, the basic quality training program in the travel and hospitality industries covers a number of tools and topics:

1. Service quality logic and processes (i.e., face-to-face interactions between employee and customers)

2. A problem-solving process that includes a diagnostic journey to identify problem causes and a remedial journey to eliminate the causes

3. Statistical tools embedded in the problem-solving process to collect information, analyze data, display data, and plan actions

TABLE 30.4   Facilities and Equipment Quality Control

Timing	Appraisal	Appraiser	Purpose	Example
Life safety dimension				
Scheduled	Process tests and checkouts	Management	Prevent potential failures	Inspection of fire alarm system
Continuity of electrical/mechanical service				
Scheduled	Process overhaul	Equipment operators	Prevent potential failures	Overhaul of the central plant air-conditioning unit
Scheduled	Process tests and checkouts	Patrol operator	Prevent potential failures	Monthly filter examinations of ventilation units
Unscheduled	Process failure identification	Entire work force	Immediate corrective action	Reporting an inoperable air-conditioning unit
Cabin/guest room inventory management yield				
Scheduled	Plan review	Management	Corrective action	Reducing prices when the inventory sold is less than planned
Appearance of surroundings				
Scheduled	Sensory evaluation	Management	Prevent aging of decor	Determining which furnishings must be renovated or replaced over the next 12 months
Unscheduled	Sensory evaluation	Entire work force	Correct unacceptable appearances	Reporting a stained carpet

More advanced components also may include some form of quality planning process, i.e., providing the logic to do something for the first time or to improve a process. These processes and tools are a powerful arsenal to be used in planning, controlling, or improving any aspect of an enterprise in the industries.

Special Job or Event Quality Control.   Special job or event control is distinguished in two ways. Since the process undergoes frequent information changes, the control system addresses the accuracy and the up-to-dateness of the information. The second distinction is the manner in which problems are addressed. Whereas most continuous production and service delivery processes concentrate on the chronic, severe problems first, special event or job control concentrates on the problems within each job or event. An effective way to manage event-by-event quality involves holding a pre- and postevent meeting with the customer. During these meetings, most problems will be identified from the current event. The enterprise then documents each problem in an event log. Each problem is assigned to the appropriate person in the enterprise to diagnose and remedy. All data relating to the problems of the events (i.e., theories, tests, potential solutions, and the like) are kept with the master data file of the special event or job. Since most problems with special jobs or events originate with the planning of that event or job, remedies typically involve redefining what is essential to communicate and to whom. This approach prevents problems in repeat events and like jobs.

Quality Control in Food Production.   In view of the advanced technological equipment used to control the many sensory aspects of production in the commercial kitchens of packaged food manufacturers, it may seem surprising that travel and hospitality organizations still rely on the sensory evaluation of the human beings preparing the food (e.g., professional chefs). The evaluation used by the professional chef is strongly oriented to relations with suppliers, sorting of inferior materials, verification of the process setup, and frequent process checks. The basis of the chef's quality evaluation is either conformance to standards (i.e., recipes handed down by revered teachers, personal specialties, etc.) or food that conforms to the requirements of customers. Typically, it requires the leadership of the organization to convince the professional chef that the marketplace is the final judge of quality, not the chef.

One of the most sophisticated applications of statistical process control in the industries is in a large airline catering enterprise. The worldwide flight kitchens of this progressive organization have undergone extensive process analysis (with the aid of a special consultant) to improve "first-pass yields" (i.e., the percentage of work done right within the time frame). As a result of this analysis, *the work* is able to tell the organization what the kitchen is actually capable of achieving. Should a kitchen perform above or below the norms of "like" operations, the kitchen receives special attention by upper managers. To make sure their flight kitchens continuously achieve quality and related productivity targets, this enterprise conducts internal process audits. As a result, this organization has more than doubled its profitability in an 18-month period.

Quality Monitoring in the U.S. Airline Industry.   Customer dissatisfaction in the U.S. airline industry is monitored by the U.S. Department of Transportation. Each month the office of Aviation Enforcement and Proceedings develops the *Air Travel Consumer Report.* The report is designed to assist consumers with information on the quality of services provided by airlines. The report is divided into four sections. These sections deal with flight delays, mishandled baggage, oversales, and consumer complaints. The report normally is released by the end of the first week of each month. To obtain a single copy, write to the Office of Aviation Enforcement and Proceedings, U.S. Department of Transportation, 400 7th Street, C-75/Room 4l07, Washington, DC 20590.

QUALITY IMPROVEMENT IN THE TRAVEL AND HOSPITALITY INDUSTRIES

Overcoming Resistance to Change.   Quality improvement activity was largely confined to technical training of the work force and the renovation or replacement of facilities and equipment

until the 1980s. The industry's management focus was on business results. This was the classic business school approach: Sell hard, raise prices, force production to make it cheaper, and finance creatively. The beliefs in this approach began to change for several reasons. First, many leaders were learning about the stunning improvements of companies using total quality management (TQM). Second, they began to recognize that their enterprises were producing tangible, repeatable products, not just services. Third, they realized that every product (functional or sensory) was created by some process. Fourth, they simply had run out of ideas on how to make quantum improvements with a changing environment. The old beliefs were not driven out easily. Many of these beliefs had been handed down for nearly a century, and the pride of industry experts was considerable. The stimulus for the eventual change was strong leaders. These leaders put stress on their organizations to improve while reaffirming the ability of the enterprise to meet the new challenge. Finally, these leaders illustrated how the change would benefit the work force. This approach of stress, potential, and payoff was effective at overcoming cultural resistance to change. Currently, improvement projects are more diverse, reflecting the growing diversity of tools to realize the principles of modern quality management: customer as focal point, detailed planning, re-engineered processes, practice, and teamwork.

Quality Improvement: New Product Development.   Because of changing traveler preferences and emerging market segments, the industries have redefined target customers and repositioned themselves to be more competitive. This has led them to develop beyond the traditional broad grades or segments: luxury, deluxe, and economy. Now products (especially facilities and equipment) are designed, developed, and marketed for specific target customers. These targets are new segments within existing segments, and the products are new as well as the images, generating improved competitiveness. This product segmentation usually takes the form of tier or niche segmentation (Abbey 1995). For example, in the cruise line industry, increased availability and economy of air travel and rising costs of marine operations caused the decline of international sea travel aboard luxury ocean liners. Many companies in the industry reinvented themselves by designing and developing new facilities and equipment for specific target customers. There emerged many cruise products that occupy particular niches in the marketplace: (1) sun and shopping itinerary—1 week or less; (2) seasonal itinerary—1 to 2 weeks; (3) exotic itinerary of multiple ports with indepth shore programs—10 days to 3 weeks (Kaznova l995). As of l995, demand for cruise products exceeded the supply.

One example of tier and niche segmentation hospitality occurred in West Los Angeles in the early 1980s. A series of six "all-suite" hotels were designed and developed by a single company at six product grades ranging from economy to luxury. Each suite hotel was specially designed for people in the creative industries (i.e., motion picture, music, and advertising travelers). Since creative-industry travelers in Los Angeles have extended stayover requirements, these "artistic havens" were favored over traditional hotel products.

The new Boeing 777 was designed to anticipate the needs of the people who use and operate the plane. It features more comfortable seating, a quiet rest room, reading lights that can be replaced by the cabin crew, as well as mechanical systems that are more repairable.

Not all product development segmentation is capital-intensive. Customer-focused travel agent companies have identified new market segments and developed new products for them. Once, as a motivation to superior employee performance, organizations offered houseware, appliances, electronics, and like products. Over time, high achievers accumulated every conceivable reward and lost interest in more. Travel agencies, realizing the changing need, designed and developed comprehensive incentive travel products, creating a new industry.

Quality Improvement: Services, Special Jobs, and Events.   There was a time when quality service was perceived as unattainable, except in high-grade, high-priced products. Now, enterprises at all product grades are striving to improve service quality to remain competitive.

There are two distinct approaches used in the industries to improve service and special job quality. The first approach is to focus on the development of positive relationships between staff and guests. This leadership approach requires the selection of staff with a demonstrated talent for establishing positive interpersonal relationships and further developing that talent through training in such

subjects as relationship management. Figure 30.6 gives some examples of proven *inside-out improvement strategies* in the travel and hospitality industries.

The second approach is to redesign the service delivery processes to provide more customer focus. Success at this approach requires teamwork and worker involvement in planning and execution. These practices can improve worker pride and commitment, management productivity, and customer loyalty. These *organizational and management practices* are referred to as the *outside-in approach* (i.e., focusing on the capability of the organizational processes). The following are some examples of proven outside-in improvement strategies in the industries.

Marriott Hotels and Resorts standardized the best practice of one of its individual hotels. The quality objective was to reduce the elapsed time of the registration process. The means to reach this objective is the integration of the front desk function with the function of the bellpersons (i.e., the people who escort newly registered guests to their room and carry their luggage). To the extent possible, the front desk now preassigns a suitable guest room for arriving guests. Registration information and keys are assembled and placed in an area easily accessible to bellpersons. Arriving guests are greeted by a bellperson, who collects the appropriate key packet and escorts the guests (and their luggage) directly to their room (Hadley 1995).

The Ritz-Carlton Hotel in Dearborn, Michigan (Ritz-Carlton 1994) set out to reduce the number of defects in its guest rooms as well as increase the productivity of room cleaning and resupply. A cross-functional team, with the guidance of an advisor, re-engineered room preparation processes based on the following data: (1) cleaning and resupply defects, (2) cycle time, and (3) worker travel time. The improvements in the new work processes are described in Table 30.5.

KLM Royal Dutch Airlines has translated qualitative service issues into quantitative management tools. Their approach involves summarizing traveler survey data into 10 items referred to as the *service decathlon* (Figure 30.7).

Group A items determine how a customer feels treated as an individual. Group B items all deal with the human body's physical comfort. Group C contains items that can make flying fun.

While Singapore Airlines is praised for having outstanding cabin crews and Virgin is a top performer for entertainment, KLM strives for overall excellence. Like an Olympic decathlon, one does not have to achieve a number 1 position on all items to get the gold medal. KLM turns this service perception data into product improvements (Kaznova l995).

SUPPLIER QUALITY

Background.   Because the travel and hospitality industries use large quantities of purchased products, supply quality is a topic that deserves upper management attention. Major purchases have an impact on the organization's image and on its financial resources. Major purchases include facilities, furniture, fixtures, and equipment. They also include automated systems and creative services such as advertising and public relations. In most enterprises, food and alcoholic and nonalcoholic beverages are major purchases. Minor purchases generally involve operating supplies, such as uniforms, paper products, chemicals, and cleaning supplies. Minor purchases also include services that are outsourced, such as preventive maintenance, landscaping, copy machine leasing, and pest con-

Inside-out strategy	Purpose
"Character trait" employee selection	Select new recruits whose spontaneous behavior matches the organization's values
Personal improvement education	Rescript the personal and interpersonal behavior of the work force
Coaching, individual recognition, and rewards	Positive (or corrective) reinforcement of behaviors

FIGURE 30.6   Examples of inside-out strategies. (*Source: Frequent Flyer/J. D. Power and Associates Airline Customer Satisfaction Study—U.S. Flights, J. D. Power, Agoura Hills, CA.*)

TABLE 30.5   Ritz-Carlton Dearborn: Housekeeping Process Improvements

Process feature	Formerly	Currently	Benefit
Clean linen and terry delivery to guest floors	Clean linen was "pushed" from the laundry to the guest floor storage areas	Clean linen and terry are "pulled" from the laundry based on forecasts	Less inventory needed No stock-outs Fewer delays
Sequence of guest room cleaning and resupply	Option of the individual worker	Master cleaning schedule based on customer requirements	Less delay at the front desk Fewer room assignment deficiencies
	Separate cleaning and minibar resupply functions	Minibar resupply is combined with room cleaning	Lower labor cost Less intrusion on the guest
	Progressive work by one person	Concurrent team approach	Job enrichment Fewer inadvertent errors
Quality control	100% inspection	Self-inspection Random audits	Increased attention and responsibility by the work force
Quality improvement	Informal	Formal process involving workers	50% reduction of defects 10% reduction in worker travel time Productivity increased 25% Improved employee satisfaction from 75% to 91%

Group	Service decathlon item	Contribution, Overall Score
A	1. Friendly crew	25%
A	2. Efficient crew	18%
B	3. Ground services	9%
B	4. Meal service	9%
B	5. Drink service	9%
B	6. Seat comfort	9%
B	7. Cabin environment*	9%
C	8. Entertainment	4%
C	9. Punctuality	4%
C	10. Information	4%
	Overall score	100%

trol. In the airline industry there is a growing trend to outsource "under the wing" support services such as fueling, baggage handling, maintenance, and the like.

How Suppliers Are Selected.   Suppliers to enterprises in the travel and hospitality industries are generally selected on three criteria: (1) capability to meet customer requirements on time, every time, (2) knowledge of how their products are used by the enterprise, and (3) cost of the product. Supplier evaluation against these three parameters is usually determined by (1) visiting

the supplier's facility and assessing the capabilities by reviewing data, interviewing people, and making observations, or (2) interviewing customers of the supplier. Less frequently suppliers are also selected on their willingness and ability to improve quality and related productivity.

Although most enterprises in the travel and hospitality industries seek a "partnership" with their suppliers, some organizations maintain an adversarial relationship to maximize short-term gains. Most organizations understand that the real cost of a purchased product must include the cost of inspection and corrective action needed. However, some enterprises continue to buy on original price alone. (The case study earlier involving the hotel resort yogurt machine is a good example of relying solely on original price.)

Dependence on Specifications and Brand Names.   Organizations in the industries purchase hundreds, even thousands, of products. The organization defines product requirements in specifications or by accepting the characteristics of a trusted brand name product. Usually, there are separate approaches to developing specifications depending on whether the product is a current product or a new product. The current-product approach begins with selecting a sample that is fit for use and then asking the supplier to describe or specify the product. The new-product approach begins with a description of the organization's requirements, which the supplier then uses to develop samples for testing. The organization selects the product that is fit for use and then has the supplier describe or specify the product. It is important to note that specification development is an example of quality by design. Only through extensive testing and real-world use can the enterprise determine the supplier's capability or management of quality.

Dependence on Receiving Inspection.   Manufacturing organizations understand that quality control of purchased products can be achieved with various practices. These practices involve reviewing the process of the supplier rather than inspecting the final product. These process reviews include process audits (by the supplier or the customer) and reviews of process data that accompany delivery of the product. Unfortunately, most travel and hospitality organizations depend on 100 percent inspection by specialists. The dependence on this ineffective method can be attributed to several conditions. The first condition is that for many products there is a limited number of suppliers. With more demand than supply, there is no motivation for the supplier to improve. The second condition is that many suppliers and customers are willing to endure an adversarial relationship. The third condition is that few suppliers and customers have an understanding of the cost of poor quality and related productivity penalty.

Considerations in Determining the Number of Suppliers to Select.   Usually a large number of suppliers can be identified for every product need, but organizations typically prefer to have as few suppliers as possible. There are arguments for and against single-source supply. Figure 30.8 displays these arguments.

Each travel and hospitality organization must relate these factors to its own situation. Single-source supply has its place in the travel and hospitality industries, and its use is increasing.

Arguments *for* single-source supply	Arguments *against* single-source supply
• Reduces time to negotiate with suppliers, process orders, and receive incoming goods • Builds trust between supplier and customer • The arrangement reflects the synergies of a partnership effort • Opportunity for economies of scale • Supplier can offer full benefit of expertise	• There is a lack of specialized or expert information for each product within the organization • There may be fewer products available within a product line • Customer may give up price leverage

FIGURE 30.8   Analysis of single-source supply.

Benchmarks in the Travel and Hospitality Industries.   The U.S. airline industry has the most readily available and comprehensive data on customer satisfaction in the travel and hospitality industries. These data are the result of an annual study (since 1993) by *Frequent Flyer/J. D. Power and Associates Airline Customer Satisfaction Study—U.S. Flights.* The study is based on a survey of frequent travelers who make, on average, more than 25 trips by airline per year. The study measures the relative importance of each of 10 components of customer satisfaction and the performance of nine major U.S. carriers in each of the component categories. The components, ranked by relative importance, and the leader in each category for l995 are presented in Table 30.6.

The International Air Transport Association (IATA) conducts customer satisfaction performance surveys among transatlantic long-haul passengers on the major airlines between North America and Europe. Although individual airline scores are confidential, it is possible to find interesting aspects of overall performance from aggregate data IATA provides.

PROGNOSIS OF QUALITY IN THESE INDUSTRIES

Dramatic Changes in the Organization of Work.   In the years ahead, enterprises in the travel and hospitality industries will dramatically adjust the way they work to achieve quality, productivity, and profit. Rather than putting the needs of the organization first and then motivate the work force to adapt, they will first address the social needs of the work force to increase their energy, attention, and commitment to the company mission. The social needs are described as the six critical human requirements (Cabana 1995): (1) a sense that people are their own boss, (2) opportunity to learn on the job and keep on learning, (3) an optimal level of variety, (4) mutual support and respect, (5) a sense that one's work is meaningful, and (6) a desirable future. These needs are best addressed collectively by self-directed work design and control, i.e., by self-directed work teams. A *self-directed work team* is a small group with a common goal. It is enabled and allowed to make decisions, with the understanding that the decisions must be by team consensus. Only the group can succeed or fail. Rather than relying on one person, a manager, for leadership, each team member masters some management functions, and team members learn to rely on each other. The responsibilities of self-directed work teams may include identifying customer needs, designing and improving the way work is done, setting goals and monitoring progress, scheduling and planning the work, managing budgets and profitability, and designing, producing, selling, and distributing products and services. The self-directed approach is of benefit to the workers and to the organization in terms of the quality of the work performed. Furthermore, managers have more time than ever to work on new initiatives. Self-directed work teams also bring on another shift in thinking. The work force becomes a group of multiskilled individuals performing broad, meaningful duties rather than unskilled, easily

replaceable people in narrowly defined jobs. Not surprisingly, the more skills workers learn, the more desirable is their future.

Several organizations in the industries have begun to experiment with self-directed work teams. Marriott Hotels, Resorts and Suites uses a self-directed work team approach in its New Jersey Reservation Office. As a result, the performance of the office has improved, especially in reducing the number of abandoned calls.

The Ritz-Carlton Hotel Company has allowed its hotels to reorganize for improved quality productivity and profit. Their hotel in Tysons Corner, Virginia, converted each and every work area from a traditional hierarchy to a self-directed work team over a 2-year period. Since self-directed work teams are vulnerable to overemphasizing their part in the organization, the hotel connected the self-directed teams into five seamless process teams. These process teams were based on the way customers came in contact with the hotel: (1) prearrival team, (2) arrival, stayover, and departure team, (3) dining services team, (4) banquet services team, and (5) engineering and security team. As a result of these efforts, the hotel has made significant improvements in quality, productivity, and profitability.

Emphasis on Process Management.   The needs of the organization also will change. Travel and hospitality organizations will place more emphasis on process management as part of a strategy to adapt to change and to achieve better quality, productivity, salability, and higher profits.

Threats of an Electronic World Where Efficiency Rules.   A business scenario exists, in the view of many futurists, where the growth of communications technology and the overriding concern for efficiency create the conditions for a virtual corporate office space (Cleveland l996). The travel and hospitality industries would be permanently affected should this scenario dominate the future. The reasons for this are explained as follows: New technology such as the hologram will be available by the turn of the century. A *hologram* is a real-time, three-dimensional laser image that can be projected to another location. This means that people can be in contact with each other electronically but are not in physical proximity. People will be able to choose where they do their work, such as their home. With the virtual office at home and the ability to contact coworkers or customers virtually, travel will decrease, hotel nights will drop considerably, and people will decrease the number of miles traveled each year.

The likelihood of this radical change is great because the unrelenting demands for cost reduction, high efficiency, innovation, and constant change are universal. With people working at their homes, organizations will close their offices. This can occur because your digital screen does not just connect you to the other person's office, it takes you down the hall of the virtual office so that you make the kinds of contacts you did in l996.

The same futurists contend that the realization of this efficiency scenario may be limited because people will feel disintegrated and distressed. The stress and strains of this efficient electronic world could cause the return of a relatively familiar office in which the "human factor" dominates. In any event, the long-term business strategy of the travel and hospitality industries should address these powerful future forces.

GOVERNMENT SERVICES: REINVENTION OF THE FEDERAL GOVERNMENT

Al Gore

THE COMPELLING NEED TO TRANSFORM GOVERNMENT

As President Clinton has told the nation, he and his team have worked hard since 1993 to create a leaner, but not meaner, federal government, one that works hand in hand with states, localities, businesses, and community and civic associations to manage resources wisely while helping those Americans who cannot help themselves. In January 1996, the President stated, "We know big government does not have all the answers. We know there's not a program for every problem. We know, and we have worked to give the American people a smaller, less bureaucratic government in Washington. And we have to give the American people one that lives within its means. The era of big government is over. But we cannot go back to the time when our citizens were left to fend for themselves."

For the first time in a generation, we live in a balanced-budget age, and although we may disagree on the route of achieving this objective, we share a common destination. The budget will be balanced. This new environment, together with the birth of the information economy, the death of the Cold War, and an assortment of end-of-the-century jitters, has raised an old question with a new sense of urgency: How should the federal government operate?

President Clinton identified this question early in his first term of office, and 3 years ago he asked me to begin working on it. I'm proud of what our federal employees have done to reinvent government. With their help, their ideas, and their leadership, we are eliminating 16,000 pages of regulations. We are implementing the suggestions that federal employees who work on the front lines have been providing to us, suggestions that have never before been heard clearly on a sustained basis, and

indeed have sometimes not even been offered because of the fear that those who suggested changes might somehow be subject to retaliation. However, by hearing and implementing their suggestions during Phase I of our reinvention efforts, we have created the smallest government since the administration of President John F. Kennedy. Indeed, we have reduced the size of the federal work force by more than 350,000 positions from 1993 to the present. Because of our efforts and our partnership with federal employees, the government work force as a percentage of the civilian work force is now smaller than it has been since 1933.

We haven't just shrunk the size of the government. Again in partnership with federal employees, we are actually making it work better. We've got a long way to go, and we understand that very well, but we have made progress, and we're beginning to make even more rapid progress. For example, the Federal Emergency Management Agency no longer has the reputation for being slow and bureaucratic—it is now renowned for its assistance in response to disasters, and is praised on a bipartisan basis every time it is called upon to respond. The Social Security Administration now gives world-class service to our senior citizens. The Small Business Administration has reduced its size, cut its paperwork dramatically, and increased its loans. Compared to the steady growth of the bureaucracy year-in and year-out, to which our country was formerly accustomed, these recent achievements since 1993 represent a new pattern and are remarkable.

ROLE OF THE PRESIDENT'S MANAGEMENT COUNCIL

Agency leadership in implementing our efforts to transform government has primarily been provided by the President's Management Council (PMC), a new organization established by President Clinton in 1993, when he began his first term of office. The President asked me to serve as Chairman of the PMC, which is composed of the Chief Operating Officer of every Cabinet department and several other agencies. They, in turn, have directly advised the agency head regarding the agency's overall management needs, and have directed the formulation of specific agency plans for transformation. Members of the PMC have been responsible as well for implementation of the administration's general management reforms associated with the reinvention of government. These general reform efforts are designed to improve customer service, streamline the personnel, procurement, and budget systems, analyze field office structures, and reduce the size of the federal work force, while ensuring more efficient and effective operation of the large systems which carry out the agency's primary mission.

The PMC has worked closely with employee representatives and associations of government managers to make labor-management partnerships a reality. They have also worked closely with senior federal management officials, as well as with members of Congress, to analyze agency plans, systems, operations, and outcomes associated with these reforms. On behalf of the President's Management Council, the Federal Quality Consulting Group[1] was asked to develop guidance and training materials in order to provide consistency in agency quality management efforts with the criteria specified in the Malcolm Baldrige National Quality Award used in the private sector, and similar criteria used in the Presidential Award for Quality. Senior federal executives on loan to the Federal Quality Consulting Group continue to provide this guidance to agencies and assist them in their reinvention efforts.

THE FIRST PHASE OF REINVENTING GOVERNMENT

In past years, debates about government programs were usually dominated by discussions over how much the government should spend, rather than on what the spending would accomplish. For most

---

[1]The Federal Quality Consulting Group may be reached at 1700 G Street, N.W., Washington, DC 20552, telephone (202) 632-6068.

Americans, however, the debates were largely academic, since for well over a decade the public has been saying that government simply is not working. Clearly, dramatic steps had to be taken to restore public confidence in government.

The first phase of reinventing the federal government occurred during the President's first term of office. It was characterized by agency zeal as voluminous rules and regulations were read, consolidated, or eliminated. Agencies tried a wide variety of service quality initiatives, and conducted training and skills development on the part of managers and supervisors primarily, and new quality initiatives began to take hold.

Initial steps in quality management were designed to make government smaller, better managed, and more efficient. The administration announced our vision for the federal government, "To create a government that works better and costs less." We called the first phase of reinventing government "Creating a Customer-Driven Government," and used the following model for agency quality improvement initiatives.

This model is flexible and allows agencies to choose from a variety of service quality approaches to the establishment and evolution of a quality organization. As indicated by the "Learning and Improvement Cycle" of the model in Figure 31.1, we realize our efforts at improvement must be ongoing.

THE SECOND PHASE OF REINVENTING GOVERNMENT

Americans expect and deserve commonsense government—a government that performs well, uses their tax dollars wisely, views them as valued customers, does not impose excessive burdens, and makes a positive impact on their lives when it addresses such problems as crime and poverty and the challenges of employment and education.

Consequently, during the second phase of reinventing government we initiated five basic steps to achieve reform and decide how the federal government will operate in the future:

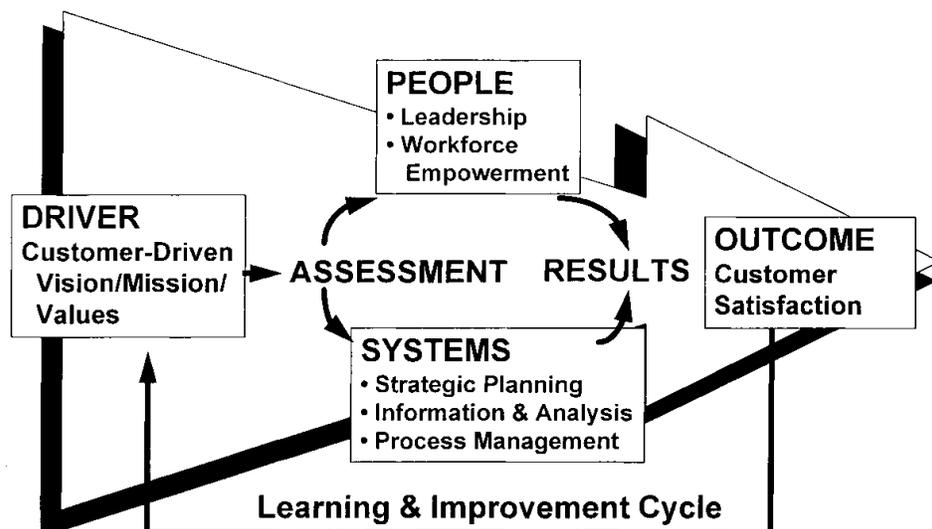
1. Improve customer service dramatically
2. Increase the use of regulatory partnerships
3. Create performance-based partnership grants
4. Establish single points of contact for communities
5. Transform the federal work force


FIGURE 31.1 Creating a customer-driven government—transforming both culture and systems.

Improve Customer Service Dramatically.   The first step in reforming government and achieving quality organizations in a balanced-budget age was critical. It was designed to restore America's confidence in the federal government. On March 4, 1996, I pledged to the American public on behalf of President Clinton that the federal government would immediately begin to deliver visible, recognizable, and measurable improvements in customer service. For example, a commitment made by the Passport Office in the U.S. Department of State resulted in shrinking the long lines for service.

Agency commitments to transform their operations and services will be posted in the Internet to make it easier for taxpayers to hold us accountable. We want to hear from taxpayers about their experiences in receiving services from federal agencies and departments, and specifically with regard to how we're doing in keeping the commitments that are posted on the Internet. Our address is www.whitehouse.gov. Look in the "What's New" section, and you'll see the commitments.

During Phase I of reinventing government, when we first started talking to government agencies about customer service, very few of them really understood what we meant by the phrase "customer service." Frontline employees viewed customer service as keeping their supervisors happy, and the culture of the organization has tended to reinforce that view in the past. Customer service for many heads of agencies meant pleasing Congress and particularly the appropriations subcommittees of Congress. Entire federal programs were designed and implemented without ever really finding out what the customers wanted in the first place. And since government had little idea of who its customers were, the idea of setting measurable standards for customer service was really a strange concept.

Working with federal employees, we have changed that. We went out and looked at how the best in business delivered first-rate customer service, and we've started doing the same for our customers. For the first time, most government agencies have established and published customer service standards, and they have engineered their processes to figure out how they can meet those standards and steadily improve on them. Now, just as Federal Express customers know that they're guaranteed to have their package delivered overnight, taxpayers going to a Social Security office will know that they will be seen within 10 minutes. Students calling for information on direct loans will know that they will get through to a live human being within 35 seconds.

These and over a thousand other measurable standards mark a dramatic change in the way government views and treats its customers. We're seeing the signs of success already. For example, an independent survey concerning the provision of 800-line telephone service rated a regional office of the Social Security Administration higher than any American business competing in that category.

We have recently established one-stop Internet access to the federal government through the U.S. Business Advisor. We're redesigning the telephone book blue pages so that people will be able to look under "P" for passports, not "S" for State Department. We've challenged agencies by setting a goal that "everyone in America will know" that government service has improved and continues to get better.

Increase the Use of Regulatory Partnerships.   The second way we're transforming government is to make partnerships with the private sector the rule and not the exception. So far, such partnerships have mainly been in the form of pilot projects scattered through the regulatory agencies. We are bringing these partnerships into the mainstream of our regulatory philosophy.

The vast majority of Americans believe that their government has an important role in ensuring their safety and protecting their environment. Government oversight has helped make our workplaces safer and kept our food safe and healthy. Strong enforcement of environmental statutes has helped to restore the health of rivers and has brought back the bald eagle. Our challenge is not only to maintain that progress, but actually to do better.

We know that regulatory agencies can do better by focusing on results as well as process. We've seen it work. In Maine, the Occupational Safety and Health Administration (OSHA) realized that all of its fines and penalties on businesses that were not complying with workplace health and safety rules were producing a lot of income, but they weren't producing any improvement in workplace safety. So they abandoned the old way of doing business and formed alliances with industry management and labor, and focused on results. They have identified and corrected 14 times as

many hazards as they did in the old way. Productivity is up, and most importantly, injuries in the workplace are down by one-third in their jurisdiction.

In Miami, the Customs Service used to force companies to spend as much time on government paperwork as on their business. One company had to fill out 700,000 forms each year. Then, Customs sat down with these firms and ascertained what was really needed, and what wasn't. Now that company files one form per month. By streamlining work processes and seeking better results, Customs has been able to confiscate more illegal drugs—seizures are way up—while at the same time helping legitimate businesses grow. Meanwhile, the people who were waiting in lines, after getting off international airline flights, are moving through much faster than before. As a matter of fact, their complaint now is that they're having to wait to get their baggage, and so the airlines are getting their baggage handlers together and challenging them to reinvent the way they handle that job so they can be good enough for government work!

Through programs such as Project XL, Green Light, and 33/50, we have seen the Environmental Protection Agency and hundreds of companies team up to keep a billion pounds of pollutants from being emitted into the air. We've said, "If you can get the job done cleaner and cheaper, then go to it. And throw the book away. Give us a way to measure your progress toward exceeding the goal you've committed to exceed."

Why are these partnerships working? Because they are focused on results. The goal is to reduce injuries, stop drugs, and cut emissions, not to make sure that businesses are penciling in the proper lines on the proper forms. These partnerships are working because government and industry are joining hands, not locking horns. The government recognizes that many corporate leaders share the same goals and are interested in working cooperatively to achieve them. And because they know their businesses far better than the government ever could, they also know best how to attack their own problems, using all of the innovations characteristic of the private sector. Treating them as adversaries wastes those positive inclinations, and it stretches federal resources thin instead of focusing them on the biggest problems.

These partnerships will be new for many of us in government and in industry. Old habits are sometimes hard to break, and this new approach will not be without some difficulties. However, we've seen it work, and we're going to make it happen.

Create Performance-Based Partnership Grants.   The third step in reinventing government in a balanced-budget age was to forge new relationships with communities. On March 4, 1996, I announced the administration's decision to require that every time a grant program comes up for reauthorization, we will ask Congress to turn it into a performance partnership and, if necessary, consolidate it with other related programs.

So far, more than 600 separate federal grant programs, each with its own rules and requirements, have participated. We're going to shift the focus again from process to performance. Together, federal, state, and local governments will set the goals, and the communities will decide how best to meet them.

The goals are to produce better results, to increase accountability to the public for outcomes, to reduce red tape and micromanagement, and to provide greater flexibility in how services are designed and delivered. For example, among these 600-plus grant programs are a number relating to child immunization. Some provide funds to help get children to the clinic, so they can receive the vaccines that their parents have learned about. However, the goal of the child immunization program should be to increase the percentage of two-year-olds who have all their shots.

The President has called for the consolidation of 271 diverse grant programs into 27 performance partnership grants. We have created 105 "Empowerment Zones" and "Enterprise Communities" to focus on local needs, and we've started signing agreements with states to create these new partnerships. We entered into such a new partnership with Oregon several years ago, to promote healthier children, more stable families, and a more highly skilled work force. I have recently visited Connecticut to enter into a similar partnership to improve that state's poorest communities through economic development and neighborhood revitalization approached in a brand-new partnership context. We are now in the process of expanding these partnerships across the country.

Establish Single Points of Contact for Communities.   Several years ago I announced that for every single community of more than 150,000 residents, the Department of Housing and Urban Development will select a person to serve as the single point of contact. For each of these communities we're going to give the legendary "nameless, faceless bureaucrat" a name and a face recognizable in that community—an individual who can facilitate the solution of problems that these communities have which relate to the federal government.

Communities have interactions with the federal government on scores of different issues, ranging from "Head Start" to highways. To get their work with the federal government done, communities had to go door to door. Why? Because these interactions are dictated now by the way the federal government is structured, and not by what the communities need. There is no focal point for dealing with the communities' issues in the executive branch of government. We are consequently now establishing more of these community focal points.

Transform the Federal Work Force.   The fifth step in transforming the federal government is to transform the federal work force itself. Our administration's reinvention efforts have saved $137 billion and cut the federal work force by over 350,000.

To achieve this, we have submitted to Congress legislation to vastly expand the demonstration authority in civil service law. This expansion of authority will allow large numbers of government agencies to design personnel systems suited to their mission. Again, I do not anticipate any partisan opposition to this particular step. As any CEO can tell you, reinvention will be only as successful as the partnership with workers. Let me emphasize that our federal work force is one that any private sector executive would be proud of. However the personnel system they toil under is not.

We have as diverse a set of missions as any conglomerate—more so—but we use a personnel system which by law applies a single set of rules to all federal employees, from patent attorneys to park rangers. This "one-size-fits-all" approach, designed in the last century, simply will not meet the challenges of the next century. No corporation would operate this way. For example, General Electric makes light bulbs, secures mortgage loans, and leases cars. G.E. would not try to squeeze such a diverse cadre of workers into a single personnel system, and neither should the federal government.

We need a new model, decentralized and focused on the mission of each organization. It should hold federal workers to the highest degree of accountability, and give line managers more authority over personnel decisions. This is why we want to change the law and liberate people to build a government that does work better and cost less.

THE THIRD PHASE OF REINVENTING GOVERNMENT

Today the federal government is proud of having the longest-running and most successful government reform effort in history. This has been accomplished through partnerships in and out of government, and with the application of new technologies. The key to our success has been the initiatives and applications of reinvention policies by the people on the front line, providing service directly to the American people. For the first time in history the federal government has measurable standards for serving the public. We have safer workplaces, less crime, easier buying practices, faster drug approvals, and faster delivery of mail. We have cut unnecessary regulations and outdated programs, trimmed our own work force, and saved taxpayers billions of dollars. Our reinvention efforts have been renamed the National Partnership for Reinventing Government, to reflect our commitment to our vision of "America at Our Best."

I have had the privilege of seeing the workings of government through the lenses of both Congress and the White House. As the executive branch moves into a new balanced-budget world, the Congress must join us. This may mean conducting some reinventing inside Congress itself.

Members of both parties have talked about reforming the Congressional committee structure to align congressional oversight more squarely with executive branch organization. A private sector company that reported to multiple boards of directors would have real difficulty in defining its mission and improving its efficiency. Yet many of our executive agencies report to multiple committees and subcommittees of Congress. While we recognize that some overlap is inevitable, the current situation is ridiculous. For example, the Environmental Protection Agency now reports on a regular basis to 28 committees and 43 subcommittees. There are 19 congressional committees and 33 subcommittees that have jurisdiction over federal programs for children and families. Surely there is room for significant streamlining and improvement here.

Now that we set multiyear goals for overall budgeting, do we really need to stick to single-year appropriations? Can we move to more multiyear appropriations so that government managers have a more stable environment in which to plan and to invest, and so that all of the local and state governments that wait each year for the federal government to conclude its annual appropriations can also have more flexibility to plan ahead? Surely the answer must be yes, even though I know these are contentious issues.

Both parties in Congress have put forward some interesting and sound reform proposals. However, the point I want to make is that Congress must join us in the reinvention effort. In 1994 Congress passed and President Clinton signed the "Government Performance and Results Act," which provides the framework for strategic planning for almost all federal agencies. This historic piece of legislation, which had bipartisan support, sets us on a path to a performance-based government. What Congress has passed for the executive branch should be matched by its own internal re-examination. Only by working together can Congress and the executive branch, along with the states and local governments, achieve the reinvention of government in a balanced-budget era, and the provision of public services necessary for the American people.

Increase the Use of Information Technology.   Today's information technology is the great enabler for reinvention. It allows us to rethink, in fundamental ways, how people work and how we serve customers. For example, in Miami, compliance officers of the U.S. Customs Service can use their computers to compare passenger manifests with up-to-the-minute risk lists. Before the planes land, officers identify passengers who will be the focus of their inspections. Similarly, on the World Wide Web, the Social Security Administration lets you order your personal benefits estimate by filling out a form on screen, taking only 5 minutes to do so.

Not all technology applications require high-end components. More Americans contact the government by phone than any other way, so the Internal Revenue Service built Telefile to allow 20 million filers to submit their 1040EZ tax forms using touch-tone phones. It takes 8 minutes, is paperless, and has an error rate a fraction of that found on paper returns.

The potential payoff from technology is huge, but not automatic. Workable solutions can be had at reasonable costs by following these principles, derived from the best practices of the private and public sectors:

- Don't automate the old process, reengineer. The new technologies bring new possibilities, like putting services on the Web and letting customers get them when they want.

- Buy off the shelf. Commercial products provide big variety and capability, and new products are added every day. It almost always makes sense to give up a few performance features to get something that costs less and has been thoroughly tested.

- Check on investments. Tracking not just costs and schedules, but whether the new technology is paying off as promised, is critical in spending the taxpayers' money and in applying good management principles to large and small government programs.

- Integrate information. Many agencies duplicate data collected by others. For example, 40 agencies gather trade information. We are constantly looking for chances for agencies to share workload and data, thereby reducing the number of federal programs and activities, while providing outstanding service to our customers.

Focus Regulators on Compliance, Not Enforcement.   The President has issued directives which told agency heads to follow the following five strategies:

Cut obsolete regulations

Reward results, not red tape

Visit grassroots partnerships

Negotiate, don't dictate

Reduce regulatory reporting

The first strategy deals with what is in the rulebooks. We are taking steps to get rid of what's outdated, and rewrite the rest in plain English. We believe that better compliance occurs when people understand what's expected of them.

The remaining strategies deal with what is most important in reinventing regulation—improving the relationships between regulators and the regulated community. Experience shows that most businesses and communities do want to comply with regulations and will do so if they can figure out what they're supposed to do. Agencies are proving that, working with new partners, agreeing on the goals, allowing room for innovation, and providing all the help possible to those who want to comply. We are finding that because regulatory time is no longer being wasted on the good guys, agencies can better focus their attention on the few cheaters.

CREATING A MORE BUSINESSLIKE GOVERNMENT

We have asked agencies to take steps to make their agency programs and operations more businesslike. In order to help them do so, I have approached many of our country's finest companies, and have received guidance from their CEOs as to how a more businesslike government may be achieved. Help from such companies as the Cadillac Division of General Motors, Disney, Federal Express, Harley- love to my horse is an hour awa and Davidson, Ritz-Carlton, Wal-Mart, and Xerox enabled us to take first steps in creating a businesslike environment.

All this help from America's best companies is paying off for the American people:

• Social Security Administration 1-800 telephone service has been ranked the "best in business."

• General Services Administration is managing inventory like General Electric.

• National Aeronautics and Space Administration's Martian explorer phones home through an off-the-shelf Motorola modem.

• U.S. Department of Agriculture's Rural Development Agency runs its mortgage portfolio just like Citicorp.

• Food and Drug Administration is partnering with medical researchers to get safe, effective treatment to the people who need it really fast.

We believe that Americans are already receiving good service and good value from top American companies. These same Americans deserve and have the right to expect no less from government. We are grateful that America's best companies are helping us to deliver in the same outstanding manner.

IN CONCLUSION

In conclusion, as we continue to reinvent the federal government, we know that the challenge facing us is very large but not impossible to conquer. We have singled out a few agencies for special attention, those mentioned in this report, to provide an idea of the range and type of services currently

being reengineered. The challenge is great, but the desire of federal employees and agency constituents is even greater: to achieve a more customer-friendly, streamlined, and effective government. We must work together with leaders from business, state and local governments, and the university community if we are to succeed in the challenge of reinventing our government.

SECTION 32
HEALTH CARE SERVICES

Donald M. Berwick
Maureen Bisognano

INTRODUCTION

Few industries have changed so radically in structure, focus, and process as health care in the United States has in recent years. Integrated delivery systems have replaced hospitals as the powerful force in health care delivery. The aim of the system has moved from caring for patients with disease and injury to improving the health of entire communities. Process redesign has produced changes in the kinds of care provided, the site in which care is received, and the extent to which the patient is an active participant in the plan for care.

Health care is America's second largest industry, surpassed in total expenditures only by education. A trillion dollars changes hands each year in the purchase of medical products and services, with care being given in over 6300 hospitals, 1000 health maintenance organizations, 720,000 nursing homes, and 200,000 medical offices. Health care involves the work of over 600,000 physicians in the United States, 1,900,000 nurses, 155,000 dentists, and hundreds of thousands of others in a myriad of allied health professions and support services.

The complexities of the system are evident in a comparison with other industries; a manufacturing company employing 4000 people will categorize staff in about 50 job titles; a typical health care organization of 4000 will utilize 500 titles. This specialization, originally designed to improve quality, now creates multiple handoffs for any patient procedure and contributes to a breakdown in quality processes.

The economic scale of American health care dwarfs that in other countries. On a per capita basis, Americans spend almost 40 percent more on health care than in the next most costly health care system (Canada's), and over twice as much as in many other systems in the Western world. Over 15 percent of America's Gross Domestic Product goes to health care, with the comparable figures being 11 percent in Canada, 8 percent in the United Kingdom, and 6 percent in Denmark. Throughout most

of the last half of the twentieth century, American health care costs grew at a much faster rate than did the economy as a whole. In total dollars, the bill for health care doubled in the decade of the 1970s, and then doubled again between 1980 and 1989. On average, the medical price index, the price of a "market basket" of medical products and services, has risen 2 to 3 times faster than the consumer price index during the last third of this century. One health care economist in 1970 wrote of his dismay and disbelief that health care costs might soon rise to over 7 percent of the GDP in the United States, little imagining that, by the end of the century, that figure would more than double.

Yet despite its immense scale, American health care falls short of the social need it aims to fulfill. Because of anomalies in the financing system for U.S. health care, as of the late 1990s, over 30 million Americans lacked insurance as a means to pay for their care, and simple indicators of population health place Americans surprisingly lower in health status than many other populations in the developed world. The United States ranked twenty-first in the world in infant mortality rate (deaths in the first 30 days of life) in 1995, and American life expectancy is 3.4 years shorter for men and 2.8 years shorter for women than that of the best in the world, Japan. Surveyed about satisfaction with their health care, Americans routinely give the system a dichotomous rating: They rate *their own* doctors highly, but express strong dissatisfaction with the quality and cost of American health care *in general.*

INITIATIVES FOR CHANGE

Discontent with the high cost and variable outcomes of health care has led, in the last quarter of the 20th century, to a number of initiatives in public policy, finance, and organization of care—all in an effort to measure, control, and improve the value of care, and to increase the accountability of health care providers to the public and to insurers. Important examples include the following:

Prepaid Financing of Care.   Provider organizations are given a prospective annual budget to meet the needs of enrolled populations of patients, instead of simply charging insurers without limit for care as it is consumed. Such prepaid financing is supposed to change the incentives for providers of care from "doing more" (under fee-for-service payment) to "conserving resources" (under prepayment), and to shift the risk for the increases in cost from the payor to those providing care.

Health Maintenance Organizations.   "Managed care" systems are designed as systems of health care linked to provide health care services to members for a periodic fee, regardless of the extent of services required. In managed care systems there is often an emphasis on improving the health status of the member population to decrease the cost of care for preventable chronic disease or injury.

"Gatekeeping" and Other Forms of Utilization Review.   Providers of care must justify to insurers their choices to use expensive tests, surgery, specialty referrals, and so forth, especially if their patterns of use deviate from prevailing patterns among their peers. The controls on resource consumption are placed in the hands of a clinician who assumes the role of care manager and who orchestrates the level of testing and service delivered to the patient.

Innovations in Programs of Care.   For example, a major shift in *site of care* has occurred in the past several decades, as procedures and tests, formerly done only in inpatient settings, are now performed safely and at lower cost in outpatient offices and clinics. Only 15 years ago, cataract surgery required a week-long hospitalization and a quiet recovery period at home. Today, advances in technology and process changes permit such surgery to take place in physician offices or surgery centers, requiring only a 2-hour total visit/procedure time. Even more exciting innovations have occurred in outreach programs extending technical care into patients' homes, and in new communicationmethods to involve patients more directly in decision making about their own care, such as choosing between medical and surgical management of prostate disease and breast cancer. Telemedicine links special-

ists with rural physicians in remote areas and allows for the latest in diagnostic capabilities to reach patients who would otherwise need to travel for such access.

"Report Cards" and Measurement Systems.   The performance of health care organizations is assessed by standardized instruments, and often the results of measurement are made public to help inform the choices of payers and patients. Business coalitions in key cities across the nation have accumulated comparative cost and outcomes data to aid business leaders in the decisions on which providers will care for employees. In many companies, the cost of health insurance for employees is the number one increasing cost and these data are considered a key tool in controlling what was considered an "uncontrollable" cost.

Health care leaders are also using these comparative data and internal "balanced score cards" to define organizational priorities for change and to demonstrate progress to key stakeholders.

FOUR ARENAS OF IMPROVED PROCESS

Health services research has demonstrated major opportunities for improvement of the performance of health care processes in at least four arenas: health status outcomes, service characteristics (measures of satisfaction and ease of use of the system), breadth of access (including equity among racial and socioeconomic groups), and levels of waste.

Health Status.   With respect to health status, Americans are not nearly as healthy as they could be, given available scientific knowledge. Unintentional injuries are the major cause of premature death, and many are preventable through simple steps such as wearing automobile seatbelts, using helmets when riding bicycles or motorcycles, and fencing off swimming pools. Simple counseling by health care providers can lead many people to change their life-style choices in a more healthful direction. Almost half of all deaths annually in the U.S. are caused by alterable choices in life-style and behavior. Tobacco use, alone, accounts for 19 percent of deaths in this country, by inducing heart disease, cancer, and respiratory disease (Table 32.1).

Technical medicine also could be safer and more effective than it is. Adverse drug events—complications from medication use—occur in over 6 percent of all hospital admissions, and many are due to avoidable system errors. Unnecessary surgery and testing add hazards without benefit for

TABLE 32.1   Actual Causes of Death in the United States in 1980

Causes	Deaths	
	Estimated no.	Percentage of total deaths
Tobacco	400,000	19
Diet/activity patterns	300,000	14
Alcohol	100,000	5
Microbial agents	90,000	4
Toxic agents	60,000	3
Firearms	35,000	2
Sexual behavior	30,000	1
Motor vehicle	25,000	1
Illicit use of drugs	20,000	<1
Total	1,060,000	50

many patients. In one study, for example, more than half of the operations done on carotid arteries were unnecessary according to scientific literature. Rates of "inappropriate" care (care that, on scientific grounds, cannot help the patient) range between 10 and 50 percent for many frequently performed procedures. Cesarean section rates in the United States rose from 5 percent in 1970 to over 23 percent in 1995, without any strong evidence of clinical benefit to mothers or infants. Such inappropriate care both raises costs and introduces risks.

Service Characteristics.   Service characteristics of health care have also lagged behind those in other industries. Waiting times in health care systems—both waits for appointments and waits on-site at the time of appointment—are often very long, and many care-giving institutions experience frequent complaints from patients and families because of incomplete communication, impersonal encounters, and lapses in continuity of care. An average physician office visit takes hours and involves care by several staff members and 23 different procedural steps. The information systems in health care organizations often add to the complexity. They have not been utilized, as they have in other service industries, to produce a sense of confidence and friendliness by assuring that all appropriate information is cascaded to key staff in anticipation of patient needs.

Breadth of Access, Levels of Waste.   Access to care in the United States is generally good, but not for all portions of the population. The health care insurance system allows over 30 million Americans to remain without health insurance. Some are very healthy, and do not notice. But others are at high risk of suffering devastating health care bills, or delay their own care imprudently because of inability to pay. For lower income groups, the gaps in access may be severe. Almost one in four pregnant women in America's inner cities lacks adequate prenatal care.

Above all, the *costs* of health care in America are far from optimal. We have already noted above how great is the difference in per capita health care expenses comparing the United States with other developed nations. Some of that difference may relate to features of the U.S. system that are not available in others—for example, we have more "high technology" imaging machines and generally newer hospital facilities—but, to a large extent, the higher costs of health care in the United States represent higher levels of waste—costs of poor quality. Compared to other nations, we in the United States do more laboratory tests, use more hospital bed-days, perform more surgery, and use more minor visits to doctors. We tend to use our capital (expensive diagnostic machines, costly hospital space, and equipment) less fully, and we use many more futile interventions in the final stages of life. Unlike other markets, the health care economy is largely "supply-driven." That is, the availability of hospital beds, specialist services, and imaging equipment, for example, appears to be the greatest single determinant of the rate of use of those resources. For historical reasons, the United States has accumulated a larger supply of specialized health care than other countries, and many health economists believe that this is a *cause,* not a *consequence,* of our high rates of use and therefore a cause of our high costs. Most important, this increased use of high-cost care has apparently not led to better health outcomes for Americans.

FURTHER POTENTIAL IMPROVEMENT

The following simple list of 11 major areas for potential improvement of American health care is based on author Berwick's 1994 health service research findings. The list is only a sample; many additional entries would also be supported by available research.

Aim 1: Increase appropriateness of practice.   Reduce the use of inappropriate surgery, admissions, and tests. Important initial targets may include: management of stage I and II breast cancer, prostatectomy, carotid endarterectomy, coronary artery bypass surgery, low back pain management, hysterectomy, endoscopy, blood transfusion, chest x-rays, and prenatal ultrasound.

Aim 2: Increase effective preventive practices.   Improve health status through reduction in "upstream" causes of illness, including especially: smoking, handgun violence, preventable injuries in children, and alcohol and cocaine abuse.

Aim 3: Reduce cesarean section rates.   Reduce cesarean section rates to below 10 percent, without compromise in maternal or fetal outcomes.

Aim 4: Reduce unwanted care at the end of life.   Reduce the use of unwanted and ineffective medical technologies at the end of life.

Aim 5: Rationalize pharmaceutical use.   Adopt simplified formularies, and streamline pharmaceutical use, especially for antibiotics and for drug prescriptions for the elderly.

Aim 6: Involve patients in decisions.   Increase the frequency with which patients participate actively in decision making about therapeutic options.

Aim 7: Reduce wait states.   Decrease uninformative waiting in all its forms.

Aim 8: Reduce, consolidate, and regionalize high-technology services.   Reduce the total supply of high-technology medical and surgical care. Consolidate high-technology services into regional and community-wide centers.

Aim 9: Reduce wasteful and duplicative recording.   Reduce the frequency of duplicate data entry and of recording of information never used in medical record and administrative systems.

Aim 10: Reduce inventory costs.   Reduce inventory levels.

Aim 11: Reduce racial and economic health status inequities.   Reduce the racial gap in infant mortality and low birthweight.

American health care has enormous opportunities for improvement. Despite this, we must acknowledge that American health care is, nonetheless, in many ways the very best in the world. Patients who can afford it come from all over the world to receive their care in American facilities, and the American biomedical research community is the largest wellspring in the world of new knowledge used to improve the effectiveness of treatments. Many leaders in health care systems throughout the world have received their training in U.S. facilities, and many nations, both developed and developing, base their system designs and approaches to the prevention and treatment of disease on American models.

APPROACHES TO QUALITY CONTROL IN HEALTH CARE: HISTORY AND PREVAILING METHODS

Quality of care has been a concern of health care leaders for as long as we have written records of medicine. Quality scholar John Williamson reports the following "quality control" text in Hammurabi's code, dating from 2000 B.C.: "If a physician should operate on a man for a severe wound with a bronze lancet and cause the man's death; or open an abscess (in the eye) of a man…and destroy the eye, they shall cut off his (the physician's) fingers." Standards of ethical conduct were established in the Hippocratic Oath in the fourth century B.C. In the Middle Ages, regulations in regions of France, Germany, Italy, and elsewhere defined who was and was not permitted to practice surgery, obstetrics, and drug prescribing. In America, licensing of physicians to practice began in New York in 1760, and the first American specialty society, the College of Physicians, was founded in 1787.

Arguably, the modern era of concern for quality of medical care in America began at about the turn of the twentieth century. Academic medicine took a major step forward with the publication in 1910 of the Flexner report, which both documented the deficiencies of medical training at that time and set out new standards for the education of physicians based upon a scientific view of the practice of medicine. As a result of the Flexner report, half of the medical schools then active in the United States closed their doors, and medical training thereafter became subject to stringent accreditation procedures.

At about the same time, medical professional organizations began to dominate the landscape of professional certification. Prime among them was the American College of Surgeons (ACS), which undertook, in 1916, an extended project to study quality of care and to develop standards for American hospitals in areas such as medical staff organization, record keeping, and availability of diagnostic and therapeutic facilities. The initial findings in 1919 from the so-called Hospital

Standardization Program were disturbing; only 89 of the 692 surveyed hospitals with over 100 beds had met the new American College of Surgeons Standards.

The work of the ACS, along with other professionally driven efforts at self-inspection, led, in the 1950s, to the formation of the Joint Commission on Accreditation of Hospitals [later renamed the Joint Commission on Accreditation of Health Care Organizations (JCAHO)], which rapidly became the major accrediting body for hospitals throughout the nation. The JCAHO purpose, largely unchanged throughout the years, is to establish standards of care for hospitals and to conduct surveys that teach and promote improved systems of care and safety. The scope of work of the Commission extends from physical plant inspection to medical documentation review to interviews with hospital staff and physicians ascertaining their level of organizational involvement and their capacity to perform effectively and to improve their work. Still today, the triennial accreditation site visit from a JCAHO team is a recurring milestone for most American hospitals. Other prevailing forms of outside inspection include those from state and local health departments to review and enforce regulations bearing on the operations of clinics and hospitals, and regular procedures for licensure and relicensure of doctors and other health professionals, as administered by the state licensing board.

While the Joint Commission, state health departments, and professional boards of registration were developing as the major forms of external quality inspection for hospitals, a set of conventional forms of internal inspection gradually became routine, even traditional, inside the organization of hospitals themselves. These internal surveillance systems, many required by the Joint Commission, consist mainly of committees drawn from the medical staff, each with jurisdiction to review specific components of care process and outcome. Tissue Committees, for example, review organs and tissues removed in surgical procedures. Pharmacy and Therapeutics Committees review medical use and set pharmacy policy. Morbidity and Mortality Conferences, especially in surgical departments, review cases of operative death or complication. To staff these quality control groups, and often also to help prepare for Joint Commission surveys, most hospitals maintain Quality Assurance departments, whose members collect necessary data, prepare documents, and conduct special studies of quality-related issues. Membership is traditionally drawn mainly from nursing backgrounds.

An extensive research literature on quality of care has developed during the century in parallel with these accreditation and inspection activities. Researchers have explored methods of inspection—such as "explicit review" and "implicit review," in the jargon of health care quality assurance. Explicit review consists of reviews of care processes against written criteria. For example, such a review may ask: Did patients with anemia on screening tests receive the correct follow-up laboratory tests according to a preexisting protocol? Implicit review consists of summative judgments by recognized clinical experts rating the adequacy of care without reference to specific, preexisting criteria.

One of the seminal authors in the history of health care quality research, Professor Avedis Donabedian, offered in 1966 what remains the dominant categorical framework defining possible objects of inspection, whether by explicit or implicit means: "structure, process, and outcome." Donabedian claimed that quality assessment could study the resources and organizational architecture of care (structure), the sequences of diagnostic and therapeutic activity (process), or the health status, mortality rate, and functional results of care (outcomes), and that each object of study could shed light of a different type on the overall pattern of quality of care (Donabedian 1966).

The inspection-oriented foundations of so-called quality assurance in health care took a significant step of maturation in the 1970s and 1980s due largely to research at the Rand Corporation, which was employing an experimental design to assess the effects of various forms of health care insurance on the processes and outcomes of care (Brooke et al. 1979; Lohr and Brooke 1984). As an important byproduct of their main research plan, Rand's investigators developed a carefully crafted set of surveys and measures to assess quality. They employed a very broad definition of "quality of care," encompassing patient satisfaction, ease of access, and appropriateness, as well as the more traditional definitions of health outcomes. They broadened the definition of "health outcome" itself, by describing dimensions such as emotional well-being, social and role functioning, and physical comfort, rather than stopping with simplistic, unidimensional measures of health. For example, the instrument analyzes days lost to work and the degree of effective work ability 6 weeks after a surgical procedure in addition to a more introspective measure such as complications at the time of discharge after surgery.

Most important of all, these researchers showed that simple questionnaires and record abstracting forms could have excellent properties—validity, reliability, and sensitivity to changes over time. Colleagues in other research centers built upon this work, producing, by the end of the century, a relatively well-developed tool kit of sound measures of the effect of health care on its customers.

Meanwhile, researchers concerned primarily with the processes of care (in Donabedian's sense of the word) had become aware of large variation among health care practitioners in their approach to diagnosis and therapy. Pathfinding research by Dartmouth Professor John Wennberg (Wennberg and Gittelsohn 1973) showed that, adjusted for the "case-mix" (age, gender, etc.) of the populations treated, rates of use of laboratory tests, surgical operations, and hospital bed-days varied greatly, depending on which doctor, which hospital, and what geographical region, both within the United States and among countries. In one study in the mid-1980s, for example, Wennberg found a variation in rates of hysterectomy in women before the age of 70 years of 350 percent between two cities in Maine less than 100 miles apart.

Wennberg's work, along with the many confirmatory studies that followed, raised interest in the need for *standards of practice* to reduce this unexplained variation. In the last two decades of the twentieth century, a virtual subindustry developed in the United States of both public and private groups who developed and promulgated guidelines and protocols for care, some allegedly based on scientific literature, others on expert opinion, and still others on prevailing practice patterns. Some regulatory agencies seized upon such guidelines as another component for their systems of external surveillance of quality of care, and payers (insurance companies and corporations covering their employees' health care needs) began widespread use of the guidelines to help them decide what care to pay for, and what not. National guidelines for the care of common conditions, such as cardiac chest pain, low back pain, and diabetes, emerged from the work of several federal agencies, as well (see Figure 32.1 for an example).

Using more modern information systems and claims databases, many health care systems have recently begun offering direct feedback reports to physicians as individuals and groups, showing their rates of utilization of resources or, sometimes, their degree of adherence to protocols for care. Reactions to such feedback vary. In some cultures, physicians show fear, wariness, or anger at this apparent invasion of their professional autonomy. Doctors in other systems appear to welcome the feedback, and use it to engage each other in discussion or to set in place personal learning plans. One of the most dramatic examples of successful arrangements for feedback of performance data to physicians has been the work of the Maine Medical Assessment Foundation (Wennberg and Keller 1994), which sponsors peer group collaborations of specialists who receive such data confidentially, and who then use it to explore the causes of variation among the individual members, often with prompt results in reduced variation and correction of outlier patterns.

In summary, the system's familiarity with issues of quality management comes traditionally in its use of various forms of inspection—internal and external—applied both to its work procedures (in guidelines, accreditation, and certification) and, to a smaller degree, to its outcomes. Senior health care leaders mainly seek to assure quality through accreditation of facilities and people, through periodic external and internal reviews against standards, and through the study of unusual events and complications. For the most part, more formal statistical methods for quality control are not in evidence even decades after they have become conventional in many industrial settings. Exceptions include a few technical areas in care, where statistical process control theory makes its appearance in supervisory use of run charts and control charts on a local basis, such as in clinical laboratories (where control charts are used to maintain machine calibration) and radiology units (where graphical methods are used routinely to control the temperature of x-ray film developer solutions).

QUALITY IMPROVEMENT

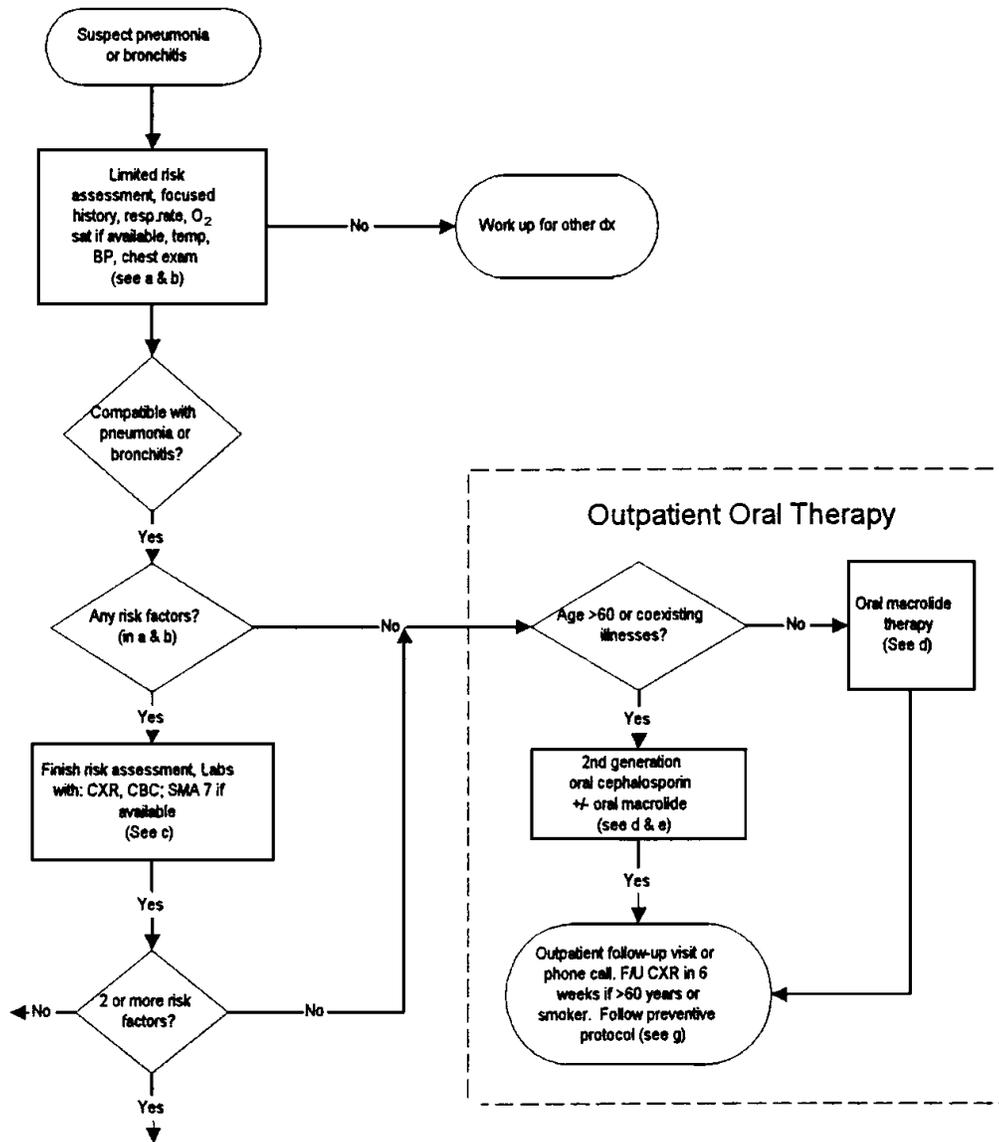
Health care's traditional reliance on external and internal inspection to maintain quality has had its expected effects on performance. The extensive inspections are very costly, but are agreed to, by providers and outsiders alike, as the best they can do. Reviews do tend to call attention to serious


FIGURE 32.1   Guideline for care of patient with pneumonia.

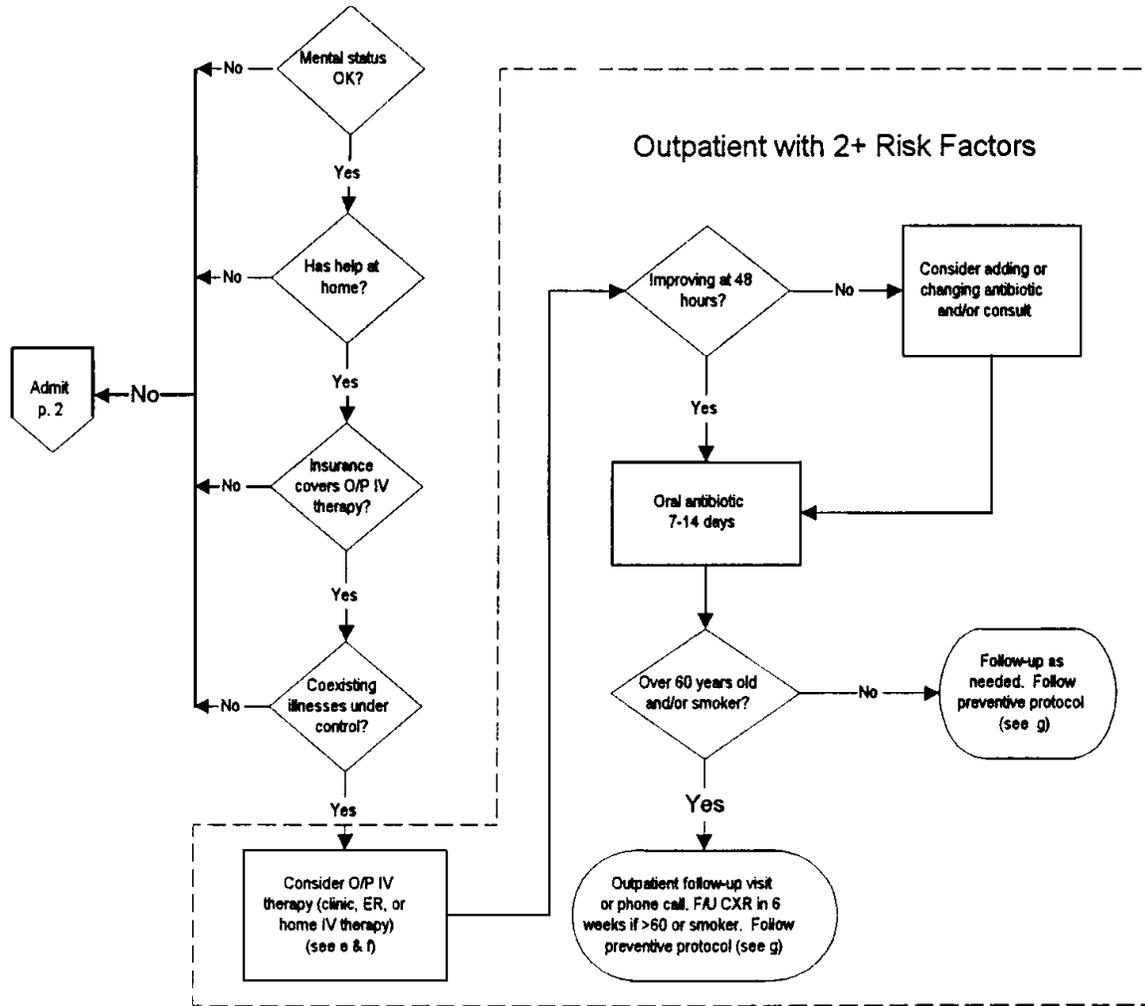
problems, some of which are remedied correctly, and others which invite overreactions that have probably added to the cost and complexity of care without much gain in quality or efficiency. One good example of waste of this type is the accretion of requirements and guidelines for medical record keeping, which have resulted today in a medical record whose size, complexity, and format confound accurate and efficient use. No modern industry outside health care keeps records as wasteful as those in medicine. On the whole, quality assurance in health care is viewed as cumbersome, occasionally revealing, and a necessary evil.

At a deeper level, however, quality improvement concepts, though they have had a second seat to inspection, are not so new at all in medicine. The Joint Commission itself developed and refined an improvement procedure, which it recommended to hospitals for their internal quality assurance procedures, and which incorporates many of the aspects of modern approaches to "plan-do-check-act" (PDCA) cycles (Figure 32.2).

In another example of going beyond the inspection model, John Williamson, the dean of American health care quality researchers, drew heavily upon an adult learning model for his work, and proposed eloquently that quality assurance should involve a "cybernetic" (i.e., feedback) process in which data on performance were systematically used to identify opportunities for further improvement. Williamson's


Risk Factors for the Immunocompetent Patient

(a) <u>History</u>
    Coexisting Illnesses
      - COPD
      - CHF
      - Diabetes
      - Chronic renal failure
      - Chronic liver failure
      - Hospitalization prior 12 months
      - Postsplenectomy
      - ETOH or malnutrition
      - Tuberculosis
      - Bronchitis
    Suspicion of Aspiration
    Age >65

(b) <u>Physical</u>
    Vital signs
      Adult: Respiratory rate >30
      Blood pressure <90/50
      Temperature >101
      SaO_2 <66 or PaO_2 <50
    Acute altered mental status
    Extrapulmonary site of infection (e.g. septic
      arthritis, meningitis, etc.)
    Coexisting illness findings

(c) <u>Laboratory</u>
    Chest film complicated
    - multilobar
    - cavitation
    - effusion
    CBC with differential
    - WBC < 4,000 > 20,000
    - Hgb < 9 or Hci < 30
    BUN & creatnine
    - BUN >20 or Creatinine > 1.2
    Coexisting illness lab abnormalities

Therapies
    (d) <u>Macrolides</u>
      Erythromycin 500 mg po qld x 10-14 days
      Blaxin (Clarithromycin) 250 mg po bid x
        10-14 days
      Zithromax (Azithromycin) 500 mg po 1st day,
        250 mg qd x 4 days
      If mycrolide intolerant, use Doxycycline 100
        mg po bid x 10-14 days

    (e) <u>Cephalosporins</u>
      Oral Therapy: Cefin (Cafuroxime) 250-500
      mg bid po x 10-14 days

If allergic, use Blaxin (Clarithromycin) 250 mg
    PO bid x10-14 days or Cleocin
    (Clindamycin) 300 mg PO every 8 hours
IV Therapy:
    2nd Generation:
      - Kefurox (Cefuroxime) 1.5 grams IV
        every 8 hours
    3rd Generation:
      - Claforan (Cefotaxime) 2 grams IV
        every 8 hours
      - Rocephin (Cefriaxone) 1-2 grams IV
        every 24 hours
If penicillin allergic, give Cleocin (Clindamycin)
    900 mg IV every 8 hours + Nebcin
    (Tobramycin) IV every 8 hours (dose by
    patients)

Notes

(f)   Medicare and Medicaid coverage is complex;
      verify insurance coverage with home IV
therapy agency

(g)   Evaluate for pneumococcal and/or flu
      vaccination with follow-up visit if needed.

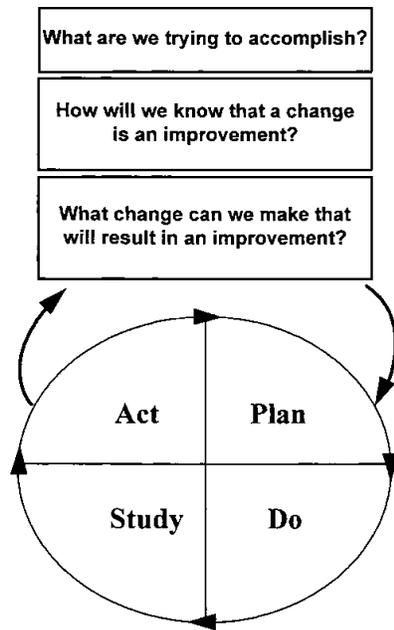
FIGURE 32.1   *(Continued)*


FIGURE 32.2   Model for improvement. (*Langley et al. 1996.*)

recommendations, as early as the 1960s, were clear harbingers of the modern approach to quality improvement and design (Williamson 1971). Nonetheless, through most of the twentieth century, health care quality activities remained those of inspection, with its primary aim of stabilization.

A new emphasis on the opportunity for improvement began to blossom in the mid-1980s. Due in part to the exploratory work of the National Demonstration Project on Quality Improvement in Health Care (Berwick et al. 1990), and in part to the entry of industrial quality professionals into positions of influence on hospital boards and in health care management, health care organizations became gradually more receptive to the ideas that stabilization was not enough, that important improvements in cost and quality could be achieved, and that new managerial methods—quality management—might help in health care, even though these methods had first appeared in other industries.

The early efforts of this sort, such as those documented in the monograph report on the National Demonstration Project, *Curing Health Care,* concentrated largely on classical business processes that appeared also in health care organizations—processes like scheduling, equipment maintenance, and transportation. In one highly successful project in 1987, for example, the University of Michigan Hospitals, working with the help of a quality professional from Corning, Inc., reduced waiting times in its ambulatory care clinic by 89 percent in a few short months. Efforts in improvement at Intermountain Health Care's LDS Hospital in Salt Lake City reduced perioperative wound infection rates from 1.9 percent to 0.4 percent, compared with the national average of 4 percent, and a standardization project to reduce the number of different prostheses used in total hip replacement saved almost $1 million annually, while achieving better functional outcomes for patients (Pestotnik et al. 1996; James 1993; Morrissey 1996).

On the basis of these initial successes, quality improvement methods rapidly spread among dozens, then hundreds, of American hospitals and other health care organizations. Senior management groups organized Quality Councils; formal Quality Improvement teams became commonplace, and more fundamental redesigns of care began to make systems more patient-friendly. In general, the health care models for managing these improvements closely paralleled those in other industries. Perhaps for this reason, the models worked more smoothly in segments of health care that, from the start, looked more "corporate" in structure.

Less-well-developed managerial environments, such as medical staffs in hospitals, office-based medical practices, nursing homes, and interprofessional processes (such as those involving both doctors and nurses) proved less susceptible to repackaged industrial quality improvement methods. Not being employees, and tending to see themselves as customers of hospitals, rather than as partners or employees, doctors, for example, exhibited difficulty understanding and buying into coordinated, corporate objectives. They objected to attending improvement team meetings regularly as contributors, and redesigning their own work to fit better into the system as a whole. The various special languages and turf boundaries that have developed in health care (and that professional certification processes perversely reinforce in an effort to protect quality) have stood in the way of whole-hearted collaboration on systemic improvement. Hospital records still often maintain separate "nursing diagnoses" and "medical diagnoses." Professions sometimes do not even share common lounge areas, cafeterias, or meeting times, and it is still common in hospitals to find "nursing notes" and "doctors' notes" in separate sections of the same medical records.

Thus medical care, perhaps even more than other industries, finds itself susceptible to forms of fragmented efforts that impede systemic vision and optimization of the whole. Even more, old habits of work die hard in medicine. Physicians, nurses, and others are trained in highly conservative modes of work; they often regard changes as dangerous until proven to a standard far more stringent than in other industries. The learning cycles (plan-do-check-act) so characteristic of robust quality improvement can therefore feel especially threatening to health care professionals trained, first of all, "to do no harm."

Like other industries that came new to improvement methods, health care organizations often simply do not seem to believe that significant improvement is possible. Many tend to regard disease outcomes as biologically predetermined, patient expectations for comfort and service as "unrealistic," and excessive health care costs as inevitable. (All these constraints are, of course, quite real, unless the processes of work can be systematically changed and improved on the basis of data—unless, that is, quality is managed actively.)

Yet, despite the cultural barriers, the promise of quality improvement in health care remains great. A deeper look at two improvement projects shows how it can work under the best of circumstances.

Case I: The Northern New England Cardiovascular Disease Study Group.

In the mid-1980s, the five hospital centers and 17 cardiothoracic surgeons performing open heart operations in the three northern New England states (Maine, New Hampshire, and Vermont) began receiving some unwelcome news from the Health Care Financing Administration (HCFA), the federal agency that administers health care payment for Americans over 65 years of age who are covered by Medicare. HCFA's leaders had begun an annual program of feedback to hospitals of their mortality rates for Medicare patients in specific diagnostic categories. Initial findings for the northern New England centers showed wide variation in death rates associated with coronary artery bypass graft surgery—from 4 percent to 9 percent among the five institutions, and from 2 percent to 11 percent among the individual surgeons (O'Connor et al. 1996).

The surgeons doubted the adequacy of HCFA's "case-mix adjustment" procedures, which used variables like age, gender, and comorbidity in a statistical model to "level the playing field" for outcomes of care among the hospitals and surgeons. If Surgeon A's patients tended, on the whole, to be older than Surgeon B's, then it seemed only fair to adjust for the increased risk of surgery in older people before declaring any differences in the two surgeons' mortality rates to be associated with the "quality" of their care. When HCFA published mortality rates, it was natural for the surgeons to suspect that any differences among them were due to unmeasured, extraneous differences in the incoming mix of patients. In defense, the surgeons began a collaboration with a Dartmouth epidemiologist to develop a better case-mix adjustment model using a prospective, comprehensive database.

A strong case-mix adjustment model emerged, able to account for some of the observed variation in death rates, but the residual differences among centers and surgeons remained large even after the new adjustment. By 1989, the cardiovascular surgeons of northern New England faced a problem: *By their own measures* the mortality rate in coronary surgery still varied by over 300 percent among hospitals and more than 500 percent among surgeons.

With remarkable courage and honesty, the surgeons decided to continue their collaboration, but not now for the purpose of playing defense against HCFA's data release. They decided to use their data to support improvement efforts, and they began with comparisons of process. Interdisciplinary teams of surgeons, nurses, open-heart pump technicians, and others made site visits among the institutions (even though those institutions competed with each other for patient referrals) with the aim of studying variations in technical approaches to surgery and surrounding support systems—patient selection, preparation, surgical technique, postoperative care, rehabilitation, and so on. The variation in processes that they observed astounded them, and reinforced their own intent to discover and document "best practices" in care. They found important innovations within their own group in approaches to control of bleeding, reduction of time on the heart bypass machine, use of medications, patient education, and much more.

Within a year, the payoff for this collaborative improvement effort began, and, thanks to their careful system of prospective data collection, the surgeons soon documented the improvements on their own charts. Between 1989, when the first improvement efforts began, and 1991, the Northern

New England Cardiovascular Disease Study Group documented a 40 percent decrease in operative mortality rates for coronary bypass patients in the region, adjusted for case-mix by their own statistical model. What is more, the decrease occurred not only among the hospitals and surgeons originally at the high end of the variation first reported by HCFA, but among all of the surgeons and centers combined. Even the best got better.

Although they eschewed the jargon and formalisms of classical industrial quality improvement, the Northern New England Group used many of the basic, driving principles: benchmarking, measuring process and outcome variables over time, breaking down barriers among centers and departments, setting ambitious improvement aims, maintaining control charts to classify variation correctly, innovating in small plan-do-check-act cycles, and maintaining a system for reflection and learning from their own experiences. (The group met regularly as a whole at least four times a year throughout the project period—and, as of 1996, they are still meeting regularly.)

Case II: Collaborating to Reduce Delays.   Late in 1995, 28 organizations from across the United States and Canada joined in a collaborative improvement effort to reduce waiting times and delays. Frustrated by delays in operating room starts and turnaround times, emergency room waiting, and delayed access to office appointments, these organizations, ranging from community hospitals to major integrated delivery systems, began to test a focused improvement model (Figure 32.3) based on a common aim, to reduce the delay by 50 percent over the course of 1 year.

Teams from each of the organizations met in at a learning session organized by the Institute for Healthcare Improvement. With a specific organizational goal for their own organization in mind, the teams learned from experts in the field about lean process methods and principles for improvement in handoffs and queueing. Each team worked to learn and to apply the concepts to tests of change back in their organization's area of study. Sewickly Valley Hospital tested the following changes in improving operating room flow:

- Scheduling unpredictable cases at the end of the day or in a separate room
- Working to optimize surgery team utilization rather than operating room utilization
- Doing tasks in parallel and converting internal tasks to external to reduce turnover time between cases
- Staggering start times for the first cases of the day (Nolan et al. 1997)

Team members learned from the rapid cycles they tested at their own sites and from the other participant teams as well (Figure 32.4). Two subsequent learning sessions reinforced skills and encouraged many cycles of testing changes that accumulated to substantial progress for a number of the organizations (Nolan et al. 1997).

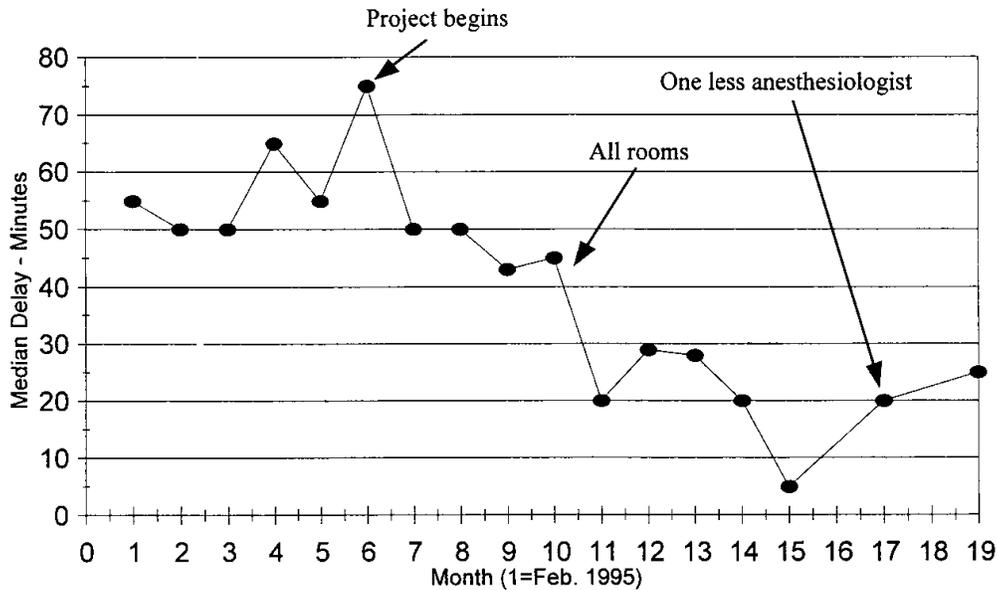
FIGURE 32.3   Framework for improving performance. (*Joint Commission Accreditation of Health Care Organizations.*)


FIGURE 32.4   Sewickley Hospital: median delay 11 a.m. and 2 p.m. (*Nolan and Schall 1996.*)

Delays have long been a chronic symptom within health care systems, and these organizations have demonstrated results now that are being shared internally to widen the reach of the projects in each. The results provided some energy to an industry struggling with substantial cost reductions; these teams proved that customer satisfaction improvement and waste reduction can happen at the same time. These cases and hundreds of other early successful (and unsuccessful) experiences in applications of quality improvement methods in health care settings underline lessons such as the following:

1. *In health care, as in all other known examples of successful improvement, the role of leaders is crucial:*   Improvement must be a led and managed undertaking; it does not happen by accident. This leadership challenge is especially acute in health care organizations, which often have traditions of divided leadership (among nurses, doctors, and administrators, for example) or dysfunctional barriers among staff areas.

2. *Breaking down barriers among functional areas is necessary for effective system changes:* Medical care has a strong tradition of suboptimization of functions, especially where professions (medicine, nursing, pharmacy, physical therapy, etc.) have taken exclusive control over activities within their own boundaries. The advantages of this professional autonomy have been great, as each profession has refined its technical skills and sense of discipline. But the price has been high, as well, as each profession's special vocabulary, technical priorities, physical space, and prerogatives have combined to decrease anyone's ability to view the system of care as an integrated whole. Members of successful health care teams have crossed disciplinary boundaries, and cut new windows on shared processes. Dr. Robert Master, a Boston-based physician, has redesigned care for a challenging population of patients by eliminating these disciplinary boundaries. The patients, severely challenged with chronic diseases such as end-stage neuromuscular disorders, cerebral palsy, and quadriplegia, historically received costly care in hospitals. Their care was directed by specialists, and many lived in medical centers. The pattern of their care was not directed toward independence. Dr. Master changed all that, working with a theory that these patients should be at home, not in hospitals. He created a team of providers, with nurse practitioners taking the lead role in coordination and management. The effect of the role reversal has been dramatic improvement in both cost and quality. Today 87 percent of all medical contacts for these patients occur in the home. Chair cars, ambulances, clinic fees, and specialist charges are almost things of the past. The use of specialists has dropped to $26 per member per month (pmpm), which is about the same as a normal HMO spends per person for speciality care for a normal, healthy enrolled population ($22 pmpm). Whereas Medicaid claims data show that normally 55 percent to 70 percent of all dollars for patients like this

go to the hospital sector, in Dr. Master's program, this has fallen to 30 percent (Master 1997). His program spends $140 pmpm for nurse practitioner services, $60 pmpm for primary care physicians, and only $26 pmpm for specialty care. Quality reviews show better outcomes and higher satisfaction than ever before, and there has been literally no voluntary disenrollment. (Berwick 1996).

3. *Sound data, soundly analyzed, are as important in improving health care as in any other industry:*   With voluminous medical records, constant physiological monitoring, response to extensive regulatory reporting requirements, and increasing levels of computerization, health care is awash in data. But improvement teams often find that the data lie unused, unrefined, and displayed, if at all, in uninformative lists and charts, rather than in graphs, run charts, and control charts that "tell a story" on the basis of which theories for improvement can be developed and tested. Culturally, doctors seem especially receptive to data-based approaches to improvement. Physicians left cold by philosophical explanations of the principles of quality improvement can come alive in a simple presentation of evidence of variation or of tests of a hypothesis about the cause of a recurrent defect. More than a few health care improvement efforts have accelerated once the potential benefits of measurement and display of information were demonstrated.

4. *"Customer focus" is as meaningful in health care as in any other industry:*   When the concept of "customer" was first introduced by quality consultants into health care organizations, an allergic reaction occurred. "I don't have 'customers,' " was an angry, recurrent refrain from doctors and nurses, "I have 'patients.' " The reaction seemed to come from a misunderstanding that "focusing on customers" somehow demeaned the importance of the doctor's technical expertise or commitment to professionalism.

But the idea of customer focus was, in fact, entirely convergent with the trends of quality research in health care throughout the last quarter of the twentieth century. The investigators in the Rand health insurance experiments and others in the 1970s and 1980s developed an important focus on "patient-based measurements" of quality of care, including the insight that patient self-reports of health status and function were among the most reliable and valid forms of assessment of the outcomes of care. (Until then, most "outcome" measures were of variables observed by the doctor—like blood pressure, pulse, and fever—rather than variables reported directly by patients.)

The concept of "patient-centered care" (health care that continually views itself from the patient's perspective and adjusts processes to meet needs) also made inroads into health care, most impressively in places like the experimental "Planetree Units" established in a few American hospitals to test entirely new forms of interaction with patients. In Planetree settings, patients wear street clothes, instead of hospital smocks, and are invited to read and to write in their own medical records.

Becoming more receptive to the concept, health care leaders now understand that they serve multiple "customers," including patients, families, payers, communities, and referring institutions, and that each has legitimate and important needs. Each also defines "quality" somewhat differently. For patients and families, "quality" includes dimensions of health status outcome, accessibility, communication, comfort, dignity, cleanliness, convenience, problem resolution, and respect for the individual's time, among others. Payers value all of these (as representatives of the insured population), but also insist strongly upon cost control based on rational parsimony and waste reduction, and upon the timely provision of accurate accounting information and benefits management. Increasingly, communities as a whole demand from health care new forms of participation in collaborative health improvement, respect for the environment, and coordinated services, especially for the elderly and people with multiple problems.

As the flow of patients among institutions becomes more complex, demands increase for smooth coordination of referral patterns, "seamlessness" as patients move among sources of primary care (where they may first receive a diagnosis of, say, breast cancer), secondary care (where initial tests and treatment may begin), tertiary care (where high-technology procedures should be concentrated), and community services (for rehabilitation, employment support, social service, home care, and so forth). The watchword for redesign and improvement of health care in the 1990s has been "integration," as new amalgams of providers—hospitals merged with each other, physician-hospital organizations, vertically integrated systems with hospitals, offices, laboratories, and nursing homes—seek to create this seamless system of former fragments.

5. *Cost containment through improvement is attainable in health care:*   But the consciousness about the favorable relationship between cost and quality is only dawning. For many decades, a "more-is-better" attitude dominated thinking about health care quality. America overbuilt health care, providing technology, hospital beds, specialty services, and laboratory capacity that, as mentioned above, not only vastly exceeded the supply of these services in other developed countries, but also acted as drivers of demand and cost. In a fee-for-service financing environment, it was easy for health care organizations to maintain wasteful levels of inventory, inefficient programs for use of capital, high levels of scrap, and, in comparison to analogous processes in industry, low productivity.

Increasingly familiar with process improvement methods, many health care organizations defined cost reduction as Improvement Priority 1. No one knows yet what levels of savings can be achieved while improving quality through a thorough war on waste in health care systems, but the evidence abounds of inappropriate practice, redundant and complex processes, excessive inventory, and wasteful waiting. Table 32.2 lists some examples of cost savings achieved by health care improvement teams through relatively simple process changes.

Deaconess Hospital in Boston used an improvement method from General Motors to reduce excess inventory from operating room shelves and saved $200,000. Standardizing operative stapling devices and prostheses helped Mayo Clinic to hold costs down. Changing the way that nurses, therapists and nutritionists team up to provide care has dramatically reduced complications such as infections and skin breakdown at several hospitals and resulted in cost savings with better patient outcomes.

6. *Benchmarking is useful:*   Despite their professional collegiality, health care organizations and professionals traditionally work in remarkable isolation from each other. Few doctors routinely visit with colleagues to discover differences and innovations, and few methods exist by which hospitals and health maintenance organizations can discover best practices and copy each other. That is changing. Health care organizations are consolidating into integrated systems whose components can have easier access to each other, and students of quality management in health care have discovered the power of benchmarking through visits, trade associations, and collaboratives. Sometimes, the first "wake up" call has come from the payer community, as in Cincinnati, San Francisco, and Chicago, for example, where payer collaboratives have collected and published performance data on managed care plans. In one case, payer data first showed the care planorganiza-

TABLE 32.2   Quality-Improvement Steps at Intermountain Health Care

Samples of projects large and small that reduced operating costs in 1994

Project	Expense reduction
System project:	
Standardizing hematology procedures	$259,000 in supplies,
Standardizing chemistry reagents	$58,000 in equipments
Decrease in costs of coronary artery	$209,000 in supplies
bypass surgery	$245,000 (since 1993)
Facility-specific project:	
Emergency room lab turnaround time	$18,000 in salary and supplies
Fast-track extubation	$575,500 in shorter length of stay
Decreased retake rate for x-rays	$11,200 in film costs

Long-term clinical care improvement efforts

- 50% decrease in adverse drug events since 1991, with much of that coming in the first year. A computerized alert system was a key factor in avoiding prescriptions that could pose a risk to patient.
- 80% decrease in postoperative wound infection rates, reducing an incidence of nearly 2% in 1990 to a fraction of a percent in 1994.

Source: Intermountain Health Care application for the National Quality Health Care Award.

tions that their rates of hysterectomy varied eightfold from the highest plan to the lowest—a fact they did not know until the payers documented it.

Once alerted to the variation, curious health care organizations can make good use of benchmarking to discover new ways to approach their own work. Sometimes the best benchmarking is outside health care entirely. The Mayo Clinic leadership team has made fruitful visits to winners of the Malcolm Baldrige National Quality Award—companies like AT&T, IBM, Eastman Chemical, and Milliken—and has directly grafted process ideas from those pioneers into the work of the Clinic.

7. *Involvement of all staff in improvement is powerful:*   The dedication to excellence of health care workers at all levels is no surprise, but until recently most organizations have had difficulty tapping that energy to support systemic improvements. As a result, improvement in health care has tended to move slowly, lacking the momentum of total involvement. But counter examples are emerging. At Wesley Medical Center in Wichita, Kansas, a single project on reducing waiting times in the operating room, which began as part of Wesley's participation in a national collaborative benchmarking effort, was replicated internally within a few months as the hospital's leaders built upon what they had learned to support delay-reduction projects in 85 departments.

8. *Financing systems can be a major barrier to improvement:*   The suboptimization of professions and functions in health care has its mirror image in traditional payment systems. As one example, consider the perverse incentives in the compensation of hospitals in a capitated system (in which a strong incentive exists to shorten a patient's length of stay to save money) where doctors are still paid separately for each inpatient visit (so that shortening length of stay reduces physician incomes).

With the hospital aiming to reduce resource consumption, and the physicians (who control the ordering of all tests and the length of a patient's stay) reimbursed for each day of stay, and in some cases for the analysis of each test ordered, conflicts arise quickly in what improvements should be made. In another recent case, a hospital successfully reduced the frequency of unnecessary admission of patients with chest pain by better identifying in the emergency room those who did (or did not) have a heart attack. Their success led to a safe reduction in the total cost of chest pain treatment because people without heart attacks were more likely to avoid admission, but naturally caused an increase in the cost-per-admitted-case for that smaller number of patients who actually entered the hospital. (After all, a larger proportion of admitted patients were now turning out actually to have had a heart attack, and required the full resources of the hospital for diagnosis and treatment.) An unwise, but very important, health care insurance company, noticing that the *cost per case* was rising, and failing to notice the savings on a population base, caused a major crisis in the hospital by threatening to cut off reimbursement because of "excessive cost."

A third, and even more compelling, example of perverse financing affected the Magic Valley Medical Center in Twin Falls, ID (Roessner 1993). The leadership of the hospital, having made a commitment to help Magic Valley become "the healthiest community in America," made a major investment in leading the reduction of bicycle head injuries in the community by supporting the use of bicycle helmets. Helmet use did increase, head injuries in children fell by almost 50 percent in three months, and the hospital harvested both the satisfaction of saving lives and the severe economic problem of a shortfall in Emergency Department revenues as those well-paying cases of head injury decreased dramatically. Only a firm sense of mission allowed them to stay the course (Roessner 1993).

Clever managers have been able to maintain momentum for improvement despite these absurd payment paradoxes, but, for the longer term, payers and providers of care are coming to realize that the basic structure of finance in American health care is less favorable to rapid, strategic improvement than it may be in other industries. Innovations that consolidate payment and make rational systemic improvement more attractive are now beginning. The most significant of these changes is the expansion of *capitated* payment, in which provider systems are paid for the total costs of care and illness for populations, and in which, therefore, rational savings at one point in the system can be reallocated elsewhere, and in which the incentives of professionals, institutions, and consumers of care are better aligned.

THE FUTURE

Major trends toward better quality of care are now well underway in health care. Integrated delivery systems, more sophisticated information systems, and capitated payment are all helping to focus energies on improvement—especially on waste reduction. Better informed about the performance of health care organizations, consumers and payers are beginning to make their choices about where to receive care based on technical and service quality characteristics, as well as on price. The new century will witness the maturing of a quality-driven health care system, probably with at least the following characteristics:

1. *Much improved service quality:*   The time is ending when health care customers will tolerate—or must endure—waiting times, communication lapses, and process failures that have long ago become intolerable in other industries. Rental agencies, hotels, airlines, or retail stores that had the same waiting times as the average hospital or doctor's office today would be out of business quickly. Quality improvement in health care will drive new standards of service in health care.

2. *Decreasing total costs:*   With a refined understanding of the nature of waste, it is probable that leading health care organizations will achieve completely unprecedented production efficiencies within the next decade. We have at least the international comparisons to sustain confidence that excellent care is achievable at far lower cost than prevails in America today. The early success of individual project teams, able to return the same 6-to-1 or 10-to-1 return on investment while improving the experience of customers, needs only to be rolled up into strategic, deployed, systemwide improvement efforts to yield enormous savings for the system as a whole. Health care leaders are smart enough to build on this success over time.

3. *Health care will downsize, especially in high-technology services:*   Because of health care's unusual characteristic of "supply-driven costs," effective cost containment will require a smaller, tighter industry than we have as the 1990s close. We can expect fewer specialists, hospital beds, and sites of high-technology service per capita within the next decade. This should not spell a decrease in quality or service. On the contrary, research suggests that a "volume-outcome" relationship exists for many forms of technical care. Hospitals performing a small number of sophisticated procedures each year tend to have worse outcomes than those doing more. On two counts then—cost and outcome—the American public will be well-served by a consolidation of sources of advanced technical care into fewer, larger specialized centers.

4. *Prevention will take on new energy:*   The "upstream" causes of disease are in many cases controllable, but not within the classical boundaries of health care delivery. A rational public will maintain and increase investments in injury prevention, smoking cessation, reduction of alcohol and drug abuse, increasing physical exercise, and wise diet. At this moment, health care financing favors none of these, but the quality of outcomes depends on shifting the pattern of investment.

5. *Participative decision making will become more widespread:*   Important research now shows that, when patients become involved in making decisions about their own care (for example in choosing between medical and surgical treatment for prostate disease, in selecting from among therapeutic options in breast cancer, and in self-monitoring in diabetes and asthma), satisfaction, outcomes, and costs all tend to improve. The trend is so strong that it will make good business sense for health care organizations to build upon this notion of partnership as a core concept in the design of care systems of the future.

6. *Information systems and remote communication will advance:*   The greatest technical advances of all in the next phase of development of health care may be more in the realm of information management than in diagnosis and treatment. By the early twenty-first century, we can expect common use of automated patient records, computerized order entry, regular monitoring of both processes and outcomes of care, and remote forms of "telemedicine." It is already possible for the world's best interpreters of MRI scans or CT images to receive on-line images good enough to interpret locally from almost anywhere in the world. The well-trained nurse who answers a phone call from an anxious mother in the middle of the night can be next door or a thousand miles away and be equally effective in coordinating care. We are only a few steps away from remotely guided

procedures, in which technical experts can not only talk, but also act, from a remote site. The potential for improvements in cost, outcomes, and service is extraordinary.

7. *Job boundaries will change:*   The traditional professional classifications of medical care—doctors, nurses, respiratory therapists, laboratory technicians, and dozens of others—reflect the historical configuration of care systems. As the configuration changes, so will the jobs. This type of change is progressing much more slowly than logic or need would dictate, due largely to the well-established forms of professional self-regulation. But the boundaries are fraying, and fundamental change will sooner or later arrive. Many tasks and procedures currently done by doctors could easily be reallocated. Repetitive technical tasks may be done more competently and less expensively by technicians; just as intravenous lines formerly inserted only by doctors are put in today far more comfortably by IV teams, so may the colonoscopies, hernia repairs, fracture setting, and angiographies of the future be done well by people with highly focused training. Managed care systems and well-run clinics are already assigning to physicians' assistants and nurse practitioners tasks previously only given to doctors. Expert computer systems, which are already helping doctors to choose antibiotics or to make difficult diagnoses, will become better complements to traditional approaches to diagnosis. [The visionary Dr. Larry Weed suggests that expecting doctors to remember all pertinent diagnostic options is like expecting travel agents to remember airline schedules; to him, neither makes sense in the computer age (Weed 1968).]

8. *Organizational boundaries will change:*   As professions evolve, so will organizations. In fact, the heart and core of the American health care system of the twentieth century—the hospital—may become a dinosaur in the twenty-first. Gradually, it is becoming the case that patients not sick enough to be in intensive care units may not be sick enough to require a hospital bed at all. Better alternatives will exist. In the future, the whole hospital may be an intensive care unit; other patients will be at home or in a new kind of step-down setting. Sick asthmatic patients already skillfully use in their own homes devices and drugs that 10 years earlier would have been found only in emergency rooms.

9. *"More is better" will give way to "First, prove it works."*   A fundamental shift in the burden of proof for health care practices will take firm hold in the coming years. Scientific evidence and public consciousness are converging into a realization that health care does not generally provide what people want most: health; and that excessive care produces excessive risks. Combined with the problem of high cost, this consciousness should make providers and patients both more wary of technology than they have been in the past and more inclined to question the need for a test or treatment than to request it. One example of this new, more prudent attitude is in the work of the U.S. Preventive Services Task Force, which in 1989 and then again in 1995 produced a *Guide to Clinical Preventive Services,* reviewing the scientific evidence for and against over 200 preventive services—like screening tests, counseling on risk factors, and immunizations (U.S. Preventive Services Task Force 1996). The Task Force report documents strong evidence in favor of some preventive practices, but, even more impressively, shows that little or no evidence exists to support many others, some of which are in common use. Table 32.3 lists some of the recommendations in the *1995 Guide.* The general trend is toward what some call "evidence-based practice" in medical care; and it will mark a new, more scientific era in clinical work.

10. *Breakthrough performance will emerge:*   In the end, the momentum behind quality improvement in other industries has not come from theory, it has come from evidence, especially evidence owned by the competition. Great cars from competitors, not great ideas about cars, caused the American automotive industry to change. So it will be in health care. It is only a matter of when. The crucial turning point will have come when there exists for health care what Toyota was for the automobile—a breakthrough example, operating at an unprecedented level of performance and built for less than anyone had theretofore imagined possible. We do not yet have such a model in medicine. We have breakthroughs in process, superb cost reductions, and exciting new designs. But all of these achievements remain at the level of individual process, product, or service. We have improved parts, in some cases dramatically, but no one has yet fundamentally improved the whole—an entire system of care.

It is, at last, just within the reach of health care leaders to do so early in the twenty-first century. The rewards will be thrilling, and, as a consequence of that achievement, both health care and health itself in the early twenty-first century will be forever transformed.

TABLE 32.3   Guide to Clinical Preventive Services

Screening for hypertension		
Intervention	Level of evidence	Strength of recommendation
Periodic blood pressure measurement in persons aged ≥21 years	I	A
Measurement of blood pressure in children and adolescents during office visits	II-2, II-3, III	B

Screening for breast cancer		
Routine mammogram every 1–2 years with or without annual clinical breast exam		
Women aged 40–49	I	C
50–69	I, II-2	A
70–74	I, II-3	C
≥75	III	C
Annual clinical breast exam without periodic mammograms		
Women aged 40–49	III	C
50–59	I	C
≥60	III	C
Routine breast self-exam	I, II-2, III	C

Screening for cervical cancer		
Regular Pap testing in women who are or have been sexually active and who have a cervix	II-2, II3	A
Discontinuation of regular Pap testing in women aged >65	III	C
Routine cervicography or colposcopy	III	C
Routine testing for HPV infection	III	C

Screening for prostate cancer		
Routine digital rectal exam	II-2	D
Routine prostate-specific antigen or other serum tumor markers	I, II-2, III	D
Routine transrectal ultrasound	II-2, III	D

Screening for lung cancer		
Routine chest x-ray or sputum cytology	I, II-1, II-2	D

Strength of recommendations:

A. There is good evidence to support the recommendation that the condition be specifically considered in a periodic health examination.

B. There is fair evidence to support the recommendation that the condition be specifically considered in a periodic health examination.

C. There is insufficient evidence to recommend for or against the inclusion of the condition in a periodic health examination, but recommendations may be made on other grounds.

D. There is fair evidence to support the recommendation that the condition be excluded from consideration in a periodic health examination.

Level of evidence:

I. Evidence obtained from at least one properly randomized controlled trial.

II-1. Evidence obtained from well-designed controlled trials without randomization.

II-2. Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.

II-3. Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence.

III. Opinions of respected authorities, based on clinical experience; descriptive studies and case reports; or reports of expert committees.

SECTION 33
FINANCIAL SERVICE INDUSTRIES

Charles A. Aubrey II
Robert E. Hoogstoel

INTRODUCTION

What is financial service? Financial services are services related to cash and other financial assets. There are seven types of service that financial services institutions may perform. The first four are distinctly *financial* services:

1. Safekeeping of customers' currency or other assets and fiduciary responsibility for them.

2. Conversion, transfer, and transformation of currency and other customer assets.

3. Adding value to customers' assets by means which may include:

- *Return on deposits:*   Providing return on capital or assets which the customer places, deposits, trusts, or invests with the financial institution.
- *Investments and loans:*   Providing the customer with capital or other assets to generate value.
- *Insurance:*   Providing protection against possible financial loss in the event of certain predefined risks.

4. Underwriting or guaranteeing customer projects through some combination of advice, marketing of customer instruments (stock and bonds, for example), and guarantee of minimum financial support (providing line of credit, buying an amount of stock, or insuring against a loss).

   The last three services are common to many service institutions and are not unique to financial services.

5. Interacting with customers in a variety of ways, including sales presentations, responding to customer service inquiries, and providing advice.

6. Accounting and reporting to detail and summarize the transactions related to the customers' relationship, including billing and tax information.

7. Providing a profit to the owners of the company—those who provide the operating capital (common to all kinds of companies).

THE FINANCIAL SERVICE SECTOR

The financial service sector comprises companies engaged in the creation and delivery of financial services. Traditionally, these companies are organized by industry, where each industry is concentrated on a common line of business, such as commercial lending, credit card services, or casualty insurance. Commercial banks, savings and loan institutions, brokerage firms, investment companies, investment banking institutions, insurance companies, credit card companies, and credit companies (including pawn shops) are all part of the financial service sector.

This tidy description of the organization of the financial service sector provides a convenient point of departure. It should be kept in mind, as discussed below (Sector Organization; Boundaries; History), that the sector is undergoing rapid change and this description does not always square with the growing complexity of the sector as it is emerging.

Sector Organization; Boundaries; History.   A special word should be said about the boundaries which divide the various industries within the financial services sector, their history, their present status, and the implications these boundaries have for the activities within each of the industries. Most commercial and retail customers are in the habit of labeling financial institutions on the basis of a memory of financial institutions of the recent past. Labels like "bank," "savings and loan" and "credit union" are generic terms which were once precisely defined in the United States by the regulations which governed the financial services sector. U.S. consumers associated these generic institutions with their products: loans, deposits, and transactions related to them. Similarly, insurance companies were associated with the insurance products they created and sold, and brokerage and investment firms were associated with packaging, promoting, and selling investment in stocks, bonds, and other assets, such as real estate.

There is good historical reason for the structure of the financial services industries. In 1933, at the depth of the Great Depression, which was precipitated by the stock market crash of 1929 and subsequent bank failures, the U.S. Congress reacted to the economic devastation by passing the Glass-Steagall Act (Werner and Stoner 1995). Because Congress saw the root cause of the Great Depression to be the involvement of banks in the promotion of securities, Glass-Steagall limited this activity. This act and other regulatory measures drew boundaries around various segments of the financial services sector and prohibited the companies within each of these industries from participating in business outside the limits of their respective industry territories. Thus, banks were pro-

hibited from dealing in securities, brokerage firms were prohibited from performing certain banking functions, and so on. The resulting model of distinct financial businesses was, to a great degree, adopted and enforced internationally by a great majority of countries.

Today, various legislation in the United States has modified portions of the Glass-Steagall Act. The pattern began to change in 1980, with the passage of the Depository Institutions Deregulation and Monetary Control Act, which took the first steps to reduce differences between commercial banks and thrift institutions. By 1994, with the passage of the Riegle-Neal Interstate Banking and Branching Efficiency Act, which removed restrictions on interstate bank branch operations, the system of regulations which had maintained the pattern of financial services for over half a century was virtually gone. The effort to redefine and restructure the industry which began in 1980 is clearly evident in the mergers, acquisitions, and restructuring throughout the financial services industry in the late 1980s and 1990s.

As a result of this deregulation, the lines of demarcation are becoming blurred. For example, today banks can earn up to 10 percent of their revenue through underwriting activity. They can sell securities and the insurance of other companies (though they cannot underwrite them). They are forbidden to make the related investment decisions or to hold the resulting portfolio.

Another example of the blurring lines is seen when a bank sells mutual funds or allows sales agents of an insurance company to operate in a bank branch. Such cooperative arrangements enable the bank to offer a more complete line of financial services in order to keep and attract customers. Such intra-sectoral cooperation has extended competition beyond the competition that existed between organizations within a sector; the competition now takes place between sectors. Table 33.1 summarizes the activity of the financial services companies, by industry, represented in the 1996 Fortune 500.

Customers now face a wide choice of providers for services that once resided securely in companies of a single industry. For example, checking accounts, once the exclusive domain of the commercial bank, can now also be obtained from a savings and loan, a savings bank, even from a stock brokerage or mutual fund provider.

DEFINITION OF QUALITY IN FINANCIAL SERVICES

Juran (Section 2, How to Think About Quality) proposes a definition of quality which we will use here. Quality is the combination of: (1) features which attract customers and satisfy their needs and (2) freedom from deficiencies, which avoids dissatisfying customers.

TABLE 33.1 Profile of Financial Services Sector

Industry (no. of organizations)	Revenue*	Profit*	Profit as a percent of:			Employment	Revenue per employee
			Revenue	Assets	Equity		
Commercial banks (55)	$271,691	$32,728	13	1	15	1,041,623	$260,834
Insurance: life and health (mutual) (21)	$180,286	$4,438	3	1	11	255,396	$705,908
Diversified financial (15)	$105,264	$9,660	10	1	18	232,804	$452,157
Insurance: property and casualty (stock) (27)	$100,947	$13,953	8	2	13	296,814	$340,102
Insurance: life and health (stock) (20)	$89,053	$4,426	7	1	11	209,567	$424,938
Insurance: property and casualty (mutual) (9)	$60,337	$2,657	8	3	11	116,187	$519,309
Brokerage (7)	$53,957	$2,452	5	0	10	105,561	$511,145
Savings institutions (8)	$16,373	$1,226	8	1	10	41,983	$389,991

*000,000 omitted.

Features. Features are those attributes or characteristics that combine to constitute a product.

The thing sold to customers is some bundle of services, generally referred to as "product." Usually, the product includes some tangible elements (a report, a receipt, cash in hand) and much that is intangible (a feeling of safety and security; speed of information access by 24-hour telephone line; speed, accuracy, and pleasantness of response to an inquiry). In many cases the intangible aspects are more important to the customer than the tangible ones.

Salable services require features that customers want and need. Sales and revenue depend on an understanding of those wants and needs throughout the duration of the supplier's relationship with the customer—from initial inquiry, through sales presentation, purchase decision, and the customer's subsequent decisions, conscious or unconscious, to maintain the relationship or make further purchases.

The variety of features which financial products and services offer is growing each year. The growth is propelled by the ever-growing capabilities of available computer hardware and software. One result is increasing customization of financial products to the needs of individual customers and classes of customers.

In addition to features associated with services generally, there are three features that are especially important to financial services: fiduciary responsibility; return on an investor's investment (ROI) (from the borrower's viewpoint this is interest paid on a loan); and risk.

The suitable combination of fiduciary behavior, return on investment, and risk is an important feature that customers use to: (1) decide what company to do business with, (2) select which products and services to utilize for each company the customers choose, and (3) how much of the product or service the customers will utilize or purchase.

Features: Fiduciary Responsibility. Fiduciary responsibility is the exercise of prudent judgment and acting in the best interests of the customer. It includes keeping the customer's assets safe, as well as those of the company, and earning the best return possible given the amount of risk the customer and company have agreed to accept. These responsibilities are clearly written in company policy and procedures. In the case of larger transactions, such as underwriting stocks or bonds for issue, commercial loans, trusts, arranging large customer investment portfolios, or managing large company insurance portfolios, the fiduciary responsibilities are also written in the contract.

Fiduciary responsibility is an important feature of any financial transaction. As important as its actual exercise is the customer's perception that it is being exercised. Once the customer loses faith in the fiduciary responsibility of an institution, that trust may be impossible to repair. When many customers lose faith simultaneously the result can be calamitous for the institution. In the early 1980s, Continental Illinois National Bank was forced to "write off" over $1 billion of loans. (Writing off is a recognition by the managers that there is no hope of recovering any of the principal or interest due on the loan.) The effect of the disclosure of this massive write-off was to stimulate a "run" on the bank, in which many depositors, fearing the loss of their assets, sought simultaneously to withdraw funds from the bank. They withdrew so much money the bank became illiquid. The Federal Reserve stepped in and loaned the bank what was necessary to meet depositor demands, but the damage was done. The bank's stock value dropped from over $20 per share to under $2, where it remained until dramatic steps were taken, including rechartering. Many customers never returned. Half of the 16,000 employees lost their jobs.

Features: Return; Interest paid. Return on investment (ROI) and interest rate paid (I) on a loan are computations of the same quantity (the annual cost of money, in percent) from two different viewpoints—that of the investor and that of the borrower. Where the loan (or investment) period is 1 year, the computation is straightforward:

$$I = \text{ROI} = \frac{S - P}{P}$$

where P = the amount borrowed (or the amount invested) and S = the amount paid back (or the amount collected) at the end of one year.

Complexity increases as the number of interest periods increases, and when fees, compound interest, currency translations, taxes, and the like are introduced. As the computation becomes more complex, it also becomes more difficult for the customer to compare competing financial products.

The largest and most sophisticated customers have complex models to make the calculation and comparison. The small retail customers must do the best they can from what they read and are able to calculate. For example, it is very difficult to compare the interest cost of an automobile purchase loan with that of a lease, despite the fact that many laws exist in retail consumer financial services to simplify the products and allow comparison by the consumer. Because of these difficulties, some consumers depend on their financial institution and accept on faith its advice on investment return and interest rate.

High-trust fiduciary responsibility, linked with other features of very high importance, such as ease of doing business, computer access, and personalized service may reduce the importance of return on investment or interest rates paid. As long as these rates are in the "ballpark" compared to competitors, they may become less important features.

Features: Risk.   Risk is a correlate of return. Greater risk generally accompanies greater return. All financial transactions are accompanied by risk—conditions which threaten the success of the transaction and realization of the return.

The risk associated with a transaction is generally expressed in terms of the uncertainty of success, in the language of probability and statistics. For a given transaction, the best data available are used to create a statistical model as a prediction of the outcomes of the transaction. Risk is expressed in terms of the dispersion or spread of those outcomes.

The quantification of risk is illustrated by the risk associated with investing in a hypothetical stock index fund. (An index fund is a mutual fund comprising a package of common stocks selected to emulate the price behavior of some stock index such as Standard & Poor's 500.) This hypothetical fund will emulate the Dow-Jones Industrial Average ("the Dow"), chosen because among stock indices representing the behavior of the U.S. stock market, the Dow has the longest history, having been established over 100 years ago. Though an imperfect representative of the broad market, the Dow will serve to illustrate the relationship of income and risk.

Although every investment primer and the prospectus of every mutual fund will tell the prospective investor that past performance is no guarantee of future performance, the fact remains that past performance is important and often is the only guide to future performance. Table 33.2 is a portion of the data table based on the annual closing value of the Dow for the years 1914 to 1990, inclusive. We assume that dividend income from our stock is small compared to the price appreciation over time. Likewise, we assume the costs of trades to keep our portfolio composition identical to the Dow are negligible. Thus, we define the income from the fund for a given year as that year's capital appreciation. From these values it is possible to compute the effective annual rate of return on investment for 76 periods of 1 year, 75 periods of 2 years, 74 periods of 3 years, and so on to the one period of the entire 76 years. For each of those groups of periods, we can compute the sample standard deviation *s*.

The assembled results of these computations provide a statistical description of the behavior of the Dow over the 76-year period. Those with confidence that the Dow will continue to behave like this over the long term can use this model to predict the statistical picture of future behavior. In any case, the numbers give a sense of the magnitude of risk faced by an investor in this hypothetical fund.

The distribution of annual interest rates for each of the 76 years, is assumed to be reasonably approximated by the standard normal distribution. On this basis, we use the sample standard deviation *s* as an estimate of the standard deviation σ (sigma), and estimate the probability of any given range of return for an investment in the "fund." For example, for any given year, absent any other knowledge of the market conditions, we can say that with about 95 percent probability the ROI will fall between $\pm 1.645s$ of the average annual ROI. The computation yields values of these limits of -39.56 and $+49.92$ percent.

Before despairing that the range is too large to be of use in decision making, it is well to remember that in predicting next year's performance from the vantage point of this year, we have much more information on which to base the prediction than is suggested by these data; further, the data have more to tell under further analysis (see Figure 33.1).

The data tell us that over the period covered the expected (average) annual return is 9.5 percent; 5 percent of the individual years experienced a return of -4.0 percent or less; 95 percent of the individual years experienced a return of 29.0 percent or less; thus, 90 percent of the time the annual

TABLE 33.2 Dow-Jones Industrial Average: Annual Closing Prices, 1918 to 1990

Year	Close	Annualized percent return for varying investment periods				
		1 year	2 year	3 year	4 year	5 year

return lay between −4.0 percent and 29.0 percent. These values become, for lack of any better basis for prediction, our estimates of probability for a time horizon of 1 year. Similarly, we estimate the 90 percent envelope of probabilities for the time period (in years) N of 2, 3, 4, etc.

The data, plotted in Figure 33.2, help us visualize and quantify the uncertainty suggested by these numbers and the way in which time reduces uncertainty. The long-term average return of 9.5 percent, while attractive, is by no means certain in an investment of just 1 year. The range from 4.0 to 29.0 may be unacceptably wide. The prospect of such uncertainty may drive us to invest in a bank certificate of deposit with a rate of return of only 5 percent, but with far narrower limits of uncertainty.

Credit application data can be compared with statistical models of data on repayment behavior of loan holders to assess creditworthiness of the loan applicant, based on the estimated risk of loan default. For life insurance products, mortality data are statistically modeled to create and price life insurance products on the basis of estimated risk of death of a beneficiary while the insurance is in force.

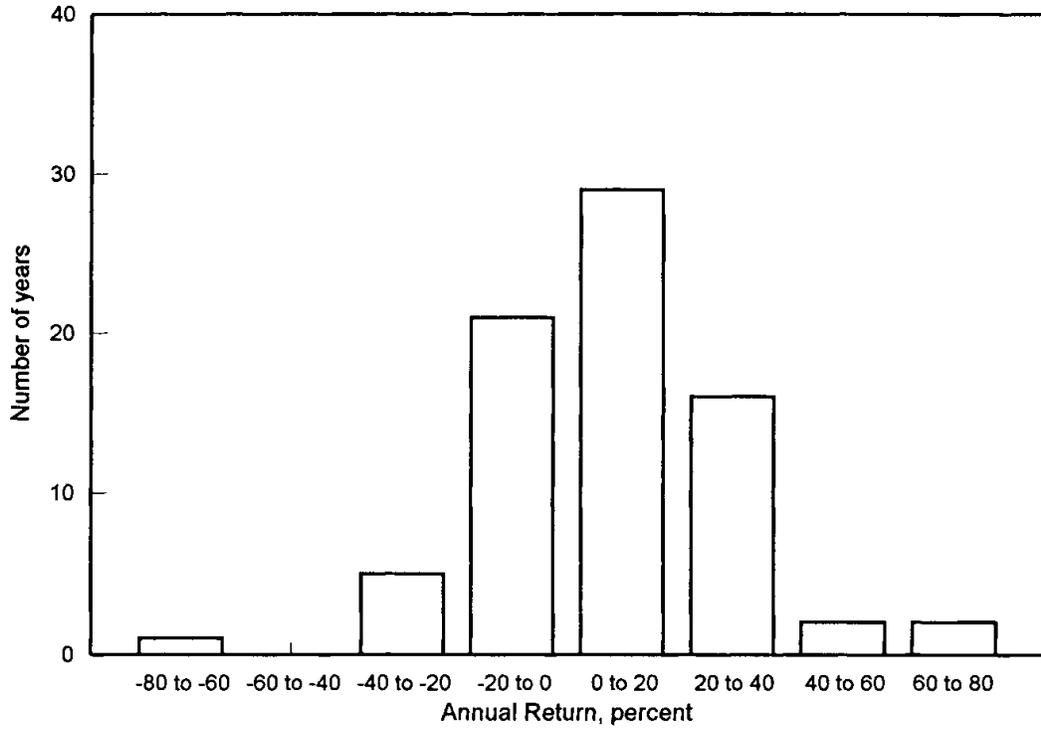
Risk and Risk Assessment. A key to profitability is accurate risk assessment. When a financial institution underwrites a project, it is investing funds in the completion of that project in expectation of a competitive return on that investment. Some level of risk is always associated with profitability, irrespective of the product, service, or the industry which offers them. In financial services the risk is the more apparent because the product itself directly involves money.


FIGURE 33.1 Distribution of annual ROI values for the years 1918 to 1990 of a hypothetical fund of the Dow Jones Industrial Average. (*Source: Adapted from Dow-Jones Averages 1885–1990, Phyllis S. Pierce, ed., Business One Irwin, Homewood, IL, 1991.*)
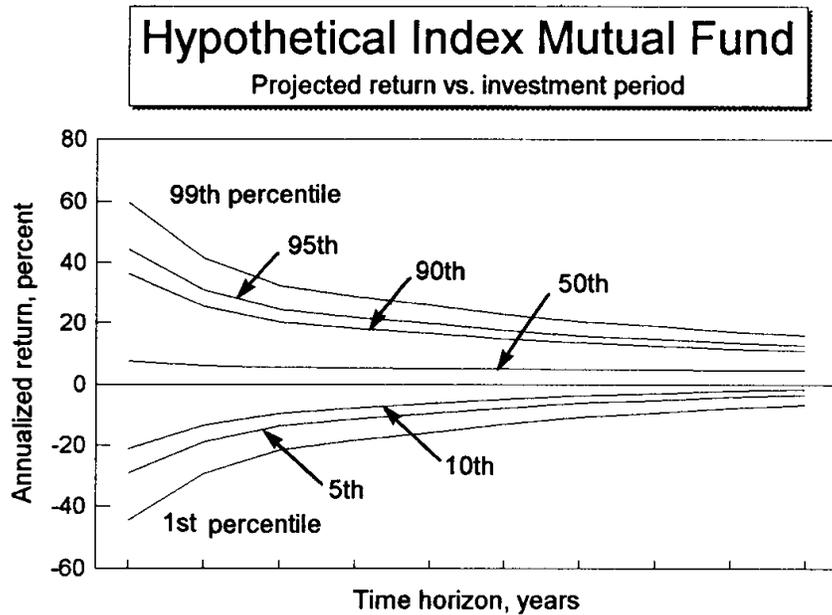

FIGURE 33.2 Risk versus investment time horizon. (*Source: Adapted from Dow-Jones Averages 1885–1990, Phyllis S. Pierce, ed., Business One Irwin, Homewood, IL, 1991.*)

It is important for both parties to a financial transaction to be able to assess the comparative risk of the transaction; the penalty for mistake may in some cases exceed the amount of the investment. Both parties will seek to make the ratio of cost of risk to reward acceptably low. The ratio is an important measure on which a customer bases such decisions as selection of financial-service provider, selection from among competing financial products, and allocation of investment among selected products. In other words, the estimated ratio of cost of risk to reward is an important measure of quality in financial services.

Defects or Deficiencies.   A defect or deficiency occurs whenever a product fails to perform as designed or as promised. Defects can be tangible (e.g., incorrect terms on a loan document, a deposit or delivery of currency in incorrect amount, missing pages in an insurance policy, delivery of stock or bond certificates too late to complete a trade, unavailability of an automatic teller machine) or intangible (e.g., surly behavior of a bank teller or customer service inquiry clerk, misquote of loan application fee, failure to open the office or switchboard at the advertised time, chronically busy telephone lines, failure to answer an incoming telephone call).

Many of the features and deficiencies mentioned above are common to services in general. Significant features that are most usually associated with financial services are fiduciary responsibility, risk, and financial return (or interest paid).

Challenges and Obstacles for Quality in Financial Services.   There are a few quality issues which stand out in the financial services sector: creating uniformity of service, comparison with leaders in other service sectors, quality-initiatives fatigue, downsizing and consolidation, and automation.

Creating Uniformity of Service.   Many financial service organizations have branch operations and extensive telephone service networks. In this environment, creating and maintaining uniform service of the highest level is extremely difficult. A customer who is overserviced at one location and underserviced at another will probably be disappointed. In most financial service companies it is primarily the actions and attitudes of people that constitute the service. Trust in individual employees is as important as trust in the institution and in the branch office. Therefore, hiring, training, developing, motivating, and rewarding are extremely important.

Comparison with Leaders in Other Service Sectors.   There is a carryover effect from other service companies, even companies in other sectors. Fast, competent, friendly and high-value service from a fast-food restaurant, a dry cleaner, or an auto repair shop creates expectations for the same from bank, broker, and insurance agent. Many surveys show that financial services lag in this respect. [See the discussion under The American Customer Satisfaction Index (ASCI), below.]

Quality-Initiatives Fatigue.   Many financial service organizations went through "Quality" in the past three decades: "smile training" in the 1960s, quality circles in the 1970s, and culture modification in the 1980s. Having tried all these, they either feel they have done it all or are just tired of all the quality initiatives which have come and gone without much effect.

Downsizing and Consolidation.   Financial services, like many other sectors, is experiencing corporate downsizing and consolidation. For example, between 1980 and 1990 the number of commercial banks in the United States fell from 14,000 to 12,000, and by 1996 to 9800—a reduction of 30 percent in just 16 years. Although the pattern in other western countries like Canada and Great Britain is to consolidate into five or six giant institutions, experts in the United States have predicted that several thousand commercial banks will remain in this country in the long run. In fact, in banking, dozens of banks start up successfully each year to serve customers that larger consolidated banks are not satisfying.

Consolidation is also the prevailing trend in other financial services—brokerage, savings bank, insurance, credit card, mortgage, and trust.

The reduction of personnel has been even greater than the reduction in the number of institutions. When a merger occurs, a reduction in combined staff of from 10 to 20 percent is common. In addition, ongoing efforts at productivity improvement and cost reduction have created a sectorwide reduction in work force of between 5 and 8 percent. These changes have placed a significant burden on the remaining staff, and in many cases have been reflected in reduction of service to customers.

Automation. Much increase of efficiency and productivity has come from automation in financial services. In banks, for example, computerizing customer interfaces and transaction activity cuts cost significantly. Unfortunately, it also keeps customers out of the branches, where sales of new service traditionally occurs—person to person. Pressure from shareholders to increase profits has caused many companies to reduce costs by automating operations and eliminating staff.

PROOF OF THE NEED—EVIDENCE OF QUALITY TROUBLE IN FINANCIAL SERVICES

There is much evidence of customer dissatisfaction with the quality of financial services. Some of the evidence follows:

The American Customer Satisfaction Index (ACSI).
The index is a cross-industry measure of the satisfaction of U.S. household customers with the quality of the goods and services available to them. Included are goods and services produced within the United States and those provided as imports by foreign firms that have substantial market share or dollar sales. The index provides an objective economic measurement of the improvement needed in financial services as well as in other industries. The ACSI is cosponsored by the University of Michigan Business School, where its methodology was developed, and the American Society for Quality (ASQ, formerly the American Society for Quality Control). Results of the first ACSI assessment, based on data collected May 10 to July 22, 1994, were released in October 1994.

The ACSI measures customer satisfaction on a uniform scale scale from 0 to 100, where 100 is best. The first value of the national ACSI was 74.5. This baseline measure is the benchmark for comparing customer satisfaction over time. The ACSI covers seven sectors of the economy and key industries within each sector. These sectors are (1) Manufacturing/Nondurables, (2) Manufacturing/Durables, (3) Transportation/Communications/Utilities, (4) Retail, (5) Finance/Insurance, (6) Services, and (7) Public Administration/Government. These sectors account for 75 percent of the Gross Domestic Product. (For a detailed description of the ACSI, contact the American Society for Quality, 611 East Wisconsin Avenue, Milwaukee, WI 53201-3005; phone 414-272-8575.)

Table 33.3 shows those financial service companies large enough and receiving enough national responses to receive individual indices. The index values may be interpreted as relative ratings. Of special interest is the fact that the 3-year trend is slightly downward, suggesting an opportunity for companies applying quality management methodology to gain a competitive edge.

Quality Costs.
Section 8, Quality and Costs, proposes four categories of quality-related cost: prevention, appraisal, internal failure, and external failure. Examples of these costs from the financial service sector follow:

Prevention: New product review, quality design or quality planning activities, training programs, creation of written policies and procedures, analysis of quality information, and conduct of quality improvement projects.

Appraisal: Inspection of incoming work, supplies, and material; periodic inspection of work in process; checking, balancing, verifying, and final inspection of account transactions; conducting customer surveys; and analysis of customer correspondence/complaints.

Source: American Society for Quality, Milwaukee.

Internal failure: Machine downtime, scrap and waste due to improperly processed forms or reports, and rework of incorrectly processed work.

External failure: Investigation time for complaints, payment of interest penalties, reprocessing of an item, scrap due to improperly processed or incorrect forms or reports, time spent with disgruntled customers, and lost business due to providing poor service.

The sum of failure costs plus the portion of appraisal cost necessitated by a high failure rate is referred to as "cost of poor quality." These are costs which would disappear if the product or service were defect-free.

The sum of all four categories of quality costs constitutes the total cost of quality. Experience shows that the latter three categories, called the "cost of poor quality," range from 10 to 30 percent of sales income or 25 to 40 percent of operating expense, not including the cost of funds. This magnitude, frequently verified, represents a large opportunity for improvement. Organizations such as Banc One Corporation, American Express, and Prudential Insurance Corporation use cost of poor quality to drive quality improvement. The data in Table 33.4 give examples of this opportunity in one large bank organization.

Customer Loyalty and Retention. Customer loyalty is the purchasing behavior exhibited toward a financial services provider by a customer who places a major percentage of his or her financial services business with that provider. Customer retention means keeping a customer as a buyer of services.

In financial service companies the rates of customer loyalty and customer retention are often so low that as much as 30 percent of the customer base is lost each year, equivalent to a complete turnover in a little over 3 years. The typical American household uses six different financial service

organizations, where one to three could provide the services required. The principal reason for this seemingly unnecessary spreading around of work is poor quality of service. Financial service companies too frequently treat their products as commodities. They often seem unwilling or unable to distinguish their products from those of their competitors, and fail to develop in their customers a feeling of loyalty to the product or brand or to the organization. In that circumstance, the customer's cure for dissatisfaction is to quit and take the business to another provider. At the same time, while companies may be unable to retain customers, they recognize that their competitors share the same problem. This gives rise to marketing efforts aimed at capturing the business of the disaffected customers of other companies by means such as advertising the ease of switching accounts, provision of free checks, instant replacement of existing insurance policy, or waiving of transfer fees in a new brokerage account.

When poor quality service translates to a lack of customer loyalty and poor customer retention, the costs are almost always larger than they appear at first. Casual analysis of a lost account may suggest that the account was small anyway, with little loss to the company. Deeper analysis frequently reveals that in earlier times—say 6 to 12 months before—the customer had multiple accounts, all with healthy balances. The customer departed a little at a time, not all at once, and in that time took substantial business away.

Further, the cost of replacing a customer is demonstrably greater than the cost of retaining one. The least costly means of gaining sales and market share is to treat the existing customer well, rather than trying to create a replacement.

For more on customer loyalty and customer retention, see Section 7, Quality and Income.

DESIGNING WORLD-CLASS FINANCIAL SERVICES

Customer-Driven or Technology-Driven Product Development?   New products and features come to market in two essentially different ways. The first depends on a product based on the "great idea," a novel idea of great potential benefits around which a marketing effort is developed. The automatic teller machine (ATM) is an example of such a product. The customer

can, by introducing a magnetically coded identification card, withdraw cash from any one of a network of machines at any time. For banks, the principal attraction is the reduction of the substantial labor cost of the withdrawal transaction (the cost of a teller to handle the face-to-face transaction, and the costs of processing, transporting, and storing the resulting paper records); for the customer, the advertised benefits are speed and convenience of withdrawing cash at any time of the day or night.

One of the drawbacks of this product development strategy is its reliance on the great idea. Great ideas are difficult to come by and the investment required to promote them can be prohibitive.

The second way to develop product is to begin with a clearly researched profile of customer needs, and design the product with features that address the most important of those needs. While the resulting products may not create dramatic competitive breakthroughs, the approach enables the company to maintain for the product line an acceptable rate of improvement and, for each improvement, acceptable odds of successfully launching and sustaining it.

There is a third way to develop new products which bears mentioning. It is to copy competitors in introducing new products rather than to take the initiative in developing new product. Some refer to this as the "lemming" process, after the legendary behavior of lemmings, which follow the crowd regardless of consequences. Such a process assures that its practitioners will never know the success that the big idea can bring, or even the success which is based on a thorough understanding of customer needs. The lemmings will always be late to benefit from emerging trends. When a trend becomes a boom, and the boom leads to overcapacity, the lemmings are frequently the first victims of the bust that follows.

Developing World-Class Products and Services.   The product development process starts with identifying current and potential customers. Next, "listening posts," the mechanisms by which to discover the needs of these customers, are established. These listening posts may be strategically placed individuals (such as sales personnel or customer service personnel), customer surveys, telephone listening/recording, complaints, customer interviews, focus groups, field service personnel, advisory councils, and so on.

In some organizations, sales personnel and customer transaction personnel use every interaction as an opportunity to probe and ask specific questions. See Table 33.5.

When the listening posts are well designed and the information they generate is well coordinated, their contribution can help to develop new products and to sell existing product that is already developed of which the customer is not aware.

USAA and American Express are companies which collect and analyze information generated in all types of customer contact. All written and telephone complaints, compliments, and inquiries are collected, classified, and analyzed. The resulting information provides a clear indication of what is going well, what needs to be improved and what new needs are emerging from the customers.

Information from the listening posts helps to identify needs and to assure that they are associated with the appropriate set of customers, in order to improve service, add features, and develop new products.

For example, funds transfer between accounts is a product useful to an individual who makes transfers among multiple accounts in one bank, as well as to a company with far-flung operations making transfers among hundreds of accounts. While the basic transaction is the same for both customers, the required documentation differs greatly. The individual may be perfectly well served by a monthly statement of all transactions and balances. The company will likely need daily end-of-day statements delivered to multiple locations.

TABLE 33.5   Questions to Discover Customer Needs

• Is there anything else I can do for you?
• Are there any problems or needs today you have in managing your financial affairs?
• Are there any products or services you wish we offered?
• Are you aware of any products on the market that we don't offer?

Needs, once identified, must be translated into measurable terms. This is especially true in the service environment, in which there may exist a belief that "intangible" is a synonym for "immeasurable." Thus, a "fast" transaction must be expressed in days, minutes, or seconds. "Easy" portfolio liquidation must be described in terms which make clear who is authorized to do the liquidating, when they may do it, under what controls, and so on.

Once needs are so translated, the translation must be validated or modified by the customer. Table 33.6 is an example of customer needs and translation for terms associated with one product: check truncation. (Check truncation is a feature associated with the checking account statement. For an account with the check truncation feature, the account statement contains the vital information for each check cleared, but the actual written and processed checks are not returned.)

Each of the needs, clearly stated and measurable, is addressed by appropriate product features. When all the product features are developed, the product emerges and the delivery process can be developed. World-class companies have found that the customers should be consulted at each step of this development process to be sure that the product being developed continues to meet the need. Table 33.7 extends the example of check truncation to product features and process features.

TABLE 33.6   Check Truncation: Needs and Translation

Needs					
Primary	Secondary	Tertiary	Translation	Units of measure	Sensor
Security	Account insurance		Institution, account insured by FDIC	Insurance in place, advertised; Y/N	Consumer

CONTROLLING QUALITY AND CUSTOMER SERVICE

Measuring from the Customer Perspective—What They Think Is Important.
Controlling quality of service depends on the measurement of performance in terms of the features that matter to the customer— primarily the external customers, but the internal customers, too.

The time to develop measures and performance levels that meet customer needs is during the design of the product. For existing products that have already been developed and are being delivered today, performance measures that do exist are too frequently based on the needs of internal customers.

Developing customer-oriented performance measures to assure products is a task that requires the help of listening posts, discussed above. Most useful is the customer satisfaction survey process.

The customer satisfaction survey begins with the study of the complete service cycle for the product for which measures and performance standards are to be developed. Figure 33.3 shows, from the customers' perspective, all of the features of the product through its entire life. Then each feature is written into a "satisfaction" and an "importance" question (Figure 33.4). Next, an actual performance question is written for each feature. Figure 33.5 offers an example.

In the example of Figure 33.5, suppose a disbursement time of 48 to 72 hours correlates with "satisfied," and 24 to 48 hours correlates with "very satisfied." The goal for funds transfer should be to achieve "very satisfied," and the corresponding numeric goal is 24 hours. Goals should always be set to create very satisfied customers. Customer loyalty research shows that customers who are merely satisfied are not loyal. A satisfied customer is 51 percent likely to buy again, almost literally as likely as not, whereas very satisfied customers exhibit an 85 percent probability of buying again. These probabilities explain why so many individuals and companies have multiple suppliers of financial services. It is difficult for an organization or its products to sustain a customer at "very satisfied," so the customer buys from multiple organizations.

It is instructive, using survey data from questions of the sort in Figure 33.4, to assess the importance of each feature on a simple scale (1 = low to 4 = high), and to use the same scale to measure satisfaction performance. Table 33.8 shows a 2 × 2 matrix into which the pairs of values—importance and performance—can be plotted to guide the measurement effort. Each quadrant suggests an action. The features whose importance ranks high (3 or 4) fall in the right-hand column. All of these must be measured. For any which have no measure, one must be devised. The performance standards can be determined by correlating the numerical performance reported by the customer to the customer's reported level of satisfaction.

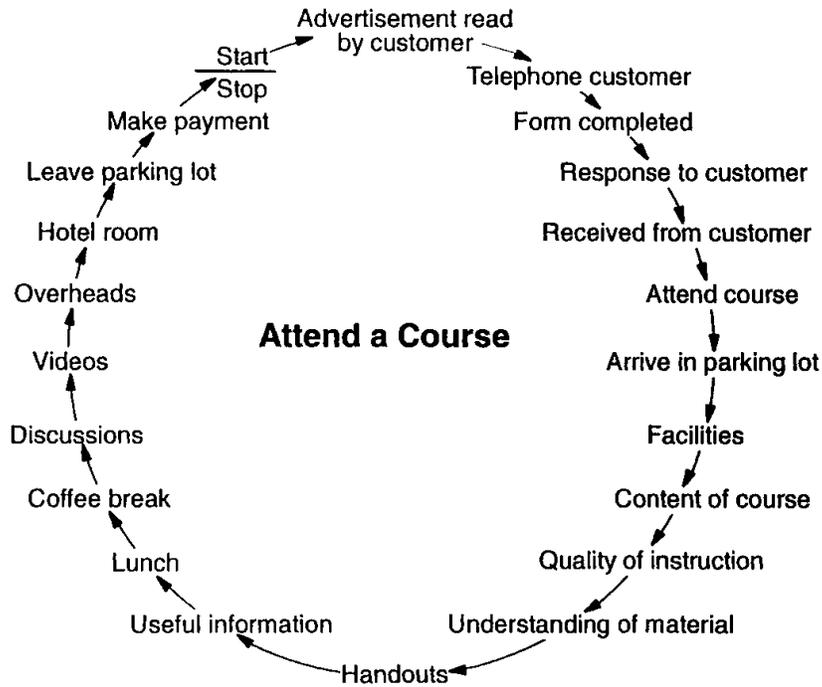
Through the administration and analysis of periodic surveys, and through the continuous improvement of service that survey results stimulate, it can be expected that the list of questions can


FIGURE 33.3   Service cycle (attend a course).

A. How satisfied are you with following branch staff service features?

	Very satisfied	Somewhat satisfied	Somewhat dissatisfied	Very dissatisfied
1. Greeting you with a smile	1	2	3	4
2. Concerned and caring	1	2	3	4
3. Helpfulness	1	2	3	4

		Low (1, 2)	High (3, 4)
		IMPORTANCE	

be narrowed to a few which capture the essence of customers' assessment of performance. An ongoing monthly survey of a small random sample will assure that service remains at "very satisfied" or is moving toward it.

Internally, proxy measures are needed to track those features that are important to the customer. In the financial services environment, with such extensive use of information technology, many measures can be collected automatically, for 100 percent of transactions and in real time. The time saved in automatic measurement can be used for improvement. Where manual measures are required, sampling should be used. (For more on sampling, see Section 46, Acceptance Sampling.)

Performance measures are processed in a feedback loop. As the data are collected, either by sample or through the automated system, the actual performance is compared to the standard, and action is taken on the difference.

The detailed plan for this measurement—who does it, how often it should be done, with how large a sample—is documented in a control matrix or control plan. Table 33.9 is an example. The plan provides the procedures for sampling and comparing to a standard and specifies the actions to be taken if performance does not meet standard. A graph of the actual data against the standard displays the quality level for easy comprehension and action. The tool that is used most often is a control chart. (See Section 45, Statistical Process Control.)

In successful organizations, performance reporting is designed to facilitate continuous improvement. For example, organizations with duplicate operations want to discover best practices within the organization so as to make them the performance standard throughout. Table 33.10 is an example of a performance report from a multibranch bank. Examples of measures and their standards for a full service, multibranch commercial bank are shown in Table 33.11. Examples of measurement feedback reports for a credit card company are provided in Tables 33.12 and 33.13.

TABLE 33.9 Control Matrix/Plan

					More than two per shift	Notify supervisor and improvement team	Balance clerk

THE CUSTOMER AS A SUPPLIER

In service organizations, the customer is often a supplier, too. The brokerage customer, in placing an order, must supply the detailed transaction data: buy 100 shares of General Motors stock at a price not to exceed $150 a share. The bank customer that prepares a shipment of coin and currency to be deposited is supplying material input to the bank's sorting/counting process. If the customer, as supplier, errs in providing input, the service provider will be unable to deliver output that will satisfy the customer's needs.

The financial service provider's best defense against customer blame for error in output is to prevent customers from making errors in input. Three approaches used by financial service providers are customer education, errorproofing customer input, and monitoring the quality of customer input.

Customer Education to Be a Good Supplier. At a large bank, a study of a sample of out-of-balance deposit transactions (in which the deposit claimed by the customer does not match the bank's count) revealed that a major cause of the condition was the occurrence of unsegregated currency and coins in the deposit. Further, in addition to the extra work required to balance the deposit, the need to sort the coin and currency imposed its own cost on the transaction. Analysis showed that the total effect was to double the cost of the deposit transaction, a cost which all customers bore, though the increase in cost was caused by only 10 percent of the customers.

Those few customers were targeted for training. The bank's deposit department sent a delegation to the companies' premises to train the personnel responsible for preparing the deposits. The result was to reduce processing time at the bank by more than half, which, in turn, reduced costs and allowed a price reduction. The deposit error rate was reduced from 15 percent to $1/10$ of 1 percent. The customers reported a reduction of over 30 percent in time spent in deposit preparation. Bank and customers both benefited from this customer education.

Errorproofing. There are a number of ways to errorproof customer input. Paper forms for input by mail, fax, or in person serve as a checklist to assure complete input. Menus—on-screen or by voice—guide input by telephone, kiosk, or computer terminal. "Help" buttons can further assist electronic entry. Requiring the customer to verify a playback of the entered data is another form of errorproofing. Another technique is to have the customer enter the data or information twice and validate the corresponding data entries that don't match. Errorproofing as a part of training makes a powerful combination for reducing customer input error.

Monitoring and Measuring Customer Input. In the application of training and errorproofing, it is important to monitor customer input to verify effectiveness and expose any need for additional improvement. Monitoring should be done as close to the input transaction as possible—to correct errors quickly and to keep error costs down. The ideal is to monitor input as the customer is making the entry. The customer can be given immediate corrective feedback and training in how to prepare and conduct the transaction properly the next time. Training can also include spot tips on errorproofing the transaction, such as double checking, checklisting, and the like.

QUALITY IMPROVEMENT—THE NEVER-ENDING JOURNEY

Continuous Customer Input—More on Customer Listening Posts.   In addition to their importance in product development and in quality control, customer listening posts are also useful in helping identify what needs to be improved. The customer-complaint desk is a particularly effective listening post for improvement ideas. Customer satisfaction studies and customer loyalty studies also provide useful input for quality improvement efforts.

Customer Complaints and Recovery.   For several reasons it is useful to centralize customer complaint and inquiry management. First, it is useful to create a cadre of experts to deal with customer problems. When customers call, it is best that they are greeted by knowledgeable personnel who have available all the tools they need and know how to use them. Availability and capability are extremely important in dealing with customer problems. The speed with which the problem is solved will have a significant impact on the customer's final satisfaction. It is a worthy goal to solve a problem at the first call, if possible, and in the same day in any case. Research shows that each time it is necessary to recontact the customer or transfer an inquiry, customer satisfaction drops by 8 to 10 percent.

The process of fixing the customer problem is called "recovery." The centralized customer complaint group uses a number of strategies for recovery to minimize the customer's dissatisfaction. These include making an apology, replacing the product (including service) quickly, conveying a

sense of understanding and empathy, making recompense for value lost, offering a token compensation, and following up later with the customer to be sure that all reasonable effort has been made to put the matter right.

Customers left unsatisfied by a recovery effort represent a loss in at least five ways: (1) they will likely stop giving business to the offending organization; (2) they will probably give future business to a competing one; (3) they may give the offending organization negative publicity by reciting their story of dissatisfaction to business colleagues who are potential customers; (4) they will likely never offer good word-of-mouth publicity, as they might have had the recovery experience been good; and (5) their tie to the offending organization, measured by intent to repurchase, could actually have been strengthened by the combination of initial problem and subsequent recovery, properly handled.

Table 33.14 compares the repurchase intent of customers of a financial services firm who had an unsatisfactory recovery experience to customers who had a very satisfactory one.

This repurchase behavior demonstrates that effective recovery is important as a part of the effort to retain present customers. Courting customers through good recovery practice amounts to an effective and inexpensive alternative to creating a new customer to replace each one driven away by poor recovery. That this makes good business sense becomes clear upon study of the costs associated with developing a new customer, closing the account of a departing customer, and replacing the lost income stream. Additionally, financial service organizations find that immediately after a problem has been fixed the customer is ripe to be cross-sold a service (10 to 20 percent of the time the customer will buy). When an attempted sale follows the fixing of a problem customer satisfaction scores go up 3 to 5 percent more than they do as a result of only fixing the problem, and 5 to 10 percent if the sale is successful.

It should also be recognized that as a customer's relationship with a financial service provider develops, the contribution of that business to the firm's profit increases. The longer-term customer has a larger portfolio, a higher balance, uses more services, and therefore incurs higher fees and provides economies of scale with consolidated accounts and statements.

As important as it is in the short run to solve the immediate customer's problem, it is equally important in the long run to capture information about the problem, code it, and consolidate all such infor-

mation as a database to help identify what processes need to be improved. An example of a complaint and inquiry management process which features such a consolidated database is shown in Figure 33.6.

Continuous Improvement—Project by Project.   In Section 5, The Quality Improvement Process, the general principles of quality improvement are laid out in detail. The present section highlights some examples of the application of these principles in the financial services sector and resulting lessons.

To focus the improvement effort on quality of customer service can provide high payback for an organization.

TABLE 33.14 Repurchase Intent

Type of customer	Percent who intend to repurchase	Percent who will recommend purchase to others
Typical satisfied customer with no problem	51	65
Customer with problem; unsatisfied with recovery	30	46
Customer with problem; very satisfied with recovery	79	88

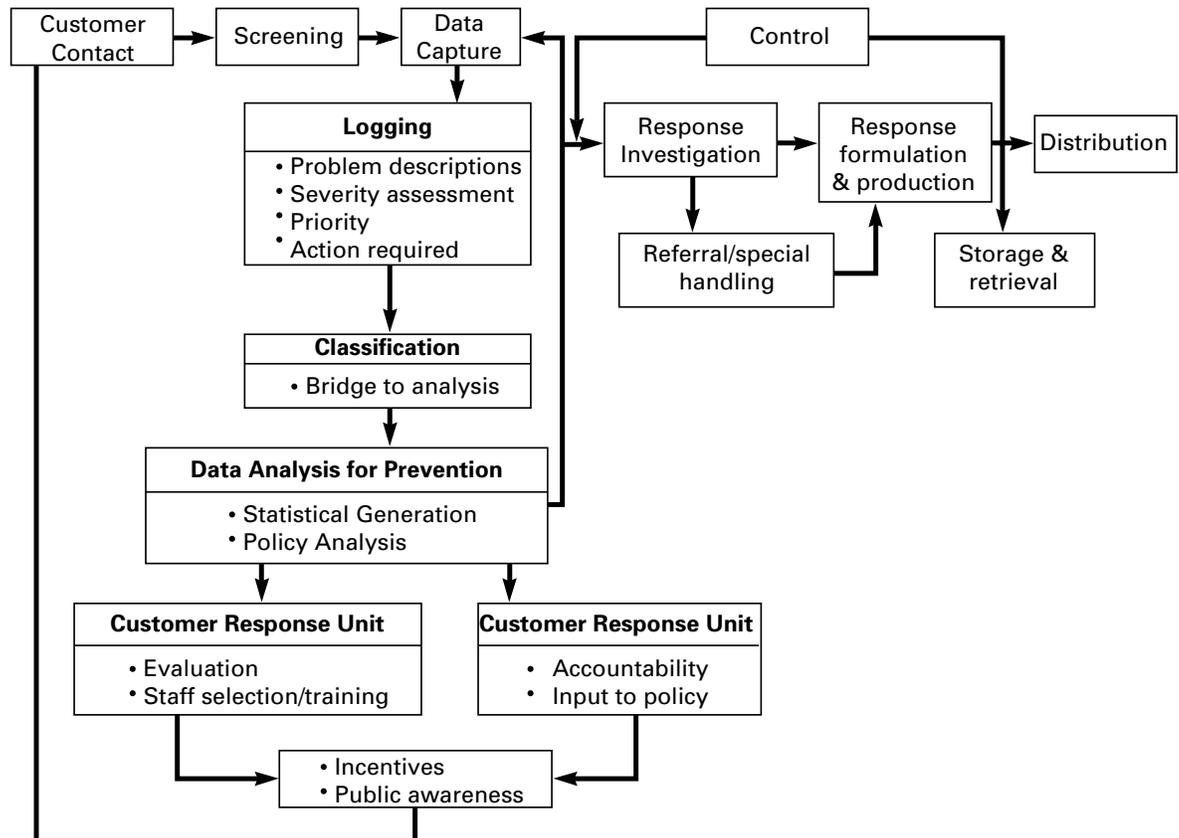
Source: TARP.


FIGURE 33.6 Customer-response framework: complaint/inquiry management.

In the first year of a quality improvement process, Banc One realized a net savings and revenue enhancement of three-quarters of a million dollars; in the sixth year, net savings and revenue enhancement exceeded 16 million dollars.

In 1991, a study was conducted of over 1000 improvement teams at 35 financial institutions (Aubrey and Gryna 1991). The most successful teams, measured in terms of saving and revenue enhancement, defect reduction, customer satisfaction improvement, and increase in employee satisfaction, shared some important characteristics:

- *Team makeup:* Mix—75 percent officer/manager level, 25 percent nonexempt; average team size—7; "ideal" team size—4 or 5
- *Team member selection:* By management
- *Training:* Two days minimum
- *Project selection:* By management or the quality council

- *Projection Duration:*   Three to four months, meeting weekly for 90 minutes.
- *Improvement tools used:*   Brainstorming, Pareto analysis, surveys, cause and effect diagram, data collection, flowcharting, work simplification, and cost/benefit analysis.

Table 33.15 is a partial list of projects completed by a large interstate bank during a single year.

In medium- to large-size organizations, tracking projects makes it possible to manage their progress, share essential information about them with other parts of the organization, and to replicate solutions where appropriate. A quality improvement tracking report system is illustrated in Table 33.15.

Project reporting is most effective when it is on line with search mode. In addition to general publicity through press and house organs, it is useful to publicize projects with potential for replication directly to the areas which would benefit from it, to exploit all possible opportunities for replication.

IMPLEMENTING AND GETTING STARTED WITH TQM IN FINANCIAL SERVICE

Section 14, Total Quality Management, covers in detail the process of planning and introducing TQM. The present section offers a few illustrative examples from financial services.

Training and Resource Commitments.   Training must be conducted and carried out first with the chief executive officer and the chief operating officer down through all levels of management within the organization. As an example, training for quality was of the utmost importance to NatWest USA. A total of 2500 employees—including the chairman, president, and every senior and executive vice president received training.

TABLE 33.15   Quality Improvement Projects at a Large Bank

Project no.	Department/branch	Project title	Identified cost reduction/revenue enhancement, $
1	Accounting services	Computer output team	466,000
2	Consumer credit collections	Retail collections job descriptions	366,421
3	Financial administration	Employee expense reimbursement	341,040
4	Bank card	Late fee review	288,388
5	Commercial banking	Account profitability/private banking	220,303
6	Operations	Cash and due team	220,124
7	Commercial loan	Commercial loan services	212,610
8	Interbank/cross-function	Cash management	168,364
9	Corporate banking	Small business lending	161,000
10	Branches	Vault cash	153,138
11	Operations	MICR reject	146,656
12	Commercial loans	Commercial loan standardization	145,446
13	Bank card associates	Credit procedure review	142,740
14	Special industries group	Credit services	138,000
...	...	...	
61	Asset/accounting	Collateral protection insurance	27,400
62	Bank card/collection	FCS/CMS nondelinquent accounts	26,926
63	Commercial banking	Commercial loan documentation	25,650
64	Operations analysis	PC maintenance	25,640
Total cost-reduction opportunity			6,054,895

All of NatWest USA's 4700 employees attended a 1- or 2-day training sessions. This training ensured a common language and approach and provided a standard set of tools and techniques to address the opportunities at hand.

Each course included a broad-based discussion of quality, creating a common definition of quality, customer/supplier relationships, identifying and meeting customer needs (for both internal and external customers), the cost of quality, quality measurement and reporting, and tools and techniques for data collection and analysis. Case studies utilizing current bank data and processes were key elements of the training.

Different kinds of training with different objectives must be made available to different types of employees. Figure 33.7 demonstrates the array of courses offered by a Fortune 500 financial service company that is relatively mature in the quality management process.

Some of the best-performing financial service companies report 10 to 15 days of training per year per employee.

Strategic Planning.   An extremely important element to sustain and drive a total quality effort is strategic planning. Quality must be integrated into the business plans of financial services companies or any company for that matter. This keeps quality from becoming an adjunct activity and elevates it in importance, as it should be, with operations, finance, marketing, etc.

It can become a strategy of its own or can be integrated with other strategies. Quality activities such as measures, goals, standards, projects, training, and teams make the strategic plan a reality by executing the strategies. See Section 13, Strategic Deployment, for more details regarding strategic planning.

Management Involvement—Professional and Personal.   Effective leadership of the quality improvement process requires senior management to set an example and tone for quality within their organizations. In some companies, this includes the designation of a chief quality officer, with responsibilities analogous to those of the chief financial officer. These responsibilities include planning and assuring that the organization's plans for quality are developed and are being carried out, assuring that quality is being managed and controlled to plan, and assuring that quality improvement is continuous. The chief quality officer is most able to be effective when the position reports to the CEO, president, or the chief operating officer of the company.

The Dawn of Revolution.   More and more financial services are becoming automated every day; this is especially true in retail services. In banking, there is a fundamental shift underway—from brick-and-mortar, people-intensive service to service which is totally electronic. According to the American Bankers Association, as of 1996 over 40 percent of transactions were electronic; the figure is projected to be 60 percent by 1998. Soon, it will not matter whether the bank, broker or insurance company is in Boston, Beijing, or Barcelona.

Managing the quality of customer service

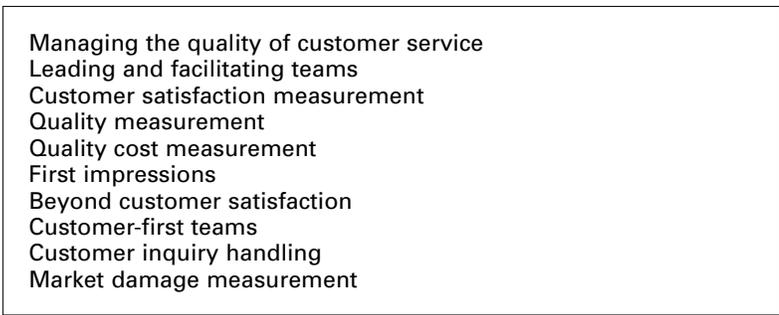

FIGURE 33.7   Content of financial service quality training.

- In obtaining a loan, the original signed note is the only physical document required; it can be transferred by overnight courier. The money and all of the other information can be sent by fax, on the Internet, and by wire transfer.

- A deposit and investment account can be set up and transactions conducted by fax, Internet, and wire transfer.

- Life insurance application and payment can also be done by fax, Internet, and wire transfer. Only the medical examination resists automation as of this writing. The results, though, can be transmitted by fax to the insurance company. A nurse can visit the applicant at home to administer a blood test, take blood pressure and pulse, and so on.

PC/modem services	58%
Internet services	53%
Screen phone services	47%
PC/third-party network	42%
Interactive TV services	26%
Other automation	25%

FIGURE 33.8   U.S. banks' service plans for 1998.

As electronic capability increases, the accompanying reduction in costs, cycle time, defects, and errors increases profit.

In the 1980s home banking ventures were a failure. Today, over 40 percent of American homes have personal computers; an even higher percentage of businesses have them. This equipment base creates a far more fertile climate for electronic financial services than existed just 10 years ago. Figure 33.8 shows what U.S. bankers planned for 1998, according to the American Bankers Association.

An electronic innovation of great potential for change in financial services is the "smart" card. The smart card resembles the credit card in appearance, but differs radically in that it contains electronic circuitry that enables it to be electronically loaded with monetary value and be relatively independent, except for a simple device to electronically read and transfer value from it. A person can receive salary or incentive payment on the card, make payments and transfers, pay for services, and get cash. This expansion of services is potentially very attractive to customers. Additionally, the card promises services that are faster, more reliable, more accurate, in a wider variety, and at lower cost.

Dozens of smart card trials are being carried out around the globe. Smart cards are being tested in France and Spain and were also tested in Atlanta at the 1996 Summer Olympics. Dutch banks, including ING Bank, are issuing the cards now and expect them to be distributed nationwide by the end of 1998. American Express pays bonus incentives to its employees with smart cards it developed.

The smart card and other elements of the electronic revolution portend great change in financial services. Improved services for customers will be accompanied by a great change in the nature and number of jobs in financial services. There will, no doubt, be more jobs requiring higher skill levels, such as customer service, programming, computer operation, and so on. In proportion, there will be fewer clerical jobs.

Companies in the financial services sector will find that the tools of quality management will provide welcome help in mastering this rush of innovation and change, and may prove to be the competitive edge.

SECTION 34
SECOND-GENERATION DATA QUALITY SYSTEMS

Thomas C. Redman

INTRODUCTION

This section discusses the ubiquity and poor quality of data. More specifically, it explains why the manager must be concerned about poor data quality and discusses the approaches to improvement. Most people recognize that if there are errors in data, they should be corrected. And indeed, good software packages can help find certain errors in even the largest databases. But new data are created at enormous rates, so the job of error detection and correction never ends. Leading enterprises have achieved superior results with so-called second-generation data quality systems, which are those focused on preventing future errors. This section is a guide to the leader who wishes to upgrade to a second-generation data quality system and reap the benefits of improved customer satisfaction, lowered costs, and more confident decision making.

This section begins with an outline of the steps taken by one executive to do so. It then summarizes critical differences between data and other resources and the complexities they engender for data quality. Next, it sketches the business case for second-generation data quality systems. Lastly, it describes good practice in defining and implementing them.

THIS REPORT IS WRONG!

To illustrate one way that implementation of a second-generation data quality system could proceed, consider a fairly large service enterprise, organized in several business units and staff functions. The enterprise is profitable, but its industry is extremely competitive and becoming more so. In this

example, the head of one business unit is frustrated that summaries of financial performance are late, incomplete, and inaccurate. Important decisions are delayed, then made in haste. Poorer decisions that are harder to implement are the direct result.

This executive decides to start a small program to explore the benefits of a second-generation data quality system. He or she selects an important data-driven business problem. (Experience suggests that areas and problems involving money, such as billing, revenue, customer accounts, and marketing, are especially impacted by poor data and can produce case studies with bottom-line results rather quickly.) A *customer need analysis* is conducted to determine who is concerned about this problem and to understand their data needs. Next, primary *sources of* (*internal*) *data are identified.* A *planning project* identifies two or three important gaps, and *improvement projects* follow. Upon completion, *controls* are implemented to hold the gains.

The people responsible for these projects share their successes with this executive's staff. The executive urges further projects and each staff member agrees to conduct a test project or two. In conducting these tests, several staff members recognize that the data cross their functions and they begin to explore *process management* as a means of working together. Another acquires important data from a commercial source, and decides to explore *supplier management.*

Not all projects succeed. But enough do and the reports that originally frustrated the executive are now much better. The staff decides to devote a portion of each bi-weekly staff meeting to data quality, effectively forming itself as a *Data Council.* And it, at the vocal urgings of the executive, decides to be more vigorous in its efforts. It agrees to aggressive improvement targets after a high-level planning effort and decides it must formalize its approach to meet them. Council members also recognize the need for *vision* and *policy,* and devote time over several months crafting them.

In parallel, our executive decides it is time to inform the CEO of his/her unit's data quality program. He or she naturally wants *recognition,* both personally and for those who led improvement efforts. More importantly, projects increasingly need the cooperation of other units, which are reluctant to provide it (importantly, few data quality systems impact beyond the span of control of their most senior sponsor). And the cycle repeats itself across the enterprise.

In time, the enterprise and executive discover the techniques described herein. They will also learn some important features of data.

PROPERTIES OF DATA

In many respects, the techniques used by the executive and enterprise mentioned previously are as described throughout this handbook. But data differ from other resources in some critical ways, and these differences can have important, yet subtle, impact on the data quality program. These differences (Levitin and Redman 1998) include the following:

Consumability: Unlike other resources, data are consumed with use.

Copyability: Data records can be copied for a fraction of the cost of the original. You simply can't do this with other resources.

Computer Storage: Data, unlike other resources, can be stored cheaply and easily in almost unimaginable quantities on computers.

Depreciability: Data, can, in principle, be immortal. While their value does not diminish with use, the utility of most data deteriorates rapidly in time.

Fragility: Paper data records are occasionally accidentally destroyed, but they are more apt to be lost. Data stored in computers are much more fragile.

Intangibility: Perhaps the most obvious difference between data and other resources is data's intangibility. While data recordings can be seen and touched, data themselves are intangible.

Nonfungibility: Fungibility means that one unit of a resource can easily be exchanged for another, assuming another unit is available. But data "units" are inherently unique. You simply cannot substitute one person's date of birth for another's.

Renewal: Whenever pertinent features of the real-world change, data values change and/or new ones are created. New data result from everyday business—each customer transaction, each shipment, indeed, practically every activity leads to new data. This happens at astounding rates. This property of data, called "renewal," does not really apply to other resources. In most cases, there is an inherent lag time until all databases are updated.

Shareability: To a larger degree than any other resource, data may be shared.

Source: In contrast to other resources, data are generated by a tremendous number of sources. In many cases, the original sources of many data sets are undocumented or even unknown. The Internet is exacerbating this problem.

Transportability: Data are also unlike any other resource in the degree, ease, and speed with which they can be transported over long distances.

Valuation: Neither markets nor standard accounting practices exist for most data.

Versatility: Data collected and used for one purpose are often used in other applications. Data-driven marketing is one such example. But some alternate uses of data are illegitimate. Data about a person's age, for example, cannot be used in a hiring decision.

Implications for Data Quality. The following are some of the more obvious ways that properties of data influence the data quality program. First, that which is "out of sight is often out of mind." As data are stored neatly away in computers, there seems to be a tendency to pay them less attention, particularly given the other compelling and highly visible problems facing the enterprise. So many enterprises are not even aware of their data quality issues. This problem is exacerbated by the lack of accepted methods of valuation. It is much easier to spur management action when there are clear monetary costs or benefits.

Second, more than anything else, the high rates of data creation (renewal) ensure that error detection and correction won't work well.

Third, since data are not tangible, they have no physical properties. This complicates measurement. Managers and technicians know how to measure physical properties such as length, viscosity, time, and impedance. But all important data quality dimensions are abstract and so are difficult to measure. For example, you can't tell by direct examination whether most data are correct.

A number of properties help create difficult political situations [see Davenport et al. (1993), Strassman (1994)]. It is interesting that while data are shareable, this is the exception rather than the rule in most enterprises. Instead, since data are relatively inexpensive to store, copy, and transport, organizations within an enterprise often acquire, store, and manage their own. This immediately raises issues of ownership—issues that are among the most brutal in many enterprises. It also makes any kind of centralized planning for data and standards difficult to establish and enforce.

A number of properties (copyability, transportability, nonfungibility, fragility, and cost of storage) conspire to increase redundancy and contribute to a "save everything" mentality, including data that are no longer useful. Yet all redundancy is not bad. For example, redundancy allows users to work with data in the environments of their choosing (for example, it helps make the office-at-home feasible).

BUSINESS CASE FOR SECOND-GENERATION DATA QUALITY SYSTEMS

Second-generation data quality systems make good business sense. The case is summarized as follows:

- Data are used by every activity conducted by the enterprise.
- Most data are of poor quality.
- Current efforts to find and correct errors don't work well.

- Left alone, the problem will become more critical as data become even more important. The Internet exacerbates this problem.
- Second-generation data quality systems cost less and produce better results.

The following subsections explain these points in more detail.

Data Are Ubiquitous.   In the previous example, the "call to action" stemmed from poor decisions. It is axiomatic that decisions will be no better than the data on which they are based. Nor should one expect any other activity that takes poor data as inputs to yield superior results. And indeed, data are ubiquitous—virtually every activity in which the enterprise engages requires data. Consider the following:

- Data are both critical inputs to and outputs of almost all "work" performed by an enterprise. Data are used to serve customers, manufacture products, manage inventory, and so forth.
- Data support managerial and professional work and, as in the previous example, are critical inputs to almost all decision making at all levels of the enterprise. Data are the means by which the enterprise knows about its other resources—financial, human, and so forth.
- Data may be combined in almost unlimited ways in the search for new opportunities, market niches, process improvements, and new products and services.
- Because definitions of common terms like "customer" and "service" are captured in data, they (data) contribute to the enterprise's culture. They "fill the white space" in the organization's chart.
- Enterprises strive to convert tacit "knowledge" into data. For example, a company's salespeople may have warm personal relationships with the company's most important customers. But for the company as a whole to serve these customers, important aspects of the relationships must be specified in data. (Some authors have noted that "data" are the raw material for "information," which in turn are the raw materials for "knowledge." The reverse direction is even more important. Specifically, knowledge created or developed by an individual or group must eventually become structured data so others can apply that knowledge.)

It is interesting to note that these activities can be taking place simultaneously, using the same data. Figure 34.1 depicts a typical scenario. The end-to-end process of information supply, new data creation, processing, and use is called an "information chain." "Information products" are the outputs along the way—the data recorded in databases, reports, analyses, and so forth.

Most Data Are of Poor Quality.   At the time of this writing, the best known data quality problem is the so-called "year 2000 (Y2K) problem." Examples of other common data quality problems include:

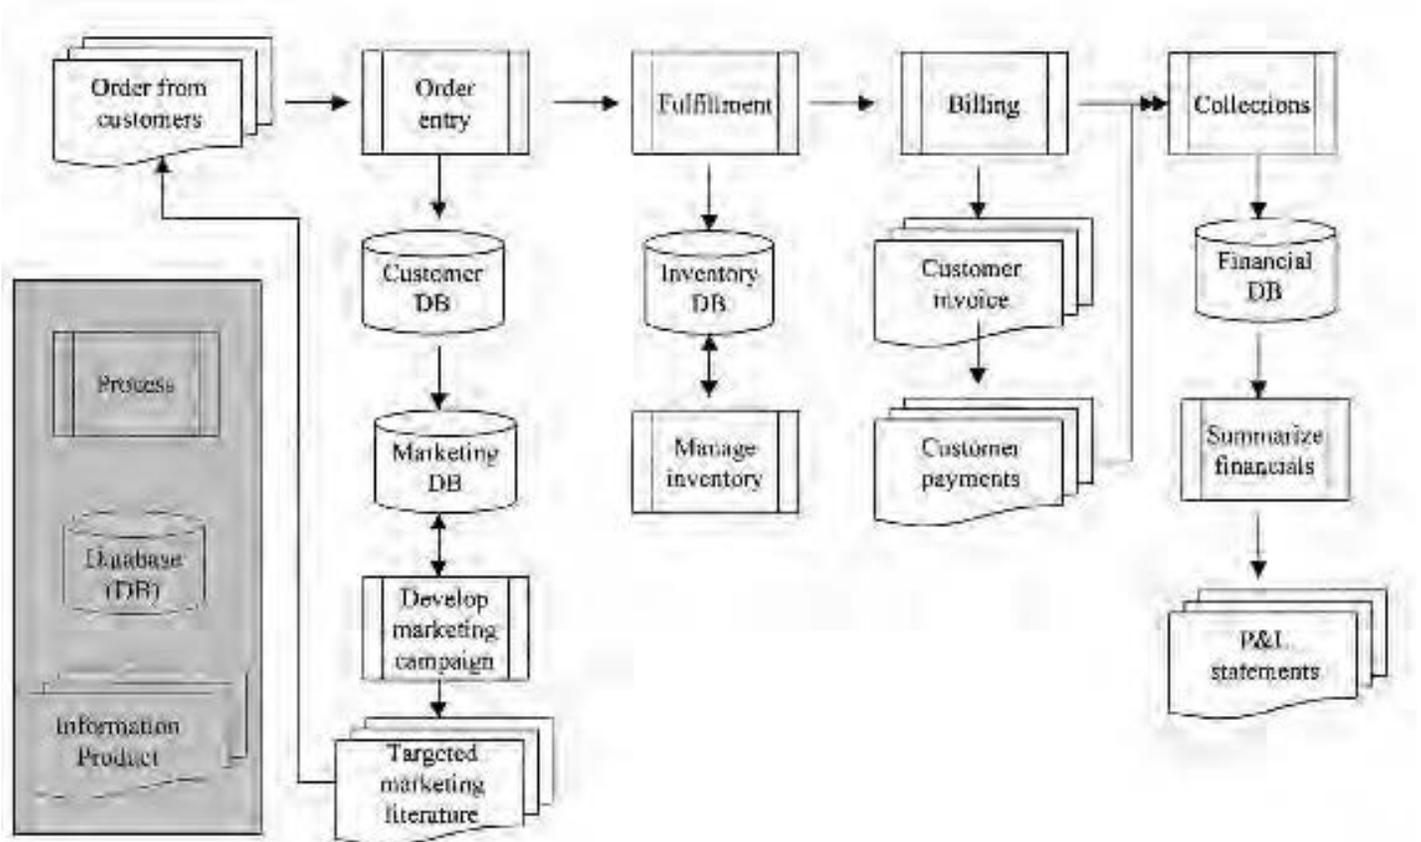
- *Low Accuracy:*   Accuracy is probably the most carefully studied data quality issue. Numerous studies yield error rates ranging from 1 to 75 percent. Direct mailers find that up to 20 percent of their flyers are returned as undeliverable; customers find billing errors; scanners report incorrect prices; etc.
- *Inconsistency:*   Data values in two databases, "owned" by two organizations within a bank, disagree. The two organizations cannot determine who their common customers are.
- *Difficulties in interpretation:*   A clothier may provide shirts in four sizes: small, medium, large, and extra large. In the computer system supporting manufacturing, these sizes are coded "1," "2," "3," and "4," respectively. Later, operators can't recall whether "1" means small or extra large.
- *Unmanageable redundancy:*   Many enterprises have any number of copies of the same data. L. P. English (1998) cites a company that had 43 such redundant databases. In addition to adding complication and expense, redundancy makes it more difficult to maintain consistency.


FIGURE 34.1 An example of an information chain (or chains depending on how the enterprise chooses to manage) and the numerous recodings in databases and information products produced.

Poor quality data seem to attack information chains like viruses—there is no way to predict exactly where they will strike next or the impact they will have.

Error Detection and Correction Yield Poor Results.   Naturally many enterprises are not blind to poor data quality. So they undertake efforts to detect and correct errors. Direct inspection is one way of doing so. Many organizations review the data supplied to them by upstream organizations to identify data they "know are wrong" because the values are outside accepted domains. Others search for inconsistencies in a collection (or collections) of data. Thus, if a customer's telephone area code = 999, the value cannot be correct. Or if the telephone area code = 212 (New York) and address zip code = 90210 (California), then at least one value must be in error. The search for inconsistencies can be quite sophisticated, involving numerous fields, several databases, and sophisticated error logic. These searches may be computerized and a number of good software programs are available. Once errors have been found, they must be corrected and in some cases, error correction logic helps do so. But correcting errors is often more difficult than finding inconsistencies. In some cases the company must make reference to the real world to determine correct values.

Even conscientiously applied efforts to detect and correct errors do not yield satisfactory results. The litigation alone from noncompliance in the Y2K problem may cost $1 trillion in the United States (Thompson 1997). Of course, "everyday" problems have costs also. The total costs across the typical enterprise are summarized in Table 34.1.

Some costs are stated in quantitative financial terms. Those affecting customers or employees are not so easily quantified but may be even more important. First, is the impact of poor data on customer satisfaction. Customers receive much data as a byproduct of the product or service they receive. The invoice for product sent is a good example. Many customers are remarkably

Table 34.1   The Costs of Poor Data Quality to the Typical Enterprise

Typical problems
Inaccurate data
Inconsistencies across databases
Inappropriate formats
Difficulties in interpretation
Unmanaged redundancy

Typical costs*
Operational costs:
Lowered customer satisfaction
Increased cost: 8–12% of revenue in the few, carefully studied cases; for service organizations, 40–60% of expense
Lowered employee satisfaction
Tactical costs:
Poorer decision making: Poorer decisions that take longer to make
More difficult to implement data warehouses
More difficult to "mine" data and re-engineer
Increased organizational mistrust
Strategic costs:
More difficult to set and execute strategy
Contribute to issues of data ownership
Compromise ability to align organizations
Divert management attention

*Operations, tactics, and strategy represent a loose hierarchy of work performed. Operations are the day-to-day tasks such as order entry, customer support, and billing. Tactics are the decisions of short- and mid-term consequence and work to support them usually made by middle managers. Strategy involves long-term direction.

Source: After Redman (1998).

unforgiving of billing (and other data) errors, reasoning that any company that can't bill them properly simply can't provide a good product or service.

Second is the impact on employees. One cannot expect the hotel clerk, dealing with irate travelers whose reservations have been lost, to have high job satisfaction. And many enterprises have dozens, even hundreds, of such "customer care" jobs. This issue occurs at the organizational level as well. When one organization depends on another for input data and those data are frequently wrong, it is natural for the former to develop a poor opinion of the latter. And their ability to work together in the future is compromised.

The Importance of Data Will Continue to Grow.   Data have always been important to commerce and their importance continues to grow rapidly. They are the fuels for economic growth in the Information Age.

Increasingly, important data are computerized. This trend has accelerated for several decades, driven by impressive advances in database, networking, and communications technologies. It has made data available to new, unsophisticated users and exacerbated issues of poor data quality. Many people have a tendency to assume that "if it is in the computer, it must be right." Such people are more easily victimized by poor quality data. Even sophisticated users cannot be expected to have familiarity with the nuances of all the data they encounter. The Internet is taking these phenomena in directions that are not fully understood. Specifically, companies are making their data, heretofore closely held, directly available to Internet users, a remarkably diverse group with disparate needs that are likely to be quite different from those of internal users. Thus, data quality issues too will become both more critical and difficult as a result.

Second-Generation Data Quality Systems. In recent years superior approaches that focus not on individual errors, but rather on identifying and eliminating root causes of entire categories of errors have been developed. Companies find they can make order-of-magnitude improvements, often by eliminating some rather simple (once they have been identified) problems. After Ishikawa (1990), we call techniques aimed at error detection and correction "first-generation techniques" and those aimed at eliminating root causes "second-generation techniques."

By a *"data quality system"* we mean the totality of an enterprise's efforts to manage, control, and improve data quality. The system includes:

- Activities aimed at understanding customer needs
- Activities aimed at detecting and correcting errors and activities aimed at preventing future errors (including control and improvement)
- Activities to build management infrastructure to do so effectively and efficiently

Second-generation data quality systems are those that emphasize prevention of future errors over error detection and correction and build management infrastructure to do so effectively and efficiently.

Practitioners have learned that second-generation data quality systems cost far less and produce much better results. Consciously applied, these systems have helped many organizations reduce error rates by factors of 10 to 100, cut cycle time in half, and reduce costs by up to 75 percent. Customer service is better and employees feel much greater involvement in their jobs, so morale improves. These results, summarized in Table 34.2, stand in marked contrast to the baseline of Table 34.1.

DATA DEFINED AND DIMENSIONS OF DATA QUALITY

Data Defined. As used here, "data" per se (or a "data collection," "data set," etc.) consist of two interrelated components, "data models" and "data values" (Fox and Redman 1994). Data models are the definitions of entities, attributes, and relationships among them that enterprises use to structure their view of the real world. Enterprises often model a given portion of the world

Table 34.2 Typical Results from Implemenation of a Second-Generation Data Quality System

Typical improvements
Accuracy improved by 1 to 2 orders of magnitude
Easy-to-read formats
Redundancy and inconsistency minimized

Typical benefits
Operational benefits:
A primary source of customer dissatisfaction eliminated
Decreased cost: Two-thirds to three-quarters of cost of error detection and correction eliminated
Important cycle times cut in half
Employees feel empowered
Tactical benefits:
More confident decision making
Re-engineering opportunities suggested
New technology implementation easier
Organizations build trust by working together
Strategic benefits:
Issues of data ownership eased
Easier to set and execute strategy

differently. For example, an employer may be interested in a person as an *employee,* the IRS as a *taxpayer.* The person is the same real-world entity in both cases, the employer and IRS are interested in different attributes. Data values are the specific realizations of an attribute of the data model for specified entities. The "123-45-6789" in taxpayer social security number$=123456789$ is a data value.

"Data records," as distinct from data per se, are the physical realizations of data stored in paper files, in spreadsheets, in databases, and so forth and presented to users in ways that (one hopes) make them easy to store and use. Note that data (i.e., the models and values) are abstract, while data records are their tangible realizations.

It is evident that data are not just random facts and figures, but rather are quite structured. Especially for computerized data, several steps must be completed before they can be used. These steps, summarized in Figure 34.2, include model development, acquisition of the values, storage, selection of what the user wants to see, and presentation to the user. All can impact customer satisfaction, though some steps are more pertinent to the computer systems, than to data. And many of them are carried out by separate organizations. Thus data models are the responsibility of those who develop databases, variously called Information Technology, Information Systems, or Information Management Systems (all abbreviated IT herein). Data values are created within or obtained from external suppliers by line organizations or business units in the course of everyday business. IT is also usually responsible for the manner in which data are recorded and presented to users.

The most important common dimensions of data quality are discussed below.

Dimensions of Data Quality.   "Dimensions" of data quality stem from user needs. The "properties" described previously are intrinsic to data. Customers naturally have needs or requirements that bear on each major constituent of data (model, values, and records). It is important to distinguish closely related needs, such as accessibility, that bear more on supporting technology, from those directly pertinent to data. Table 34.3 lists the most important "dimensions of data quality" [The definitions of many of these dimensions are quite technical and the interested readers are referred to Fox and Redman (1994) and Levitin and Redman (1995).]

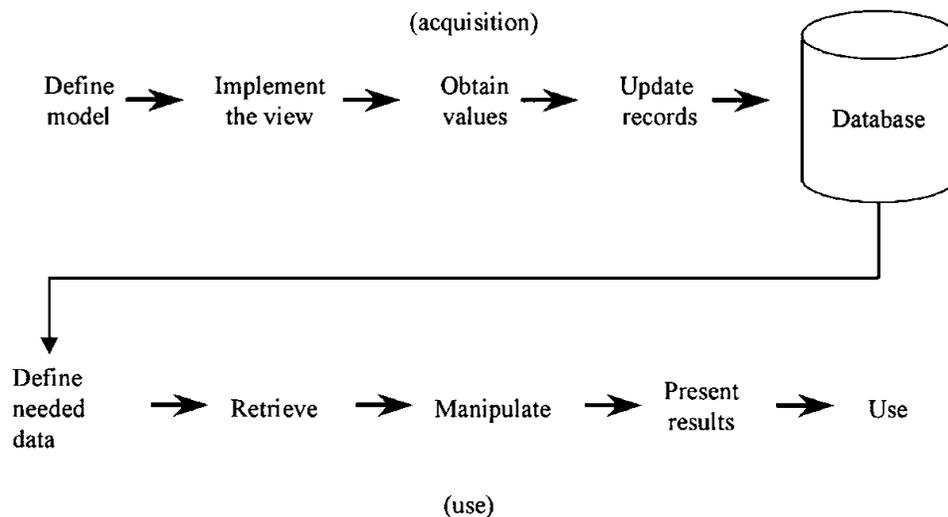
To summarize, high-quality data are data that are fit for use in their intended operational, decision-making, planning, and strategic roles. As Figure 34.3 depicts, data models and presentation define the features of high-quality data. And data values must be free of defects. Supporting technologies must make data secure yet accessible and ensure privacy.


FIGURE 34.2   The data life-cycle model features activities needed to define a data model, obtain values, store and process data, and present the user with what he/she wants.

Table 34.3   Dimensions of Data Quality*

Quality dimensions of a data model		
Scope	*Comprehensiveness*	*Essentialness*
Level of detail	*Attribute granularity*	*Precision of domains*
Composition	*Naturalness*	*Identifiability*
	Homogeneity	*Simplicity*
Content	*Relevance*	*Obtainability*
	Clarity of definition	
View consistency	*Semantic consistency*	*Structural consistency*
Reaction to change	*Robustness*	*Flexibility*
Quality dimensions of data values		
	Accuracy	*Completeness (entities and attributes)*
	Consistency	*Currency (cycle time)*
Quality dimensions of data records and presentation		
Formats	*Appropriateness*	*Format precision*
	Use of storage	*Correct interpretation*
	Flexibility	*Portability*
	Represent null values	
Physical instances	*Representation consistency*	
Other dimensions often associated with data		
	Accessibility	*Appropriate use*
	Privacy	*Redundancy*
	Security	

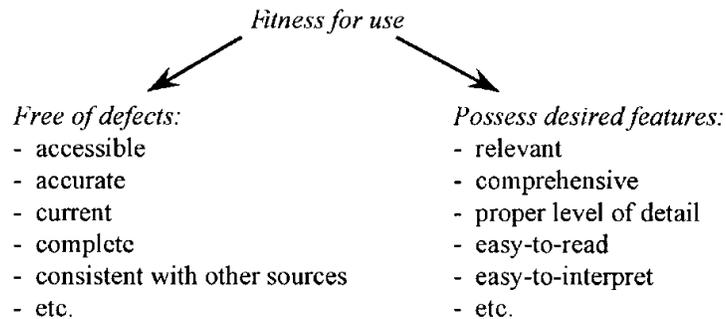
Source: Fox et al. (1994) and Levitin and Redman (1995). For an alternative formulation, see Wang and Strong (1996).


FIGURE 34.3   Data are of high quality if they are "fit for use" in their intended operational, decision-making, and other roles. Fitness implies both freedom from defects and possession of desired features. Most users associate dimensions associated with data models as desired features and the lack of other features as defects.

SECOND-GENERATION DATA QUALITY SYSTEMS

The thrust of second-generation quality systems is to consistently identify and prevent the most important root causes of future errors. This requires both proper technique and management infrastructure. This section describes each element of a second-generation data quality system. (See Table 34.4 for a list.) Each enterprise must craft and evolve its own data quality system. Four elements, senior leadership and support, quality planning, quality control, and quality improvement are required. Other elements are selected based on the enterprise's opportunities and challenges, its culture and organization, and the origin of its most important data.

Table 34.4   Elements of Second Generation Data Quality Systems

Management infrastructure	Process description
Senior leadership and support	Measurement
Data quality vision	Quality planning
Data quality policy	Quality control
Supplier management	Quality improvement
Process management	Process (re-)design
Change management	Inspection and test (data editing)
Database of record	Quality assurance
Strategic data quality management	Document assurance
Training and education	Rewards and recognition
Technical capabilities	Domain knowledge
Identification of information chains	Standards
Customer needs analysis	Quality handbook

Management Infrastructure

Senior Leadership and Support.   As we have observed, data cross organizational boundaries in the blink of an eye and the politics associated with data can be brutal. So senior leadership, support, and intervention in the conflicts that are sure to arise are essential. These may be provided by a Data Council (or a Quality Council). Senior management is ultimately responsible for crafting the data quality system and leading its implementation. It ensures that data quality efforts are directed at the most pressing business problems and opportunities. To do so, it develops and deploys a vision and policy (see the following two paragraphs), sets quality goals, selects planning, control, and improvement "projects," and provides cross-functional coordination for projects that require it. It allocates funds for data quality efforts and ensures that the enterprise is properly trained.

Data Quality Vision.   People need to know where the enterprise "is going." A vision is a "picture" of the enterprise's desired future state with respect to data and information, including a rationale for people to work to create that future state. Developing the vision forces the Data Council to think about the enterprise's long-term data and information needs to ensure business success. A vision, supported by broad communication, helps align the enterprise and motivates people to work together to achieve the desired future state.

Data Quality Policy.   A data quality policy (or simply data policy) is management's statement of intent regarding long-term data and information quality. It serves as a "guide for managerial action." It should recognize data as "business assets" and, accordingly, specify improvement objectives and management accountabilities for achieving them. The best second-generation policies delineate accountabilities along information chains from those that create data models to creators of data values to data users (Redman 1995, 1996). Like the vision, formulating policy forces the Council to think broadly and deeply about management accountability for data. Widely communicated policies help align the enterprise and provide a basis for decision making by lower-level managers.

Supplier Management.   Almost all enterprises receive data from outside. Some is purchased, while other data, such as an invoice, are the byproduct of other goods and services. The quality of these data is extremely important. Supplier management is the overall program for managing suppliers, including selecting them, ensuring that they understand what is expected, measuring performance against expectations, and negotiating improvements to close gaps.

Process Management.   Well-managed information chains ensure that data values created throughout will be of high quality. Process management (see Section 6) provides the infrastructure and technique needed to do so. Experience confirms that most individual functions within a single organization work fairly well. But "problems" and/or opportunities occur when organizational boundaries are crossed

(and as noted in Figure 34.1, data cross organizational lines in the blink of an eye). Process management focuses specifically on organizational interfaces. It provides a structured framework for utilizing many of the techniques presented in the next subsection and is a proven method for making and sustaining improvements to data.

Change Management.   Most enterprises/organizations have first-generation data quality systems. Second-generation systems require them to think and act differently and change is always difficult. Experience shows that when change is managed, the risks can be reduced (Kotter 1996). Enterprises are advised to be conscious of these issues and actively address them.

Database of Record.   Most enterprises have too much redundant data. But how to manage and reduce redundancy? It is natural to try to do so by recognizing an official "standard" data source to be used throughout the enterprise. But people have resisted what they perceive to be authoritarian directives about data, particularly when the designated source is difficult to use, inaccessible, out-of-date, or otherwise of low quality. A database of record addresses this issue directly. It provides a set of quality standards (for example, accuracy greater than 99.5 percent) and a manager ("custodian," "keeper," or "steward") charged with ensuring that the source satisfies them. Only then is the database designated as the "approved master source" for that data.

Strategic Data Management.   In most enterprises, today's data do not meet the enterprise's current needs. And all expectations are that the typical enterprise's data needs will grow exponentially in the future. Strategic data management aims to ensure that the enterprise's top-line business strategy is "data-enabled," that the enterprise has the data and information assets (especially data sources, information chains, and the ability to exploit them) to effect its strategy.

Training and Education.   Management must ensure that all involved have the knowledge, skills, and tools needed to improve data quality.

Technical Capabilities.   We now turn our attention to the technical capabilities needed to focus improvement efforts, make and sustain gains, and ensure continuity.

Identification of Information Chains.   Not all data are created equal. The enterprise should define and execute a process (either formal or informal) of identifying the data and information chains most critical to the enterprise. The data quality program should be focused on these assets.

Customer Needs Analysis.   The customer is the final arbiter of quality, so understanding who they are and their needs, prioritizing those needs, and communicating to those who need to know is essential. Good second-generation systems focus incessantly on users of data, formally document and keep customer needs, and keep them current.

Process Description.   Although data cross organizational boundaries in remarkably confused paths, managers need to understand these paths. Process description is the means of acquiring and documenting this understanding. There are many ways to conduct this process. Good descriptions of information chains include suppliers, the steps taken to produce information products, customers, and all other essential aspects (including data, organization, supporting technologies, etc.) that may impact performance. The simple act of describing what is actually happening often brings incongruities to the surface, and these incongruities become opportunities for improvement.

Measurement.   Management of data quality proceeds on the basis of fact (see also Section 9). And facts are needed at many levels of the enterprise. At a low level, measurement is the process of quantifying information chain performance, including aligning measures to customer needs, specifying the measurement protocol, collecting data, and presenting results. Good second-generation practice emphasizes measurement *within information chains* at the points of new data creation. "Data tracking" is one method to do so (see Redman 1995, 1996). It also helps solve the intangibility issue noted

previously. At the enterprise level, measurement also refers to the overall system or collection of measurement processes and management summaries to track overall progress. One important overall measurement may be the cost of poor data quality.

Quality Planning.   At the enterprise level, planning is the regular (e.g., annual) process of setting quality goals or targets and/or improvement and putting in place the means to achieve those goals. At the "project" level, planning is a team-oriented process that creates or replans new information products, information chains, or controls to meet specific customer needs. The first steps of a re-engineering project also constitute quality planning.

Quality Control.   Quality control is the process of evaluating (quality) performance, comparing that performance with standards or goals, and acting on the difference (see Section 4). Establishing and maintaining control is essential because it provides the basis for predicting that errors will not occur in the future.

Quality Improvement.   Good second-generation practice calls for use of a structured team process for reducing errors and other deficiencies in information chains and information products. This process involves identifying and selecting improvement opportunities (projects), chartering teams to make improvements, completing those projects, and "holding the gains" (see Section 5). Like the other elements of the Juran trilogy, quality improvement is essential to second-generation data quality systems. Participating in and completing projects is the vehicle by which most people are inculcated into the "quality culture."

It is important to recognize the proper role of computer, networking, and database technologies in data quality improvement. These technologies have been quite effective in enabling well-established and well-managed information chains to perform faster and cheaper. But technology alone [see also Landauer (1995) and Strassman (1997)] is not the key to improving data quality. Indeed an overreliance on technology appears to exacerbate inadequacies. Information chains must be put into reasonable working order before applying the newest technology. For years, quality gurus have advised against automating ineffective factories. So this prescription simply extends that time-tested maxim to data.

Process (Re-)design.   Some information chains are fated to yield poor results because they are poorly designed. A chain in which raw data must be manually rekeyed into several computers is a good example. It simply won't work effectively or efficiently. The planned "blueprint" of an information chain (including suppliers, the sequence of work activities, interfaces, supporting technologies, management accountabilities, and information products delivered to customers) should incorporate principles of good design. For example, the tools needed by the process owner (i.e., measurement and control) should be incorporated into a process design. Other best practices are given in Redman (1996, Chapter 14).

Inspection and Test (Data Editing).   Data editing is the process of determining if data values satisfy consistency criteria. Editing is usually applied in data clean-ups and, as such, is more properly a first-generation technique. Edits may be employed in second-generation systems at the points of data creation and entry to prevent defective data from proceeding further. Failures (and corrections) must be counted and classified and used in control and improvement projects. Editing may also be employed as part of a supplier program and is sometimes necessary for complex information products.

Quality Assurance.   A quality assurance program consists of audits to determine the degree to which the data quality system, as designed, is deployed and functioning.

Document Assurance.   Procedures are needed to control documents and data/information that relate to requirements of the data quality system. In particular, a master list of all current policies, procedures, and results should be accessible to those that need it.

Rewards and Recognition.   As noted previously, second-generation data quality systems require people to think and act differently. Rewards and recognition that provide the reinforcement and feed-

back of superior performance should be part of the enterprise's merit/compensation rating system. Specifically, compensation increases and promotion decisions should take employees' contributions to data quality into account.

Domain Knowledge. The enterprise should take care to learn more about data as a resource (see Levitin and Redman 1998), the data they use, the way data create value, and techniques to manage them. As we have noted, data are different from other resources. Intimate knowledge of their properties is critical.

Standards. Standards are accepted definitions, rules, and bases of comparison, usually developed and agreed-upon by a body with authority to do so. Standards can advance a data quality program. For example, a standard definition of common terms such as "customer" could help reduce the number of partially redundant and disparate databases. But standards have been very difficult to effect in most enterprises. The various organizations just can't seem to agree on a common definition. The root cause of the issue seems to be that the various organizations think differently about their customers and their thoughts are captured in their data models. They fear that a standard definition would compromise their relationships with customers.

There is no easy resolution to this issue. As a practical matter, it is usually best to postpone work on standards until other elements of the enterprise's second-generation data quality system are in place. And the Data Council should first gain some experience with relatively less contentious standards.

Quality Handbook. As a quality system matures, it is appropriate to codify it into a published "book" containing an enterprise's quality policy, important concepts and definitions, and procedures. Ideally the handbook is customized to the enterprise, general enough for widespread use, yet specific enough to help focus the enterprise's efforts.

CONCLUSIONS

An important analogy likens a database to a lake. Water represent the data and the streams feeding the lake represent information chains. Animals who drink from the lake and others who enjoy the lake represent users. Presented with a polluted lake, the community has three choices:

- It can suffer the consequences.
- It can filter the lake water.
- It can eliminate sources of pollution upstream.

Experience confirms that the best results are obtained with the third approach. For data, this analogy explains precisely why second-generation data quality systems are so successful.

SECTION 35
QUALITY AND SOCIETY

Joseph M. Juran

THE BACKGROUND

Human society has depended on quality since the dawn of history. In primitive societies this dependence is on the quality of natural goods and "services." Human life can exist only within rather narrow limits of climatic temperature, air quality, food quality, and so on. For most primitive societies, life even within these narrow limits is marginal, and human beings in most primitive societies live precariously. Hours of work are often long and exhausting. Life spans are shortened by malnutrition, disease, natural disasters, and so on. To reduce such risks primitive societies created nonnatural aids to their mental and physical capabilities, aids such as:

- Division of labor.
- Community forms of society, such as villages.
- Artificial shelter, e.g., houses.
- Processing of natural materials to produce nonnatural goods such as pottery, textiles, tools, weapons.
- Lessons learned. The experience of the past—when to plant crops, which berries are poisonous—is handed down from generation to generation.

The subsequent growth of commerce and of science and technology greatly expanded the extent and variety of nonnatural goods and services. As a result human beings in many modern

industrial societies live longer and safer lives. They are largely shielded from the perils which their ancestors faced. However, all those nonnatural goods and services have created a new dependence, and therefore new risks.

Life behind the Quality Dikes.   Years ago the author coined the phrase "life behind the quality dikes" to designate these new risks (Juran 1969). In industrial societies, great masses of human beings place their safety, health, and even their daily well-being behind numerous protective "dikes" of quality control. For example, the daily safety and health of the citizenry now depend absolutely on the quality of manufactured products: drugs, food, aircraft, automobiles, elevators, tunnels, bridges, and so on. In addition, the very continuity of our life style is built around the continuity of numerous vital services: power, transport, communication, water, waste removal, and many others. A major power failure paralyzes the lives of millions.

There are numerous minor breaks in the quality dikes—occasional failures of goods and services. These are annoying as well as costly. Far more serious are the terrifying major breaks such as Chernobyl, Bhopal, Three Mile Island.

Not only individuals but also nations and their economies live dangerously behind the dikes of quality control. National productivity relies on the quality of product and process design. National defense relies on the quality of complex weaponry. The growth of the national economy is keyed to the reliability of its systems for energy, communication, transport, and so on.

So while technology confers wonderful benefits on society, it also makes society dependent on the continuing performance and good behavior of technological goods and services. This is life behind the quality dikes—a form of securing benefits but living dangerously. Like the Dutch who have reclaimed much land from the sea, we secure benefits from technology. However we need good dikes—good quality—to protect us against the numerous service interruptions and occasional disasters. These same risks have also led to legislation which at the outset was bitterly opposed by industrial companies. Since then it has become clear that the public is serious about its concerns. What is encouraging is that users (whether individuals or nations) are willing to pay for good dikes.

The ability to cope with breaks in the quality dikes varies remarkably among users. Large organizations (industrial companies, governments) employ technologists or otherwise use their economic and political strengths to plan, control, and improve quality. In contrast, the individuals (consumers, the citizenry) find themselves pitted against forces which to them seem as mysterious and overpowering as natural forces seemed to their primitive ancestors.

Any one individual has only a very limited capacity to deal with these forces. However, these individuals are very numerous. Collectively their economic and political powers are formidable. These powers have emerged as a movement generally called *consumerism.* This movement, though loosely organized, has become influential in providing individual members of society with protection and recourse relative to breaks in the quality dikes.

THE GROWTH OF CONSUMERISM[1]

Consumerism is a popular name for the movement to help consumers solve their problems through collective action.

No one knows whether the *rate* of consumer grievances has grown over the centuries. However we know that the *volume* of grievances has grown to enormous numbers due to the growth in volume of goods and services. By the mid-twentieth century, consumer frustrations had reached levels which stimulated attacks on industrial companies for their alleged responsibility for consumers' problems. Then, when most companies failed to take appropriate action, the resulting vacuum attracted numerous contenders for leadership of a consumerism movement: government agencies, politicians, social reformers, consumer advocates, consumer associations, standardization organizations, independent test laboratories, and still others. A risk arose that a bargaining agent would emerge to intervene between industrial companies and their customers.

---

[1]*Note:* The text for this topic includes some extracts and paraphrases of material from Juran (1995, chap. 17).

Consumer Problems and Perceptions.   Starting in the 1970s researchers began to identify the dominant consumer problems as well as the perceptions of the groups in interest: consumers, consumer organizations, government, business, insurance companies, and so on. Table 35.1 lists the major quality-oriented consumer problems as derived from one such study (Sentry 1976, p. 5).

Consumer expectations sometimes rise faster than the market rate of improvement (Sentry 1976, p. 30.) In addition, consumer perceptions can differ from the realities. For example, many consumers believed that quality of product was getting worse; that "products don't last as long as they used to." Yet the author's studies of specific product lines have almost always found that quality has kept improving.

Consumers are generally more negative than positive on the attitudes of business toward problems of consumers. They strongly favor competition as a means of ensuring higher quality, safer products, and better prices. They also feel that most advertising is misleading, and that much is seriously misleading (Sentry 1976, pp. 7, 8, 12).

During the 1970s, consumer perceptions of the job done by specific industries varied widely. The favorable perceptions included banks, department stores, small shopkeepers, telephone companies, supermarkets and food stores, and airlines. At the other end of the spectrum, consumers had poor perceptions of car manufacturers, the advertising industry, the oil industry, garages and auto mechanics, used car dealers (Sentry 1976, p. 13).

While consumer perceptions are sometimes in error, the perceptions are important in their own right. People act on their perceptions, so it is important to understand what are the perceptions of consumers. For additional findings on consumer perceptions, see the study sponsored by the American Society for Quality Control (ASQC 1980).

Consumers generally felt that there was much they could do to help themselves relative to quality. They felt that the necessary product information was available but that the information was not being used by consumers. They had similar views with respect to product safety. They generally felt that most products were safe if used properly; also that many product safety problems arose because of failure to read the instructions properly (Sentry 1976, pp. 9, 10).

Remedial Proposals.   There are a number of these, amid much difference of opinion. The differences arise in part because of the impact on costs and prices (see below). In addition there are differences due to a contest for power. The various consumer organizations and government departments all feel that they should play larger roles, and that certain traditional powers of business should be restricted.

Ideally, the remedies should eliminate the causes of consumer problems at their source. The consumerism movement has been skeptical that such prevention will take place at the initiative of the industrial companies. Hence the main proposals have related to establishing ways to enable consumers to judge beforehand whether they are about to buy trouble.

Access to Information before Purchase.   Consumers could make better buying decisions if they had access to information on competitive product test data, field performance, and so on. Many

TABLE 35.1   Major Consumer Quality-Oriented Problems

Poor quality of many products
Failure to live up to advertising claims
Poor quality of after-sales service and repairs
Misleading packaging or labeling
Futility of making complaints: nothing substantial will be done
Inadequate guarantees or warranties
Failure of companies to handle complaints properly
Too many dangerous products
The absence of reliable information about the different goods and services
Not knowing what to do when something goes wrong with a purchased product
The difficulty of choosing which of the competing products to buy

Source: Sentry (1976), p. 5.

industrial companies possess such information but will not disclose it—they regard it as proprietary. They do disclose selected portions, but mainly to aid in sale of the product. The risk of bias is obvious.

Consumers' needs for information extend also to after-sale service, response to complaints, and so on. Here again, the companies regard such information as proprietary.

The lack of information from industrial companies has created a vacuum which has attracted alternative sources of product information to help consumers judge which products to buy and which to avoid. One such source is test laboratories which are independent of the companies that make and sell the products.

Under this concept a competent laboratory makes an expert, independent evaluation of product quality so that consumers can obtain the unbiased information needed to make sound purchasing judgments. Adequate consumer test services require professionals and skilled technicians, well-equipped test laboratories, acquisition of products for test, and dissemination of the resulting information. Financing of all these needs is so severe a problem that the method of financing determines the organization form and the policies of the test service.

Product Testing: Consumer-Financed.
In this form the test laboratory derives its income by publishing its test results, usually in a monthly journal plus an annual summary. Consumers are urged to subscribe to the journal on the ground that they will save money by acquiring the information needed to make better purchasing decisions. Advertisements of such test laboratories raise questions such as "Would you pay $100 for an appliance when independent tests show that a $75 appliance is just as good?"

In their operation, these consumer-financed test laboratories buy and test competitive products, evaluate their performance and failures, compare these evaluations with the product prices, and rate the products according to some scale of relative value. The ratings, test result summaries, descriptions of tests conducted, and so on, are published in the laboratory's journals. The industrial companies play no role in the testing and evaluation. In addition, the companies are not permitted to quote the ratings, test results, or other material published in the journals.

It is seen that the service offered to consumers consists of:

1. The laboratory's test results, which are mainly objective and unbiased.
2. Judgments of values which are subjective and carry a risk of bias, i.e., the stress of the advertising (showing the consumer that some lower-priced products are as good as higher-priced products) creates a bias against higher-priced products. More importantly, the judgments are not necessarily typical of consumers' judgments.

Despite the obvious problems of financing a test service out of numerous consumer subscriptions, there are many such services in existence in affluent and even in developing countries. In the United States, the most widely known source of such tests is Consumers Union. The test results are published in the journal *Consumer Reports.*

Product Testing: Government-Financed.
Governments have long been involved in matters of product quality, originally to protect the safety and health of the citizenry, and later, the environment. For elaboration, see below, under Government Regulation of Quality.

The most recent extension has been in the area of consumer economics. Some of this has been stimulated by the consumerism movement. A byproduct has been the availability of some product test results and other quality-related information. This information is made available to the public, whether in published form, or on request.

Government-Subsidized Tests.   In some countries, the government subsidizes test laboratories to test consumer products and to publish the results as an aid to consumers. The rationale is that there is a public need for this information, and that hence the costs should be borne by the public generally.

Mandated Government Certification.   Under this concept, products are required by law to be independently approved for adequacy before they may be sold to the public. This concept is applied in many countries to consumer products for which human safety is critical (e.g., pharmaceuticals, foods). For other products, there has been a sharp division in practice. Generally, the market-based

economies have rejected mandated government certification for (noncritical) consumer products, and have relied on the forces of the competitive marketplace to achieve quality. In contrast, the planned economies, as exemplified by the former Soviet Union, went heavily into the setting of standards for consumer products and the use of government laboratories to enforce compliance to these standards (which had the force of law).

Product Testing: Company-Financed.   In this form, industrial companies buy test services from independent test laboratories in order to secure the mark (certificate, seal, label) of the laboratory for their products. In some product categories it is unlawful to market the products without the mark of a qualified testing service. In other cases it is lawful, but the mark is needed for economic reasons—the insurance companies will demand extraordinarily high premiums or will not provide insurance at all.

An example of a sought-after mark is that of Underwriters Laboratories, Inc. (UL). Originally created by the National Board of Fire Underwriters to aid in fire prevention, UL (now independent) is involved in the general field of fire protection, burglary protection, hazardous chemicals, and still other matters of safety. Its activities include:

- Developing and publishing standards for materials, products, and systems.
- Testing manufacturers' products for compliance with these standards (or with other recognized standards).
- Awarding the UL mark to products which comply. This is known as "listing" the products.

Numerous other laboratories are similarly involved in safety matters, e.g., steam boilers and marine safety. Some of these laboratories have attained a status in their specialty which confers a virtual monopoly on performing the tests.

Another purpose of securing a mark from an independent test service is to help market the product. Companies vary in their views of the value of such "voluntary" marks. Strong companies tend to feel that their own brand or mark carries greater prestige than that of the test laboratory, and that the latter has value only for weak companies. The test services which offer this category of marks vary widely in their purpose and in their objectivity.

In some countries the voluntary mark is offered by the national standardization bodies, such as Japan Standards Association or the French AFNOR. The mark is awarded to products that meet their respective product standards. Companies that wish to use the JIS mark (Japan Industrial Standards) or the NF mark (Normale Francais) must submit their products for test and must pay for the tests. If the products qualify, the companies are granted the right to use the marks.

Data Banks on Business Practices.   Many consumer grievances are traceable to company business practices, such as evasiveness in meeting the provisions of the guarantee. The Pareto principle applies—a comparative few companies are named in the bulk of the grievances. In this way, a data bank on company business practices can help to identify the vital few "bad guys" and aid in reducing their influence.

The organizations known as Better Business Bureaus (BBB) created one such data bank. A description of BBBs and what they do is given in the following quotation from *Consumer's Resource Handbook* (1980):

> BBBs are non-profit organizations sponsored by private businesses. There are 147 BBB locations across the U.S. today, sponsored by local and national business. While BBBs vary from place to place, most offer a variety of basic services. These include: general information on products or services, reliability reports, background information on local businesses and organizations, and records of companies' complaint handling performances. Depending on the policy of the individual BBB, it may or may not tell you the nature of the complaints registered against a business. BBBs accept written complaints, and will contact a firm on your behalf.

The BBB receives complaints from consumers (among others) on unethical business practices, and endeavors as an ombudsman (see below) to get these practices changed. When citizens call the BBB, they are able to learn whether the company under inquiry has a record of complaints lodged against it.

BBBs also are active in helping consumers and local business firms to settle consumer complaints. (See below).

Consumer Education.   Beyond product tests and data banks on business practices, still other forms of before-purchase information are available to consumers. Some government departments publish information describing the merits (or lack of merits) of products and product features in general. However, the most often used source of product information is advice received from relatives and friends who have experience to share. Consumers regard such advice as reliable (Sentry 1976, p. 55).

The limiting factors in consumer use of the available independent data sources are the consumers themselves. Fewer than 10 percent of families in the United States subscribe to *Consumer Reports.* The lack of use of other helpful information (much of which is available free to consumers) may well have its origin in a school system that makes little provision to educate children in one of the major roles they will play as adults—the role of consumer.

Some observers explain "unwise" consumer behavior on grounds other than lack of education. They note that many consumers spend money on narcotic drugs, alcohol, or tobacco; kill themselves (and others) by driving too fast or in a drunken state; eat "junk" food; gamble their money away. It is understandable that some skeptics conclude that consumers who are gullible or stupid will learn only from their mistakes.

Consumer organizations are quite aware that "most consumers do not use the information available about different products in order to decide to buy one of them." (Sentry 1976, p. 10). However, consumer organizations never characterize consumers (their clientele) as being gullible or stupid. (*Consumer Reports* 1977).

The Standards Organizations.   There are many of these. For example, in the United States, those of importance to consumers include:

- Leading manufacturers and merchants, whose standards exert wide influence on their suppliers and competitors
- Industry bodies such as the American Gas Association or the Association of Home Appliance Manufacturers
- Professional organizations such as the American Society for Testing and Materials
- Independent agencies such as Underwriters Laboratories, Inc.
- The American National Standards Institute (ANSI), which is a recognized clearinghouse for committees engaged in setting national standards and is the official publisher of the approved standards
- The National Institute of Standards and Technology, formerly the National Bureau of Standards, the government agency which establishes and maintains standards for metrology

Standards for Consumer Products.   Awarding a mark presupposes the existence of some standard against which the product can be tested on an objective basis. Providing such standards for consumer products has not received the priorities given to standards for metrology, basic materials, and other technological and industrial needs. However, the consumerism movement has very likely stimulated the pace of developing these standards. Industry associations especially have been stimulated to undertake more of this type of activity.

A serious limitation on creating standards for consumer products is the pace of product obsolescence versus the time required to set standards. Usually, it takes years to evolve a standard due to the need for securing a consensus among the numerous parties in interest. For subject matter such as metrology or basic materials, the standards, once approved, can have a very long life. However, for consumer products the life is limited by the rate of obsolescence, and for many products the life of the standard is so short as to raise serious questions about the economics of doing it at all.

In some cases the obsolescence is traceable to the zeal of the marketers. For example, one measure of the quality of mechanical watches has been the number of jewels. Then some manufacturers began to include nonfunctional jewels to provide a basis for claiming higher quality. It became necessary to redefine the word "jewel."

A further problem in standards for consumer products is that the traditional emphasis of the standardization bodies has been on "time zero"—the condition of the product when tested prior to use. However, many products, especially the most costly, are intended to give service for years. Many consumer problems are traceable to field failures during service, yet most consumer product standards do not adequately address the "abilities"—reliability, maintainability, and so on. (See generally Juran 1970.)

Objectivity of Test Services.
Unless the testing service is objective, consumers may be misled by the very organization on which they thought they could rely. The criteria for objectivity include:

- *Financial independence:* The income of the test service should have no influence on the test results. This independence is at its best when the income is derived from sources other than the company whose products are under test. Failing this, the payments by the company should be solely for the testing service and in no way contingent on the test results.

  One example of failure to meet this criterion is any test service which carries on the dual activities of (1) offering a mark based on product test and approval and (2) publishing a journal of general circulation in which companies that receive the mark are required to place advertisements. In such cases the risk of conflict of interest is very high, so consumers should be cautious about giving credence to such marks.

- *Organizational independence:* The personnel of the test service should not be subordinate to the companies whose products are undergoing test.

- *Technological capability:* This obvious need includes a qualified professional staff, adequate test equipment and competent management. Whether the managers should be the sole judges of such capabilities is open to question.

So important is the question of objectivity that in cases of government controls on quality it is usual to write into the statute the need for defining criteria for what constitutes a qualified test laboratory. The administrator of the act then becomes responsible for certifying laboratories against these criteria.

The Resulting Information.
Consumer test services offer consumers a wide range of information. The principal forms include:

- Comparative data on competitive products for (1) price and (2) fitness for use, plus judgments of comparative values. In this form, the information is also a recommendation for action.

- Data on product conformance to the standards. In this form, consumers are thrown on their own to discover competitive prices and to make a judgment on comparative fitness for use. For many consumers, it is a burden to provide this added information.

- Evidence of product conformance to the standard (through the mark.) Here the consumer is largely asked to equate the standard with fitness for use and to use other means to discover competitive differences and competitive prices.

Information on conformance to standard is quite useful to industrial buyers, but less so to consumers. For consumers the optimal information consists of comparative data on fitness for use, plus comparative data on cost of usage.

Traditional test services do not provide adequate information as to certain important quality problems faced by consumers: products arrive in defective condition; products fail during use; response to consumer complaints is poor.

- *Products defective on arrival:* Test services typically conduct their tests on a small sample—one or a few units of product. These nevertheless enable the test service to judge whether the product

design can provide fitness for use. However, the sample is too small to provide information on how often units will be defective on arrival.

- *Products fail during use:* Traditionally, test services have evaluated consumer products at "time zero"—prior to use. For long-life products this is no longer good enough–there is need for information on field failure rates. Some test services now do conduct a degree of life testing, but the number of units tested is too small to predict field failure rates. There are some efforts to secure such information through questionnaires sent to consumers. An alternative source is to secure information from the repair shops.

- *Poor response to customer complaints:* Here the situation is at its worst. The test laboratory and its instruments are irrelevant, since the needed information relates to the competence, promptness, and integrity of the service organizations.

Remedies after Purchase.   Consumers who encounter product quality problems during the warranty period have a choice of alternatives. They may be able to resolve the problem unaided; i.e., they study the product information and then apply their skills and ingenuity. More usually they must turn to one of the companies directly in interest: the merchant who sold them the product; the manufacturer who made the product. If none of these provides satisfaction, the consumers have still other alternatives for assistance (see below).

Warranties.   Quality warranties are a major after-purchase aid to consumers. However, many consumers feel that warranties are not understandable. In addition, most feel that warranties are written mainly to protect manufacturers rather than consumers. Nevertheless, consumers are increasingly making the warranty an input to their buying decisions. This means also that warranties are increasingly important as marketing tools (Sentry 1976, pp. 14, 15).

By a wide margin, consumers complain to the merchant (store, dealer) rather than to the manufacturer. A third choice is to complain to the Better Business Bureau. (Sentry 1976, p. 15).

Better Business Bureaus (BBB).   The following is quoted from *Consumer's Resource Handbook* (1980).

> BBBs attempt to settle consumer complaints against local business firms. A BBB considers a consumer complaint settled when:
>
> **1.** The customer receives satisfaction.
> **2.** The customer receives a reasonable adjustment—in other words, gets what was paid for.
> **3.** The company provides proof that the customer's demands are unreasonable or unwarranted.
>
> The BBB does not: judge individual products or brands, handle complaints concerning the prices of goods or services, or give legal advice.
> More than 100 of the 147 BBBs offer binding arbitration to those who ask for it, and others are beginning programs. Arbitration is a way for people to settle a dispute by having an impartial person or board (people who have nothing to gain or lose from the decision) decide the outcome of the dispute. In arbitration, parties are bound by the decision, and it can be enforced by the courts. Do not enter arbitration lightly since you must follow the decision that is made.
> BBBs also handle false advertising cases. Your local BBB looks into local advertising, while the BBBs' National Advertising Division (NAD) checks out complaints about national advertising.
> How to Reach Them: To find a BBB, check your local phone book, local consumer office, or library.

The Ombudsman.   Ombudsman is a Swedish word used to designate an official whose job is to receive citizens' complaints and to help them secure action from the government bureaucracy. The ombudsman is familiar with government organization channels and is able to find the government official who has the authority or the duty to act. The ombudsman has no authority to compel action, but has the power to publicize failures to act.

The concept of the ombudsman has been applied to problems in product quality. Some companies have created an in-house ombudsman and have publicized the name and telephone number. Consumers can phone (free of charge) to air grievances and to secure information. In the United States a more usual title is Manager (Director), Consumer Affairs (Relations). Such a manager usually carries added responsibilities for stimulating changes to improve relations with consumers on a broad basis. In one company these efforts resulted in programs to effectuate a consumer "bill of rights," which includes rights to safety, to be informed, to choose, to be heard, and to redress. For elaboration, see Peterson (1974).

Another form is the industry ombudsman. An example is the Major Appliance Consumer Action Panel (a group of independent consumer experts) created by the Association of Home Appliance Manufacturers to receive complaints from consumers who have not been able to secure satisfaction locally.

Still another form is the Joint Industry-Consumer Complaint Board. Examples are the government-funded boards which mediate and adjudicate consumer disputes in some Scandinavian industries. The boards have no power to enforce their awards other than through publicity given to unsatisfied awards. Yet they have met with wide acceptance by and cooperation from the business people.

The concept of the ombudsman is fundamentally sound. It is widely supported by consumers and regulators as well as by a strong minority of business managers (Sentry 1976, p. 77). Some newspapers provide an ombudsman service as part of their department of Letters to the Editor.

Mediation.   Under the mediation concept, a third party—the mediator—helps the contestants to work out a settlement. The mediator lacks the power of enforcement—there is no binding agreement to abide by the opinion of the mediator. Nevertheless mediation stimulates settlements. Best (1981) reports that the New York City Department of Human Affairs achieved a 60 percent settlement rate during 1977 and 1978.

The mediation process helps to open up the channels of communication and thereby to clear up misunderstandings. In addition, an experienced mediator exerts a moderating influence which encourages a search for a solution.

Arbitration.   Under arbitration the parties agree to be bound by the decision of a third party. Arbitration is an attractive form of resolving differences because it avoids the high costs and long delays inherent in most lawsuits. In the great majority of consumer claims, the cost of a lawsuit is far greater than the amount of the claim. Nevertheless there are obstacles to use of the arbitration process. Both parties must agree to binding arbitration. There is need to establish local, low-cost arbitration centers and to secure the services of volunteer arbitrators at nominal fees or no fees. These obstacles have limited the growth of use of arbitration for consumer complaints.

Consumer Organizations.   There are many forms of consumer organizations. Some are focused on specific products or services such as automotive safety or truth in lending. Others are adjuncts of broader organizations such as labor unions or farm cooperatives. Still others are organized to deal broadly with consumer problems. In addition, there are broad consumer federations, national and international, which try to improve the collective strength of all local and specialized consumer groups.

Government Agencies.   These exist at national, state, and local levels of government. All invite consumers to bring unresolved complaints to them as well as to report instances of business malpractice. These complaints aid the agency in identifying widespread problems, which, in turn, become the basis for:

1. Conducting investigations in depth
2. Proposing new legislation
3. Issuing new administrative regulations

The agencies also try to help complaining consumers, either in an ombudsman role or by threat of legal action. However, in practice, broad government agencies are unable to become involved in specific consumer grievances due to the sheer numbers. See below, under Government Regulation of Quality; The Enforcement Process.

No Remedy.   Under the prevailing free-enterprise, competitive market system, many valid consumer complaints result in no satisfaction to the consumer. Nevertheless the system includes some built-in stabilizers. Companies which fail to provide such satisfaction also fail to attract repeat business. In due course they mend their ways or lose out to companies who have a better record of providing satisfaction. In the experience of the author, every other system is worse.

Perceptions of the Consumer Movement.   There is wide agreement, including among business managers, that "the consumer movement has kept industry and business on their toes." There is also wide agreement that the consumer movement's demands have "resulted in higher prices." Despite this, most of the public feels that the "changes are generally worth the extra cost." Consumers feel strongly that the consumer advocates should consider the costs of their proposals. However, a significant minority of the consumers believe that the advocates do not consider the costs involved (Sentry 1976, pp. 39, 40, 42, 47).

GOVERNMENT REGULATION OF QUALITY

From time immemorial, "governments" have established and enforced standards of quality. Some of these governments have been political—national, regional, local. Others have been nonpolitical: guilds, trade associations, standardization organizations, and so on. Whether through delegation of political power or through long custom, these governing bodies have attained a status which enables them to carry out programs of regulation as discussed below.

Standardization.   With the evolution of technology came the need for standardizing certain concepts and practices.

- *Metrology:* One early application of standardization was to units of measure for time, mass, and other fundamental constants. So basic are these standards that they are now international in scope.
- *Interchangeability:* This level of standardization has brought order out of chaos in such day-to-day matters as household voltages and interchangeability of myriads of the bits and pieces of an industrial society. Compliance is an economic necessity.
- *Technological definition:* A further application of standardization has been to define numerous materials, processes, products, tests, and so on. These standards are developed by committees drawn from the various interested segments of society. While compliance is usually voluntary, the economic imperatives result in a high degree of acceptance and use of these standards.

The foregoing areas of regulation are all related to standardization, and have encountered minimal resistance to compliance. Other areas do encounter resistance, in varying degrees.

Safety and Health of the Citizenry.   A major segment of political government regulation has been to protect the safety and health of its citizens. At the outset the focus was on punishment "after the fact"—the laws provided punishment for those whose poor quality had caused death or injury. Over the centuries there emerged a trend to regulation "before the fact"—to become preventive in nature.

For example, in the United States there are laws which prescribe and enforce safety standards for building construction, oceangoing ships, mines, aircraft, bridges, and many other structures. Other laws aim at hazards which have their origins in fire, foods, pharmaceuticals, dangerous chemicals, and so on. Still other laws relate to the qualifications needed to perform certain activities essential to public safety and health, such as licensing of physicians, professional engineers, airline pilots. Most recently these laws have proliferated extensively into areas such as consumer product safety, highway safety, environmental protection, and occupational safety and health.

Safety and Economic Health of the State.   Governments have always given high priority to national defense: recruitment and training of the armed forces; quality of the weaponry. With the growth of commerce, laws were enacted to protect the economic health of the state. An example is laws to regulate the quality of exported goods in order to protect the quality reputation of the state. Another example is laws to protect the integrity of the coinage. (Only governments have the right to debase the currency.) In those cases where the government is a purchaser (defense weapons, public utility facilities), government regulation includes the normal rights of a purchaser to assure quality.

Economics of the Citizenry.   Government regulation relative to the economics of the citizenry is highly controversial in market economies. Some of the resistance is on ideological grounds—the competitive marketplace is asserted to be a far better regulator than a government bureau. Other resistance is based on the known deficiencies of the administration of government regulation (see below). Some of the growth of this category of regulation has been stimulated by the consumerism movement.

The Volume of Legislation.   Collectively, the volume of quality-related legislation has grown to formidable proportions. A desk reference book (Kolb and Ross 1980) includes lists (in fine print) of appendixes as follows:

- 21 pages of exposure limits for toxic substances
- 93 pages of hazardous materials and the associated criteria for transportation
- 24 pages of American National Standards for safety and health
- 36 pages of Federal record-retention requirements
- 38 pages of standards-setting organizations

In the United States, much of this legislation is within the scope of the Federal Trade Commission, which exercises a degree of oversight relative to "unfair or deceptive practices in commerce." That scope has led to specific legislation or administrative action relative to product warranties, packaging and labeling, truth in lending, and so on.

In a sense these actions all relate to representations made to consumers by industrial companies. In its oversight the Federal Trade Commission stresses two major requirements:

1. The advertising, labeling, and other product information must be clear and unequivocal as to what is meant by the seller's representation.
2. The product must comply with the representation.

These forms of government regulation are a sharp break from the centuries-old rule of *caveat emptor* (let the buyer beware). That rule was (and is) quite sensible as applied to conditions in the village marketplaces of developing countries. However it is not appropriate for the conditions prevailing in industrialized, developed countries. For elaboration, see Juran (1970).

The Plan of Regulation.

Once it has been determined to regulate quality in some new area, the approach follows a well-beaten path. The sequence of events listed below, while described in the language of regulation by political government, applies to nonpolitical government as well.

The Statute.   The enabling act defines the purpose of the regulation and especially the subject matter to be regulated. It establishes the "rules of the game" and creates an agency to administer the act.

The Administrator.   The post of administrator is created and given powers to establish standards and to see that they are enforced. To this end he or she is armed with the means for making awards and applying sanctions on matters of great importance to the regulated industries.

The Standards.   The administrator has the power to set standards and may exercise this power by adopting existing industry standards. These standards are not limited to products; they may deal with materials, processes, tests, descriptive literature, advertising, qualifications of personnel, and so on.

Test Laboratories.   The administrator is given power to establish criteria for judging the qualifications of "independent" test laboratories. Once these criteria are established, he or she also may have the power to issue certificates of qualification to laboratories which meet the criteria. In some cases administrators have the power to establish their own test laboratories.

Test and Evaluation.   Here there is great variation. In some regulated areas, agency approval is a prerequisite to going to market, e.g., new drug applications or plans for the operation and maintenance of a new fleet of airplanes. Some agencies put much stress on surveillance, i.e., review of the companies' control plans and adherence to those plans. Other agencies emphasize final product sampling and test.

The Seal or Mark.   Regulated products are frequently required to display a seal or mark to attest to the fact of compliance with the regulations. Where the regulating agency does the actual testing, it affixes this mark; e.g., government meat inspectors physically stamp the carcasses.

More usually, the agency does not test and stamp the product. Instead, it determines, by test, that the product *design* is adequate. It also determines, by surveillance, that the companies' systems of control are adequate. Any company whose system is adequate is then authorized to affix the seal or mark. The statutes always provide penalties for unauthorized use of the mark.

Sanctions.   The regulatory agency has wide powers of enforcement, such as the right to:

• Investigate product failures and user complaints
• Inspect companies' processes and system of controls
• Test products in all stages of distribution
• Recall products already sold to users
• Revoke companies' right to sell, or to apply the mark
• Inform users of deficiencies
• Issue cease-and-desist orders

Effectiveness of Regulation.   Regulators face the difficult problem of balance—protecting consumer interests while avoiding creation of burdens which in the end are damaging to consumer interests. In part the difficulty is inherent because of the conflicting interests of the parties. However, much of the difficulty is traceable to unwise agency policies and practices in carrying out the regulatory process. These relate mainly to the conceptual approach, setting standards, the enforcement process, and cost of regulation.

The Conceptual Approach.   An example is seen in the policies employed by the National Highway Traffic Safety Administration (NHTSA) for administering two laws enacted in 1966:

1. The National Traffic and Motor Vehicle Safety Act, directed primarily at the vehicle
2. The Highway Safety Act, directed primarily at the motorist and the driving environment

Even prior to 1966, the automobile makers, road builders, and so on had improved technology to an extent which provided the motorist with the means of avoiding the "first crash," i.e., accidents due to collisions, running off the road, etc. The availability of seat belts then provided the motorist with greatly improved means of protection against the "second crash." This crash takes place when the sudden deceleration of a collision hurls the occupants against the steering wheel, windshield, and so on.

At the time NHTSA was created, the United States' traffic fatality rate was the lowest among all industrial countries. It was also known, from overwhelming arrays of data, that the motorist was the limiting factor in traffic safety:

- Alcohol was involved in about half of all fatal accidents.

- Young drivers (under age 24) constituted 22 percent of the driver population but were involved in 39 percent of the accidents.

- Excessive speed and other forms of "improper" driving were reported as factors in about 75 percent of the accidents. (During the oil crisis of 1974 the mandated reduction of highway speeds resulted in a 15 percent reduction in traffic fatalities, without any change in vehicles.)

- Most motorists did not buy safety belts when they were optional, and most did not wear them when they were provided as standard equipment.

In the face of this overwhelming evidence NHTSA paid little attention to the main problem—improving the performance of the motorists. Instead, NHTSA concentrated on setting numerous standards for vehicle design. These standards did provide some gains in safety with respect to the second crash. However the gains were minor, while the added costs ran to billions of dollars—to be paid for by consumers in the form of higher prices for vehicles.

The policy is seen to have been one of dealing strictly with a highly visible political target—the automobile makers, while avoiding any confrontation with a large body of voters. It was safe politically but it did little for safety. For elaboration, see Juran (1977).

Setting Standards.   A major regulatory question is whether to establish design standards or performance standards.

- Design standards consist of precise definitions, but they have serious disadvantages. Their nature and numbers are such that they often: lack flexibility, are difficult to understand, become very numerous, become prohibitive to keep up to date.

- Performance standards are generally free from the above disadvantages. However, they place on the employer the burden of determining how to meet the performance standard, i.e., the burden of creating or acquiring a design. Performance standards also demand level of compliance officers who have the education, experience, and training needed to make the subjective judgments of whether the standard has been met.

These alternatives were examined by a presidential task force assigned to review the safety regulations of the Occupational Safety and Health Administration. The task force recommended a "performance/hazard" concept. Under that concept, the standard would "codify into a requirement the fact that a safe workplace can be achieved only by ensuring that employees are not exposed to the hazards associated with the use of machines. Under this standard, the employer would be free to determine the most appropriate manner in which to guard against any hazard which is presented, but his compliance with the requirement is objectively measurable by determining whether or not an employee is exposed to the hazard." For elaboration, see OSHA Safety Regulation 1977. For added discussion, see Tye (1988).

The Enforcement Process.   A major deficiency in the regulatory process is failure to concentrate on the vital few problems. Regulatory agencies receive a barrage of grievances: consumer complaints, reports of injuries, accusations directed at specific products, and so on. Collectively the numbers are overwhelming. There is no possibility of dealing thoroughly with each and every case. Agencies which try to do so become hopelessly bogged down. The resulting paralysis then becomes a target for critics, with associated threats to the tenure of the administrator, and even to the continued existence of the agency.

In the United States the Occupational Safety and Health Administration faced just such a threat in the mid-1970s. In response it undertook to establish a classification for its cases based on the seriousness of the threats to safety and health. It also recalled about 1000 safety regulations which were under attack for adding much to industry costs and little to worker safety.

With experience, the agencies tend to adopt the Pareto principle of vital few and useful many. This enables them to concentrate their resources and to produce tangible results.

Choice of the vital few is often based on quantitative data such as frequency of injuries or frequency of consumer complaints. However, subjective judgment plays an important role, and this enables influential special pleaders to secure high priority for cases which do not qualify as being among the vital few.

How to deal with the "useful many" needs for assistance has been a perplexing problem for all agencies. The most practical solution seems to have been to make clear that the agency is in no position to resolve such problems. Instead the agency provides consumers with information and educational material of a self-help nature: where to apply for assistance; how to apply for assistance; what are the rights of the consumer; what to do and not to do. See, for example, *Consumer's Resource Handbook* (1980).

The failure of regulators to deal forthrightly with such consumer problems has no doubt contributed to the mediocre status given to regulators by the public, in response to the question: which (of four options) would you like to be primarily responsible for the job of seeing that consumers get a fair deal? For elaboration, see Sentry 1976, p. 70.

A Rule for Choosing the Vital Few.   In 1972 the author proposed the following as a quantitative basis for separating the vital few from the rest, on matters of safety:

> Any hour of human life should be as safe as any other hour.

To effectuate such a policy it is first necessary to quantify safety nationally, on some common basis such as injuries per million worker-hours of exposure. In general, the data for such quantification are already available, though some conversions are needed to arrive at a common unit of measure. For example, statistics on safety at school are computed on the basis of injuries per 100,000 student-days, motor vehicle statistics are on a per 100 million miles of travel basis, and so on.

The resulting national average will contain a relative few situations which are well above the average and a great many which are below. Those above the average would automatically be nominated to membership in the vital few. Those below the average would not be so nominated; the burden of proof would be on any special pleader to show why something below the national average should take priority ahead of the obvious vital few. For elaboration, see Juran (1972).

The Costs and Values of Regulation.   The costs of regulation consist largely of two major components:

1. *The costs of running the regulatory agencies:*   These are known with precision. In the United States they have risen to many billions of dollars per year. These costs are paid for by consumers in the form of taxes that are then used to fund the regulatory agencies.

2. *The costs of complying with the regulations:*   These costs are not known with precision, but they are reliably estimated to be many times the costs of running the regulatory agencies. These costs are in the first instance paid for by the industrial companies, and ultimately by consumers in the form of higher prices. For an example of a study of industry costs, see The Business Roundtable (1978).

The value of all this regulation is difficult to estimate. (There is no agreement on what is the value of a human life.) Safety, health, and a clean environment are widely believed to be enormously valuable. Providing consumers with honest information and prompt redress is likewise regarded as enormously valuable. However such general agreements provide no guidelines for what to do in specific instances. Ideally, each instance should be examined as to its cost-value relationship. Yet the statutes have not required the regulators to do so. The regulators have generally avoided facing up to the idea of quantifying the cost-value relationship.

Until 1994 the support for studying the cost-value relationships came mainly from the industrial companies. For example, a study of mandated vehicle safety systems found that:

> "…states which employ mandatory periodic inspection programs do not have lower accident rates than those states without such requirements."

"…only a relatively small portion of highway accidents—some 2 to 6 percent—are conclusively attributable to mechanical defects."

"…human factors (such as excess speeds) are far more important causes of highway accidents than vehicle condition." For elaboration see Crain 1980.

The indifference of regulators to costs inevitably creates some regulations and rigid enforcements so absurd that in due course they become the means for securing a change in policy. The companies call such absurdities to the attention of the media, who relish publicizing them. (The media have little interest in scholarly studies.) The resulting publicity then puts the regulators on the defensive while stimulating the legislators to hold hearings. During such hearings (and depending on the political climate) the way is open to securing a better cost-value balance.

The political climate is an important variable in securing attention to cost-versus-value considerations. During the 1960s and 1970s the political climate in the United States was generally favorable to regulatory legislation. Then, during the 1980s the climate changed, and with it a trend toward requiring cost justifications. This trend then accelerated in late 1994, when the elections enabled the opponents of regulation to gain majority status in the national legislatures. For added discussion, see Dowd 1994.

PRODUCT SAFETY AND PRODUCT LIABILITY

Growth of the Problem.   Until the early twentieth century, lawsuits based on injuries from use of products (goods and services) were rarely filed. When filed, they were often unsuccessful. Even if successful, the damages awarded were modest in size.

During the twentieth century these lawsuits have, in the United States, grown remarkably in numbers. By the mid-1960s they were estimated to have reached over 60,000 annually and by the 1970s to over 100,000 per year. (Most are settled out of court.) This growth in numbers of lawsuits has been accompanied by an equally remarkable growth in the sizes of individual claims and damages. From figures measured in thousands of dollars, individual damages have grown to a point where awards in excess of $100,000 are frequent. Damages in excess of $1,000,000 are no longer a rarity.

In some fields the costs of product liability have forced companies to abandon specific product lines or go out of business altogether.

> Twenty years ago, 20 companies manufactured football helmets in the United States. Since that time, 18 of these companies have discontinued making this product because of high product liability costs. (Grant 1994).

Several factors have combined to bring about this growth in number of lawsuits and in size of awards. The chief factors include:

- The "population explosion" of products. The industrial society has placed large numbers of technological products into the hands of amateurs. Some of these products are inherently dangerous. Others are misused. The injury *rate* (injuries per million hours of usage) has probably been declining, but the total *number* of injuries has been rising, resulting in a rise in total number of lawsuits.
- The erosion of company defenses. As these lawsuits came to trial, the courts proceeded to erode the former legal defenses available to companies.

  Formerly, a plaintiff's right to sue a manufacturer rested on one of two main grounds:

  A *contract* for sale of the product, with an actual or implied warranty of freedom from hazards. Given the contract relationship, the plaintiff had to establish "privity," i.e., that he or she was a party to the contract. The courts have in effect abolished the need for privity by taking the position that the implied warranty follows the product around, irrespective of who is the user.

Negligence by the company. Formerly the burden of proof was on the plaintiff to show that the company was negligent. The courts have tended to adopt the principle of "strict liability" on the ground that the costs of injuries resulting from defective products should be borne "by the manufacturers that put such products on the market rather than by the injured persons who are powerless to protect themselves." In effect, if an injury results from use of a product that is unreasonably dangerous, the manufacturer can be held liable even in the absence of negligence. (Sometimes the injured persons are not powerless. Some contribute to their injuries. However, juries are notoriously sympathetic to injured plaintiffs).

The literature on growth of the problem is extensive, as is the literature on proposals for remedy. See especially Harrington and Litan 1988 and references cited. See also Grant 1994; Smith 1991; Egington 1989; McGuire 1988; Wargo 1987.

Defensive Actions.   The best defense against lawsuits is to eliminate the causes of injuries at their source. All company functions and levels can contribute to making products safer and to improving company defenses in the event of lawsuits. The respective contributions include the following:

- *Top management.*   Formulate a policy on product safety; organize product safety committees and formal action programs; demand product dating and product traceability; establish periodic audits of the entire program; support industry programs which go beyond the capacity of the unaided company. To this list should be added a scoreboard—a measure of the injury rate of the company's products relative to an appropriate benchmark. A useful unit of measure is the number of injuries per million hours of usage, since most major data banks on injuries are already expressed in this form or are convertible to this form.
- *Product design:*   Adopt product safety as a design parameter; adopt a fail-safe philosophy of design; organize formal design reviews; follow the established codes; secure listings from the established laboratories; publish the ratings; utilize modern design technique.
- *Manufacture:*   Establish sound quality controls, include means for errorproofing matters of product safety; train supervisors and workers in use of the product as part of the motivation plan; stimulate suggestion on product safety; set up the documentation needed to provide traceability and historical evidence.
- *Marketing:*   Provide product labeling for warnings, dangers, antidotes; train the field force in the contract provisions; supply safety information to distributors and dealers; set up exhibits on safety procedures; conduct tests after installation, and train users in safety; publish a list of dos and don'ts relative to safety; establish a customer relations climate which minimizes animosity and claims. Contracts should avoid unrealistic commitments and unrealistic warranties. Judicious disclaimers should be included to discourage unjustified claims.
- *Advertising:*   Require technological and legal review of copy; propagandize product safety through education and warnings. Avoid "puffing"—it can backfire in liability suits, e.g, if a product is advertised as "absolutely safe." During advertising review, one of the questions should be "How would this phrase sound in a courtroom?"
- *Customer Service:*   Observe use of the product to discover the hazards inherent during use (and misuse); feed the information back to all concerned; provide training and warnings to users.
- *Documentation:*   The growth of safety legislation and of product liability has enormously increased the need for documentation. A great deal of this documentation is mandated by legislation, along with retention periods. (For a compilation, see Kolb and Ross 1980, pp. 547–584.)

Consumers exhibit a wide range of product knowledge, including the lowest. In consequence, actual use of the product can differ significantly from intended use. For example, some stepladders include a light platform which is intended to hold tools or materials (e.g., paint) but is not intended to carry the weight of the user. However, some users nevertheless do stand on these platforms with resulting injury to themselves.

Most modern policy is to design products to stand up under actual usage rather than intended usage. For added discussion, see Farrow 1991; see also Scofield 1986 relative to product labeling.

Defense against Lawsuits.   The growth of product liability lawsuits has led to reexamination of how best to defend against lawsuits once they are filed. Experience has shown the need for special preparation for such defense, including:

- Reconstruction of the events which led up to the injury
- Study of relevant documents—specifications, manuals, procedures, correspondence, reports
- Analysis of internal performance records for the pertinent products and associated processes
- Analysis of field performance information
- Physical examinations of pertinent facilities
- Analysis of the failed hardware

All this should be done promptly, by qualified experts, and with early notification to the insurance company. For elaboration, see Gray et al. (1975, pp. 67–93); also Kolb and Ross (1980, pp. 275–286).

Whether and how to go to trial involves a great deal of special knowledge and experience. See generally, Gray et al (1975); also Kolb and Ross (1980, pp. 275–286).

Defense through Insurance.   Insurance is widely used as a defense against product liability. But the costs have escalated sharply, again because of the growth in number of lawsuits and size of awards. In some fields insurance has become a major factor in the cost of operations. (Soaring insurance rates have forced some surgeons to take early retirement.)

Some comprehensive studies have examined the problem of insurance as applied to product liability. See McGuire 1988; Harrington and Litan 1988. See also Interagency Task Force Final Report on Product Liability (1978, chap. III), and Kolb and Ross (1980, pp. 287–327).

Prognosis.   As of the mid-1990s there remained some formidable unsolved problems in product liability. To many observers the United States' legal system contained some serious deficiencies:

- Lay juries lack the technological literacy needed to determine liability on technological matters. In most other developed countries, judges make such decisions.
- Lay juries are too easily swayed emotionally when determining the size of awards.
- In the United States, "punitive damages" may be awarded along with compensatory damages and damages for "pain and suffering." Punitive damages contribute greatly to inflated awards.
- In the United States, lawyers are permitted to work on a contingency fee basis—a concept that assertedly stimulates lawsuits. This arrangement is illegal in most countries.
- The adversary system of conducting trials places the emphasis on winning rather than on doing justice.
- Only a minority of the award money goes to the injured parties. The majority goes to lawyers and to pay administrative expenses.

By the mid-1990s some elements of this legal system were under active review in the national Congress. However, the system which has endured these deficiencies is deeply rooted in the United States culture, so it is speculative whether it will undergo dramatic change. A major obstacle has been the lawyers. They have strong financial interests in the system, and they are very influential in the legislative process—many legislators are lawyers.

In most developed countries the legal system for dealing with product liability is generally free from the above asserted deficiencies. Those same countries are also largely free from the extensive damage which product liability is doing to the United States economy.

(For some incisive comments on the deficiencies in the United States' legal system, see Grant 1994.)

Personal Liability.   An overwhelming majority of product liability lawsuits have been aimed at the industrial companies; they and their insurers have the greatest capacity to pay. As a corollary, such civil lawsuits are rarely aimed at individuals, e.g., design managers or quality managers. These individuals have little cause for concern with respect to civil liability. They are not immune from lawsuits but they are essentially immune from payment of damages.

Criminal liability is something else. Now the offense (if any) is against the state, and the state is the plaintiff. Until the 1960s, prosecution for criminal liability in product injury cases was directed almost exclusively at the corporations rather than the managers. During the 1960s and the 1970s the public prosecutors became more aggressive with respect to the persons involved. The specific targets were usually the heads of the companies but sometimes included selected subordinate managers such as for product development or for quality.

A contributing factor has been an earlier provision of the Food, Drug and Cosmetic Act making it a crime to ship out adulterated or misbranded drugs. This provision was interpreted by the United States Supreme Court to be applicable to the head of a company despite the fact that he or she had not participated in the events and even had no knowledge of the goings-on. For an analysis, see O'Keefe and Shapiro (1975). Also O'Keefe and Isley (1976).

For the great majority of industrial managers the threat of criminal liability is remote. Before there can be such liability, the manager must be found guilty of (1) having *knowingly* carried out illegal actions or (2) having been grossly negligent. These things must be proved to a jury beyond a reasonable doubt. It is a difficult proof. (Many guilty criminals escape conviction because of this difficulty.)

ENVIRONMENTAL PROTECTION

A special category of government regulation is environmental protection (EP). On the face of it, EP is a twentieth-century phenomenon. However, there is a school of thought suggesting that EP originated in a conservation movement to preserve lands that were being exploited by European colonists during the seventeenth and eighteenth centuries. For elaboration, see Grove 1992.

The Industrial Revolution of the mid-eighteenth century opened the way to mass production and consumption of manufactured goods at rates that grew exponentially. To support this growth required a corresponding growth in production of energy and materials. The resulting goods conferred many benefits on the societies that accepted industrialization. However, there were unwelcome by-products, and these also grew at exponential rates.

Generating the needed energy produced emissions that polluted the air and water. Nuclear power created the problem of nuclear waste disposal as well as the risk of radiation leaks. Mining for raw materials damaged the land, as did disposition of toxic wastes. Ominous threats were posed by ozone depletion and the risk of global warming. Disposition of worn-out and obsolete products grew to problems of massive proportions. All this was in addition to problems posed by the numerous inconveniences and occasional disasters caused by product failures during service. (See above under Life behind the Quality Dikes).

Industrial companies were generally aware that they were creating these problems, but their priorities were elsewhere. Public awareness lagged, but by the mid-twentieth century the evidence had become overwhelming. Responding to public pressures, governments enacted much legislation to avoid worsening the problem, and provided funds to undo some of the damage.

The new legislation was at first strongly resisted by industrial companies because of the added costs it imposed. Then as it became clear that EP was here to stay, the ingenuity of industry began to find ways to deal with the problem at the source—to use technology to avoid further damage to the environment. A striking example is Japan's achievement in energy conservation. During the period 1973–1990, despite continuing growth in industrial production, there was no increase in energy consumption (Watanabe 1993).

Public and media preoccupation with specific instances of environmental damage has tended to stimulate allocation of funds to undo such damage. However the long-range trend seems to be toward

prevention at the source. A recent survey estimated that during 1991, of the research and development budgets of United States industrial companies, about 13 percent was directed at technology to minimize environmental damage (Rushton 1993).

Recognition of the importance of EP is now evident in many ways. For example:

- Many countries have created new ministries to deal with the problem of EP.

- Many industrial companies have created high-level posts for the same purpose.

- Numerous conferences are being held, including at the international level, with participation from government, industry and academia (Strong 1993).

- An extensive and growing body of literature has emerged. Some of this is quite specific. See for example on asbestos, Mossman et al. 1990; on design for recycling, Bylinsky 1995; also Penev and de Ron 1994.

- Companies have also evolved specific processes for addressing the problems of EP. These generally consist of:

Establishment of policies and goals with respect to EP.

Establishment of specific action plans to be carried out by the various company functions.

Audits to assure that the action plans are carried out.

In addition, the ingenuity of companies has begun to find ways to reduce the costs of providing solutions. Table 35.2 lists some of the identified problems and the associated opportunities for solution (Rushton 1993).

TABLE 35.2 Environmental Problems and Opportunities for U.S. Industry

Problem	Opportunity
Performance chemicals and materials	
Air pollution	Emission control catalysts, clean motor fuels
Hazardous substances	Asbestos substitutes, chlorine substitutes, PCB substitutes
Land pollution	Lagoon liners
Oil spills	Oil absorbents, surfactants
Ozone layer depletion	CFC substitutes, UV hazard reduction technologies
VOC emissions	Power coatings, radiation-cured coatings, water-based coatings
Water pollution	Water treatment chemicals
Food	
Caffeine	Supercritical fluid extraction
Disposable packaging pollution	Recyclable or degradable packaging
Fat	Fat substitutes, "lite" foods
Short shelf life	Antioxidants, aseptic packaging, controlled/modified atmosphere packaging
Sugar	Low-calorie sweeteners
Environmental management	
Hazardous substance treatment	Asbestos removal, waste remediation
Hazardous substance prevention	Process redesign, spent oil recycling, waste prevention and minimization
Pollutant detection and monitoring	Analytic laboratory services, sensors
Solid waste storage and disposal	Waste recycling, incineration
Water supply	Low water consumption processes, water purification, water recycling
Health care and safety	
Automotive safety	Air bags, antilock brake systems
Bioincompatibility, rejection	Thromboresistant biomaterials, biodegradable implants
Disease diagnosis and treatment	Diagnostic reagents, instruments, services

TABLE 35.2   (Continued)

Problem	Opportunity
	Health care and safety
Equipment safety	Inspection and testing services
Medical waste pollution	Medical waste minimization, incineration.
Personal safety	Flame-retardant materials, protective clothing
Product tampering	Tamper-evident packaging
Side effects of drugs	Controlled-release drug delivery systems, biosensors

Source: Rushton (1993).

The emerging consensus is that the best solution lies in industrial efficiency (Strong 1993).

SECTION 36
QUALITY AND THE NATIONAL CULTURE

J. M. Juran

INTRODUCTION

The goal of high quality is common to all countries. This common goal must compete with other national goals amid the massive forces—political, economic, and social—which determine the national priorities. This section examines these forces and their effect on the problems of attaining quality.

The growth of international trade and of multinational companies has required that attention be directed to understanding the impact of national culture on managing for quality. To aid in this understanding, the subject is organized under the following general subdivisions:

Developing economies: The special problems of managing for quality in such economies are discussed in Section 37, Quality in Developing Countries.

Other economies: Other sections discuss the problems of managing for quality in specific economies:

- 38:   Quality in Western Europe
- 39:   Quality in Central and Eastern Europe
- 40:   Quality in The United States
- 41:   Quality in Japan
- 42:   Quality in the People's Republic of China
- 43:   Quality in Latin America

In all types of national economy, there are natural resources and limitations which influence the priority of goals. However, an even greater force is that of human leadership and determination. Historically, these human forces have been more significant than natural resources in determining whether goals are attained.

The words "capitalistic," "socialistic," and "developing" are simple labels for some very complex concepts. The broad definition of "capitalism" is private ownership of the means of production and distribution, as contrasted with state ownership under socialism. Yet all self-styled capitalistic countries include a degree of state ownership, e.g., in matters of health, education, transport, and communication. Similarly, the self-styled socialistic countries contain, in varying degrees, some private ownership of enterprises for production of goods and services. In like manner, countries which are

"developing" in the industrial sense may be highly developed in terms of other aspects of national maturity, e.g., political or social. The reader is urged to keep in mind that the words "capitalistic," "socialistic," and "developing" are used in a relative sense and cannot be considered as absolutes.

The subject matter of this section and of the companion Sections 37 through 43 are of obvious interest and importance to those engaged (or contemplating engagement) in operations of an international nature. Such operations are becoming ever more extensive as trade barriers are progressively removed. However, removal of governmental barriers has little effect on cultural barriers. These remain as a continuing problem until the cultural patterns (and the reasons behind them) are understood, appreciated, and taken into account.

In the economic sense, the capitalistic developed countries are the "vital few." The developing countries are the most numerous, occupy most of the land surface, and include most of the human population. However, it is the capitalistic developed countries which produce the bulk of the world's goods and services. This great importance (in the economic sense) suggests that those who engage in international trade should acquire a working knowledge of the cultures which prevail in the respective countries.

QUALITY IN CAPITALISTIC ECONOMIES

All capitalistic economies exhibit some basic similarities which influence the importance of quality in relation to other goals in the economy.

Competition in Quality.   Capitalistic societies permit and even encourage competition among enterprises, including competition in quality. This competition in quality takes multiple forms.

Creation of New Enterprises.   A frequent reason for the birth of new enterprises is poor quality of goods or services. For example, a neighborhood has outgrown the capacity of the local food shop or restaurant, so the clients must wait in long queues before they can receive service. In such cases, entrepreneurs will sense a market opportunity and will create a new enterprise which attracts clients by offering superior service.

The ease of creating new enterprises is a far greater force in quality improvement than is generally realized. All economies, whether capitalistic or socialistic, suffer poor quality during shortages of goods. Creation of new enterprises is one means of alleviating shortages, and thereby of eliminating an invariable cause of poor quality.

Product Improvement.   A common form of competition in quality is through improving products so that they have more appeal to the users and can therefore be sold successfully in the face of competition from existing products. These product improvements come mainly from internal product development carried on by existing companies. In addition, some product improvements are designed by independents who either launch new enterprises or sell their ideas to existing companies.

New Products.   These may be "products" or even new systems approaches, e.g., designs which minimize user maintenance. The industrial giants of today include many members founded on new systems concepts. As with product improvements, the new products may originate through development from within or through acquisition from the outside.

Competition in quality results in duplication of products and facilities. Such duplication is regarded as wasteful by some economists. However, the general effect has been to stimulate producers to outdo each other, with resulting benefit to users.

Direct Access to Marketplace Feedback.   In the capitalistic economies, the income of the enterprise is determined by its ability to sell its products, whether directly to users or through an

intermediate merchant chain. If poor quality results in excessive returns, claims, or inability to sell the product, the manufacturers are provided with the warning signals which are a prerequisite to remedial action.

This severe and direct impact of poor quality on the manufacturers' income has the useful by-product of forcing manufacturers to keep improving their market research and early warning signals, so as to be able to respond promptly in case of trouble.

Direct access to the marketplace is not merely a matter of receiving complaints and other information about bad quality, important though that is. Even more important is the access to the marketplace *before* products are launched and sales programs are prepared. In the capitalistic economies, the autonomous companies all make their own forecasts on how much they expect to sell. Their ability to thrive depends on how well they are able to realize their forecasts. The potential benefits and detriments force the companies to pay attention to the needs of the marketplace, since it provides their income.

Protection of Society.　The autonomy of capitalist enterprises enables them to misrepresent their products, sell unsafe products, damage the environment, fail to live up to their warranties, and so on. The extent of such practices has been large enough to generate extensive preventive legislation. In this connection, see Section 35, Quality and Society.

CULTURAL DIFFERENCES

There are many of these, including:

Language:　Many countries harbor multiple languages and numerous dialects. These are a serious barrier to communication.

Customs and traditions:　These and related elements of the culture provide the precedents and premises which are guides to decisions and actions.

Ownership of the companies:　The pattern of ownership determines the strategy of short-term versus long-term results, as well as the motivations of owners versus nonowners.

The methods used for managing operations:　These are determined by numerous factors such as reliance on system versus people; extent of professional training for managers; extent of separation of planning from execution; careers within a single company versus mobile careers.

Suspicions:　In some countries, there is a prior history of hostilities resulting from ancient wars, religious differences, membership in different clans, and so on. The resulting mutual suspicions are then passed down from generation to generation.

It is clearly important to learn about the nature of a culture before negotiating with members of that culture. Increasingly, companies have provided special training to employees before sending them abroad. Similarly, when companies establish foreign subsidiaries, they usually train local nationals to qualify for the senior posts.

MULTINATIONAL COLLABORATION

Collaboration across cultures is a many-faceted problem. For example, a system may be designed in country A but the subsystem designs may come from other countries. In like manner, companies from multiple countries may supply components, carry out manufacture, marketing, installation, maintenance, and so on.

Numerous methodologies have been evolved to help coordinate such multinational activities. Those widely used include:

Standardization: This is accomplished through organizations such as the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC). A special application is the Allied Quality Assurance Publication (AQAP) standards widely used by the North Atlantic Treaty Organization (NATO) countries for multinational contracting. Some of the standards used by these and other organizations are listed in Appendix III, Selected Quality Standards, Specifications, and Related Documents.

The consortium: This form involves creating an association of companies from various countries. The consortium is usually dedicated to a specific project, e.g., the Airbus. [See Debout (1978) for elaboration.]

Contract Management: In many cases, the prime contractor provides a coordinating service for the subcontractors (who may include a consortium). [See McClure (1979) relative to the F16 aircraft; see also McClure (1976).]

Technology Transfer: This is carried out in numerous well-known ways: international professional societies and their committees; conferences; exchange visits; training courses and seminars. In large, multinational companies, such activities are carried out within the companies as well. [For an example involving the use of multinational quality councils, see Groocock (1978).]

SECTION 37
QUALITY IN DEVELOPING COUNTRIES

Lennart Sandholm

A HETEROGENEOUS GROUP OF COUNTRIES

Countries are often classified as "developing" or "developed." This terminology is misleading, as countries that are classified as developing could in many respects be more advanced than some so-called developed countries; for example, when such facets of human life as morale, culture, social relations, democratic rights, and equal opportunities are taken into consideration. A clearer grouping would be into "industrialized" versus "less industrialized" countries or, alternatively, into

"economically developed" versus "less economically developed" countries. This is, in fact, what is meant by the developed versus developing classification.

Neither developing nor developed countries can be regarded as forming a homogeneous group; they show differences in terms of industrial development, natural resources, size, economic strength, access to markets, national policy, human resources, and other criteria.

The heterogeneity of developing countries is also reflected in other classification systems. The term "least developed countries" is used to denote some 50 countries in the context of United Nations discussions. These countries are the weakest partners in the international community, with the most formidable structural problems. The term "newly industrialized countries," commonly abbreviated NIC, implies countries which have recently advanced from a developing status to a developed status. This group includes some countries in Southeast Asia referred to as the "Asian tigers." As a consequence of the collapse of the Soviet Union there are "countries in transition to a market economy." This group previously had a centrally planned economy. Now they are converting to a market economy.

TRADE GLOBALIZATION AND LIBERALIZATION

The Uruguay Round of Multilateral Trade Negotiations was held under the General Agreement on Tariffs and Trade (GATT) from 1986 to 1993. The final act of these negotiations was signed at a meeting in Marrakesh, Morocco in April 1994. The "Marrakesh Declaration" affirmed that the results of the Uruguay Round would "strengthen the world economy and lead to more trade, investment, employment and income growth throughout the world." Although tariff reductions had continuously been undertaken under the GATT framework earlier, liberalization of trade had been threatened by the increased use of protectionist measures such as export restraints and import quotas. The Uruguay Round of negotiations achieved substantial results toward the reversal of protectionist measures.

The developing countries took a very active and influential part in the Uruguay Round of negotiations. These countries will be affected to a higher degree by the new agreement than by earlier agreements which involved industrialized countries only.

The new trade situation includes reductions of subsidies and tariff and nontariff barriers, more open and fair trade without protection, and rules for trade in goods, services, and "intellectual properties." This will entail greater access to new markets, as well as increased competition from imports on the domestic market. In the new competitive situation, quality will become more important to developing countries than ever before.

The contribution made by developing countries to global output is increasing rapidly. According to the World Bank (*Global Economic Prospects and the Developing Countries,* 1995, p. 65), these countries will account for 38 percent of the growth in global output in 1995–2010, compared to 22 percent in the 1980s. Their share of global output will rise from 21 percent in 1994 to 27 percent in 2010. The report states that "the increasing integration of developing countries into the global economy represents a major—perhaps the most important—opportunity for raising the welfare of both developing and industrial countries in the long term."

TECHNOLOGY IN DEVELOPING COUNTRIES

In many developing countries the manufacturing sector may be divided into a modern component, a modernizing component, and a nonmodern component, which utilize different technology.

Modern component: This component consists of the largest industrial enterprises, which are located mainly in urban areas where infrastructure and an adequate work force, including skilled workers, are available, and which use modern technology. This group of enterprises also includes

subsidiaries of multinational companies. The modern component is mainly found in the most industrialized developing countries.

Modernizing component: This component includes mainly small to medium-sized industrial enterprises, located mostly in urban but also in some rural areas, in which various intermediate levels of technology are used. Enterprises in this component might be suppliers to larger enterprises.

Nonmodern component: This consists of small industrial enterprises and artisan workshops, located largely in rural but also in urban areas, which use traditional and upgraded traditional technologies.

Discussions of the technological basis for industrial development in developing countries are often focused on the choice of appropriate technologies and their development, transfer, and implementation.

The term "appropriate technology" for developing countries is often taken to mean simple and labor-intensive technology. The concept is based on the observations that industrial technologies are designed in the developed countries and that conditions in these countries are quite different from those in the developing countries. Technologies that are more suitable to conditions in developing countries are needed.

The concept of appropriate technology includes factors other than economic efficiency and growth; for example, employment, working conditions, and provision of basic needs. This means that appropriate technologies will differ from country to country depending on the significance of these various factors.

FACTORS IMPEDING QUALITY IMPROVEMENT

Developing countries face several problems with regard to quality. The nature of these problems differs depending on the phase of development the country is in. Consequently, the solutions to the problems also differ.

An increasing number of developing countries are liberalizing their economies and adopting export-oriented policies. These changes lead to an increased awareness of the importance of quality.

Discussions that the author has had with many representatives of developing countries show that there are several factors impeding improvement of quality in developing countries, of which the major ones seem to be.

Low Purchasing Power.   The vast majority of people are poor. Their purchase decisions are based on price consideration only. The manufacturers consequently aim at low prices, using cheap and low-quality materials.

Shortage of Goods and Absence of Competition.   The shortage of goods provides some guarantee to the manufacturers that everything produced will be sold; as a result, they show very little interest in quality. Restrictions on the importation of goods, along with high custom barriers, protect locally produced goods against competition from goods produced in more industrialized countries.

Foreign Exchange Constraints.   Most developing countries have a shortage of foreign exchange, and the industrial sector of the economy has to compete with other sectors for the insufficient amount available. This leads to obsolete technology, inadequate machinery and poor material, all of which have an adverse effect on quality.

Incomplete Infrastructure.   The infrastructure is not satisfactory. In most developing countries there are shortcomings in areas such as power supply, transport, communication, and education. In addition, specific services in areas important to quality development, e.g., standardization, testing, training, and consulting, are not adequate for the needs of the enterprises.

Inadequate Leadership.   There is a short-term view on the business, which leads to a quantity-oriented management culture. Business leaders rely on a few key members of personnel. The need for an overall coordination of activities is overlooked. Quality is regarded as a technical issue only, managed by technicians. There is no proper awareness of the strategic importance of quality to the enterprise among owners and top managers.

Inadequate Knowledge.   The managerial as well as technical knowledge of personnel in industry is generally limited. In some developing countries the problem of limited knowledge is compounded by the transient nature of the work force. (It is not uncommon to find that 20 to 50 percent of work force is replaced within 3 to 6 months). Under these circumstances, it is difficult to achieve a skilled work force. The high illiteracy rate in many developing countries adds to the problem.

INDUSTRIAL DEVELOPMENT AND QUALITY

Industrial development usually progresses in identifiable phases, from a primitive, agricultural subsistence economy to a sophisticated economy producing manufactured goods for export. Five phases of development can be defined (Juran 1975), as described below.

Phase I. Subsistence Economy.   Economic activity consists mainly of the production of subsistence goods for local consumption (agriculture, fishing, etc.). Quality is low—there is a lack of quality standards, technology, test facilities, etc. Quality control takes place mainly by consumer inspection of products in the village marketplace.

Phase II. Export of Natural Materials.   In this phase the economy undertakes export of natural materials such as fruits, fibers, and minerals. Selling these goods in the international market requires adherence to international quality standards, which are usually higher than domestic standards. Quality therefore has to be improved. The contracts for export normally include the quality specifications to be met, the tests to be used, and the sampling procedures to be followed, which requires test laboratories, instruments, and appropriate knowledge. In order to provide for the necessary services, a national standards body is set up.

Phase III. Export of Processed Materials.   Local processing of materials is started, and the economy shifts to export of processed rather than raw materials, e.g., metals instead of ore, plywood instead of logs, canned instead of fresh fruit. The economy must now include the acquisition, operating, and maintenance of technological processes. International quality standards for processed products have to be met, and process controls have to be introduced. Supplier relationships concerning quality have to be developed, since packaging materials, raw materials, etc., are supplied from external sources within the country. The traditional work of the standards body is expanded. In addition, new needs arise as tools from the quality management profession (statistical methodology, quality planning, supplier quality activities, organization for quality, etc.) are introduced. This requires training and consulting services.

Phase IV. Integrated Manufacture for Domestic Use.   In this phase the economy undertakes integrated manufacture of modern industrial and consumer products for domestic use. The industries now have to manage quality in all stages of industrial production, from determining the market need through product development, design, manufacture, and marketing. This requires not only training and consulting services but also professional development through research work, conferences and seminars, publications, quality society activities, exchange of views with colleagues, etc.

Phase V. Export of Manufactured Products.   Finally, the manufactured products are sold on the international market, where they have to compete with products from other countries that have fully developed industrial economies. Foreign buyers are increasingly requesting suppliers to conform to the international series of standards on quality management systems (ISO 9000). The industries now have to develop, document, and introduce such systems. They must also, in many cases, ensure that these systems are certified by an accredited institution. This means that there is a need for training in ISO 9000 standards and auditing of quality management systems. Certification bodies have to obtain accreditation, which implies registration of certified auditors.

QUALITY ACTIVITIES

The different phases of industrial development require various activities to attain, improve, and control quality. In a subsistence economy these consist primarily of inspection by consumers.

In the early stages of industrialization there is an increasing need for standardization activities, such as the preparation of standards covering specifications, testing methods, sampling methods, etc. It is also necessary to develop applied and legal metrology, as well as a national testing capability. A certification scheme for selected products is sometimes introduced. All these tasks are usually referred to the national standards body.

As industrialization continues, new needs arise, which cannot be satisfied entirely by traditional standardization activities on a national level. These new needs have to be fulfilled primarily by in-house quality activities, e.g., quality planning, design reviews, new-product testing, supplier surveys and controls, process capability analyses, inspection planning, quality audits, quality evaluation, quality data feedback, poor quality cost analyses, benchmarking, quality improvement programs, quality policies and objectives, quality systems and organizational development. Knowledge about these activities and the appropriate tools (under the designation of quality management) is required, and this creates a need for education and training, development of quality specialists and managers, consulting assistance, etc. These needs are accommodated with measures that may include training courses, conferences and seminars, research committees, publications, and/or quality societies.

Consequently, there are a wide range of quality activities, the importance of which depends on the stage of industrial development. Basically, the activities can be grouped as follows:

Inspection by consumers: Inspection of products in the marketplace.

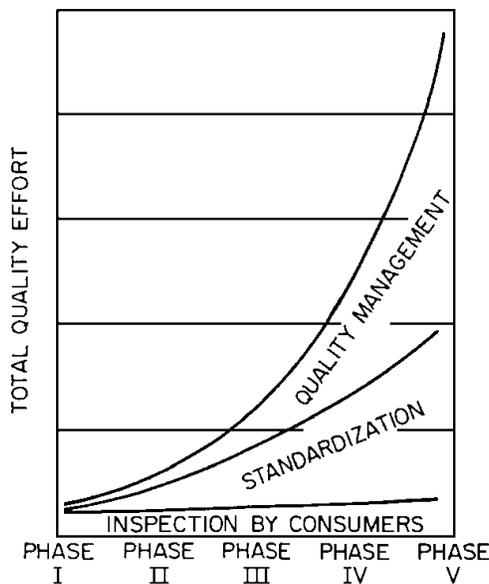
Standardization: National standards on terminology, sampling methods, testing methods, specifications, codes of practice, and quality management systems; applied and legal metrology; national testing facilities; certification; legislation.


FIGURE 37.1   The growth of total quality effort in industrial development. (*Based on Juran 1975.*)
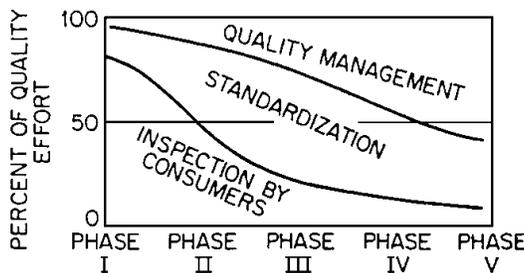

FIGURE 37.2   The relative importance of the quality activities. (*Based on Juran 1975.*)

Quality management: Application of managerial tools to plan for quality, attain and control quality, follow up and improve quality, as well as to organize for quality and develop competence in the field.

Figure 37.1 shows the development of total quality measures in the industrial development. Figure 37.2 shows the importance of the activities on a relative basis. It is clear that the dominance is shifting from inspection by consumers to standardization, and from standardization to quality management.

QUALITY MANAGEMENT

Phases of Development.   There is an increasing interest in quality worldwide. Over the past 10 years, more and more companies in industrialized countries have become involved in quality activities of various kinds. Management journals include quite a lot about quality. National and international conferences highlighting quality are held frequently.

This development is also influencing developing countries. In the more industrially advanced of these countries, the interest in quality is equal to that in industrialized countries. In other countries, interest is emerging.

Five phases can be identified in the development of quality in manufacturing enterprises as well as in service organizations (Sandholm 1996).

Dormant phase: Companies do not feel any threat in the marketplace. They earn an acceptable income. Executives are satisfied with the business results. They experience no need to give any special consideration to quality.

Awakening phase: The situation is dramatically changed. Market shares are lost. Income drops. Profit turns into loss. Executives awake and feel that they are facing a crisis.

Groping phase: Upon awakening, executives realize that they have to do something in the field of quality. But what? Trendy tools and methods are there as a possibility, highlighted very much in business literature and at management seminars and conferences. Lacking any sound knowledge in how to manage for quality, executives just select whatever presents itself. The groping phase is a period of trial and error.

Action phase: Some companies discover that the trendy tools and methods do not lead to excellent results. They then start to carry out an effective program for changing the situation. Such a program includes a change of the internal culture, as well as improvements of products and processes.

Maturity phase: A real sign of maturity is when quality is no longer talked about in the enterprise. Full customer satisfaction is achieved through perfect processes in all areas of the organization. The concept of quality applies not only to products, i.e., the goods and services produced and supplied, but also to all supporting activities. A total quality approach is applied, which includes all processes and functions, as well as the involvement of everyone in the organization. Quality is just a natural aspect of the work, permeating the entire organization. Executives regard quality in the same natural way as they regard finances. The maturity phase has been reached by successful Japanese companies. In the West, the list of winners of the Malcolm Baldrige National Quality Award in the United States and the European Quality Award in Europe contains companies that can be fairly considered to have reached the maturity phase.

In Western industrialized countries, the dormant phase continued up to the end of the 1970s, when the awakening came as a result of Japanese competition. The awakening phase in Japan had taken place 30 years earlier. The groping phase in the West is going on right now. The maturity phase is still to come in most Western companies.

The dormant phase has prevailed in most developing countries due to governmental policies of protecting local manufacturers from competition from abroad. However, the governments in many developing countries introduced policies implying liberalization of the economy and opening up the market for foreign competition early in the 1990s. For local enterprises this meant that they entered into the awakening phase, which was rapidly succeeded by the groping phase.

Developments in Western industrialized countries have a strong impact on what is done in the field of quality in developing countries, particularly those countries which are more industrialized. The methods and tools which become trendy in the groping phase in the West will be applied (somewhat later, though) in developing countries as well.

A list of trendy methods and tools includes "Zero Defects," quality circles, statistical process control (SPC), quality function deployment (QFD), seven tools, "TQM," ISO 9000, benchmarking, process re-engineering, etc. There is a phenomenon of methods and tools of this kind emerging, being highlighted for some time and then fading away.

A veritable explosion took place in this field in the 1980s, when it dawned on many Western companies that they were being driven out of business by Japanese companies. Companies in the West found that they had to do something and were willing to try anything.

There is nothing wrong with these methods and tools as such. The fault lies in how they are implemented. They are used as general methods and tools for quality improvement and, used in this manner, will only lead to marginal improvement. They ought to be used only when an analysis indicates that they are the appropriate measures to eliminate specific problems or to better meet the needs of customers. The same is true for all other methods and tools which are part of the quality profession and which have not yet been widely publicized, even though they may have much greater effects on the results achieved.

Areas of Interest.   During the 1990s there has been an increasing interest in three areas: total quality management, ISO 9000, and national quality awards. In this respect, the more industrialized developing countries do not very differ significantly from countries with a developed market economy.

Total Quality Management.   The concept of quality has formerly been discussed exclusively in relation to products, i.e., the goods and services which an organization produces and supplies. Nowadays, quality is increasingly discussed in a broader context. The concept most commonly referred to is total quality, which includes the quality of all internal processes and functions as well as the involvement of everyone in the organization.

In this context, reference is often made to the term "total quality management." An increasing number of conference papers referring to total quality management in the title are being presented. Many of these papers, however, do not actually deal with total quality management. They propagate certain narrow concepts or tools. Presentations on the experiences of companies in developing countries really practicing total quality management are, in fact, rare.

ISO 9000.   The international series of standards for quality systems, ISO 9000, has had an immense impact. A growing number of enterprises in developing countries are taking ideas from these standards as a basis for developing and introducing procedures for their own quality activities, primarily relating to product quality. More and more quality activities are tending to focus on ISO 9000.

For most enterprises, the driving force behind the development, documentation, and implementation of a quality system based on the requirements in the ISO 9000 series of standards is commercial. Enterprises in developing countries find that they are no longer accepted as suppliers by customers in industrialized countries if they do not apply a documented quality system. Or they may find that they are losing market shares to competitors who do have a quality system based on the ISO 9000 standards.

National standards bodies are very active in promoting the use of ISO 9000. Promotion material is distributed frequently. ISO 9000 receives extensive publicity in the media through these bodies. Conferences and seminars are organized to highlight the merits of ISO 9000.

A certain infrastructure on a national level is a prerequisite for using the ISO 9000 approach to quality (see below, under Institutional Infrastructure). The enterprises need services in areas such as

consulting, training, auditing and certification. In addition, the infrastructure shall provide for the accreditation of certification bodies, as well as for the registration of certified auditors for quality systems (see below, under Certification).

The United Nations Industrial Development Organization (see below, under External Assistance) has conducted a survey of developing countries and emerging economies in Latin America and the Caribbean, Africa, Asia, and Eastern Europe on the subject of the ISO 9000 series of standards and the implications of these standards upon the trade of those countries (United Nations Industrial Development Organization 1996). Special attention was paid to the situation of small and medium-sized enterprises. The survey showed that awareness of ISO 9000 was highest in Latin America and lowest in African countries. The highest awareness was among multinational companies and large national enterprises, while small and medium-sized enterprises showed a low awareness. ISO 9000 was perceived to be of most importance for exporters, particularly in Latin America and Asia. This was not the case in Africa. It had hardly any importance for importers and little relevance for producers for the domestic market.

The International Trade Centre UNCTAD/WTO (see below, under External Assistance) has published two books on the implementation of the ISO 9000 standards in small and medium-sized enterprises in developing countries. One is a guide (International Trade Centre UNCTAD/WTO and International Organization for Standardization 1996), published jointly with the International Organization for Standardization (see below, under External Assistance), that provides guidance on methodology for implementing the elements of ISO 9000 quality management systems as well as guidance on preparing enterprises for third-party certification. The second book is a handbook (International Trade Centre UNCTAD/WTO 1996) dealing with basic concepts of quality management. The book explains the structure and content of the ISO 9000 standards and discusses the establishment, implementation, auditing, and third-party certification of quality management systems.

National Quality Awards.   In order to promote quality, national quality award schemes are set up in an increasing number of developing countries. These schemes started to emerge early in the 1990s in the more industrialized developing countries. The schemes are based on either the Malcolm Baldrige National Quality Award (in the United States) or the European Quality Award.

The quality awards have become an important ingredient of national programs to promote an awareness of quality among manufacturers and service providers (see below, under National Promotion).

UNIDO Quality Program.   The United Nations Industrial Development Organization (UNIDO) has designed a program for quality development in enterprises in developing countries (Maizza-Neto et al. 1994). The program, called the UNIDO Quality Program, is based on a systemwide approach to continuously improving every aspect of an organization's production process to achieve higher levels of quality—while simultaneously holding down costs. The program recognizes that poor product quality and low productivity are major impediments to the viability of many enterprises in developing countries.

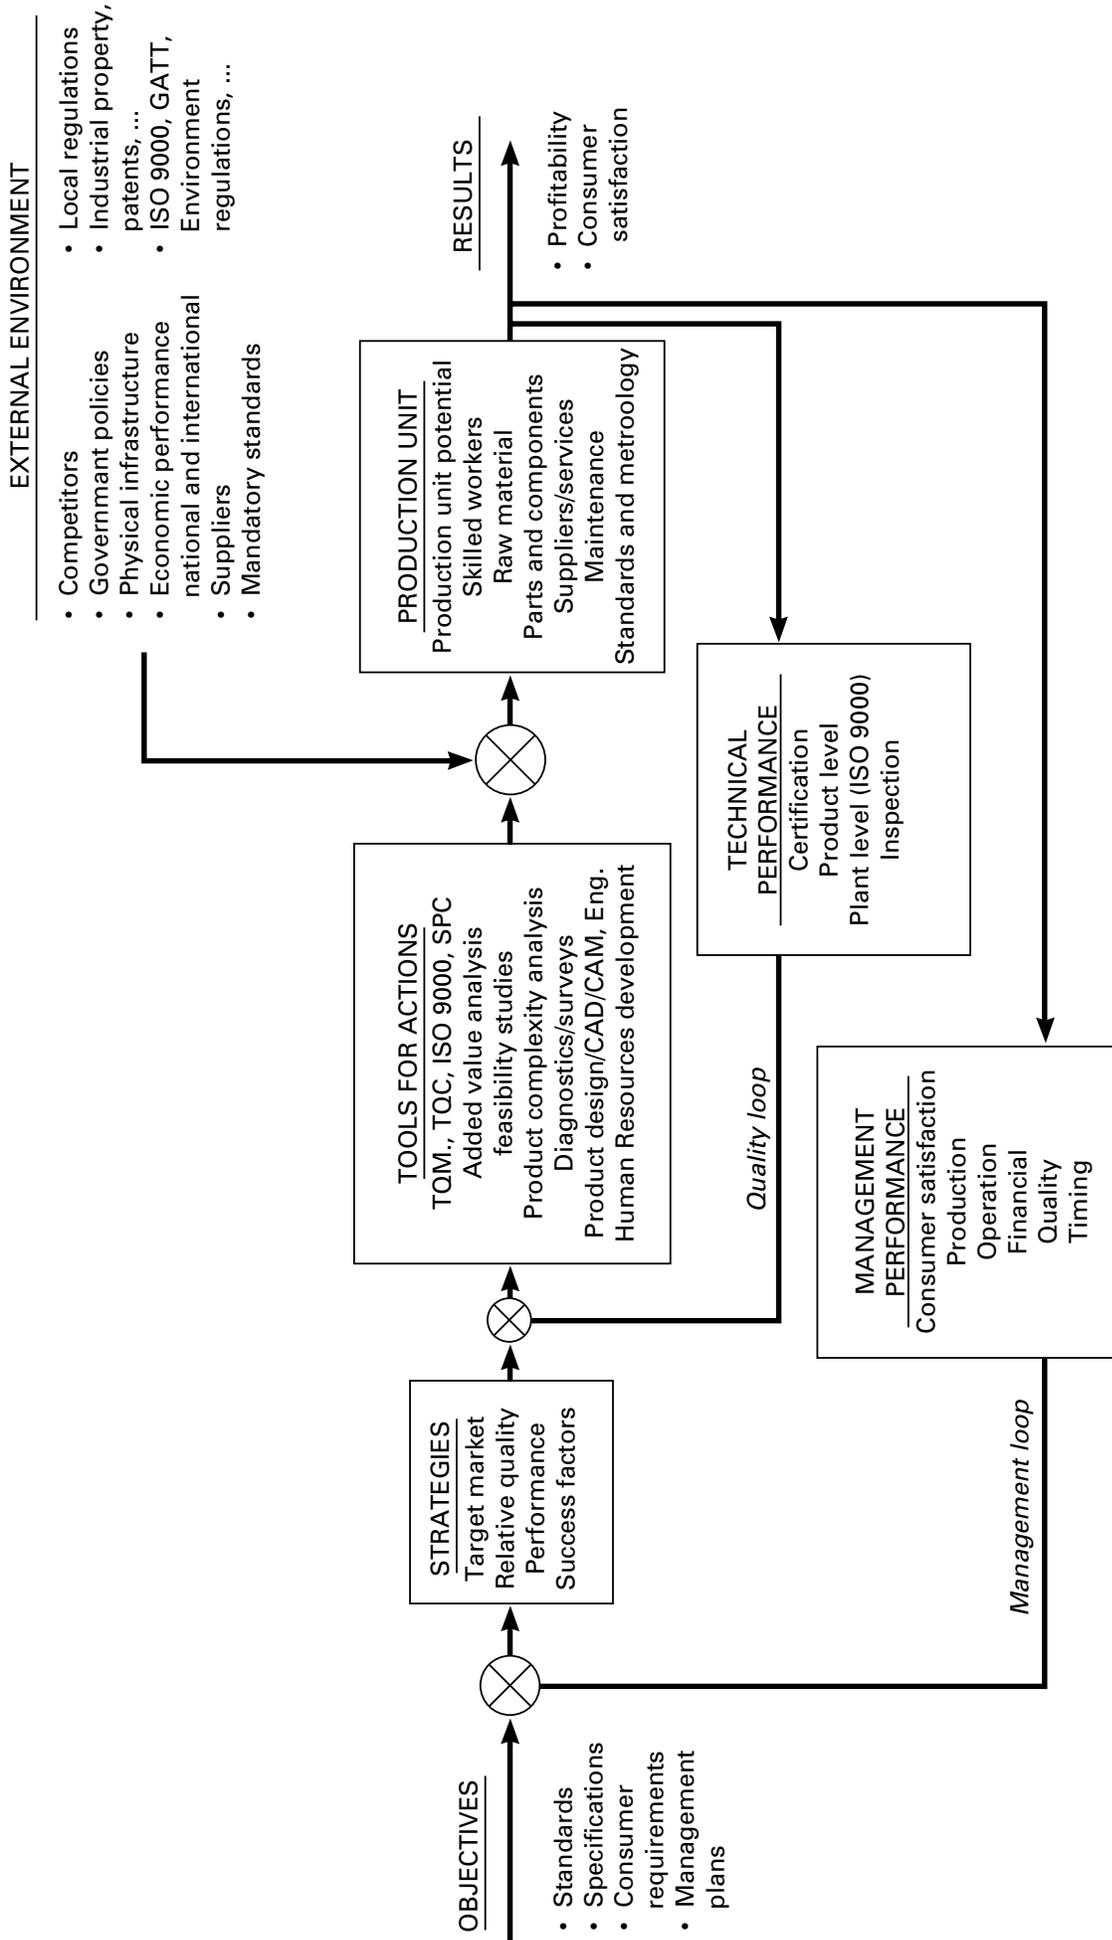
The system has two major parts: an inner quality loop and an outer management loop (Figure 37.3). The inner quality loop involves the main activities that are responsible for compliance with specifications and the creation of consumer satisfaction. The outer management loop has to do with the operational performance of the enterprise. Operational indicators are developed. These will show the entrepreneurs that the effect of an important strategic decision can be detected and corrected. The implementation starts with a survey to identify subjects which the entrepreneurs themselves consider to be important. Once the priorities for changes have been identified, the technical assistance of UNIDO, in the form of the expert advice of national and international consultants, is available to support the modernization of interested pilot enterprises. The results are continuously evaluated through the operational indicators. For the evaluation of these indicators, UNIDO has developed two computer softwares: BEST (Business Environment Strategic Toolkit) and FIT (Financial Improvement Toolkit). BEST assists the entrepreneurs in the operation and management of the enterprise, while FIT assists in financial decisions concerning strategy.


FIGURE 37.3 The inner quality loop and the outer management loop in the UNIDO Quality Program. (*Maizza-Neto et al. 1994.*)

37.9

The approach described above has been successfully implemented in 95 companies, in the capital goods sector, in 10 Latin American countries. The same approach is planned for the food processing sector of seven African countries.

NATIONAL EFFORTS FOR QUALITY

The problems related to quality in developing countries are of such a nature that they cannot be solved on a company level only. In fact, efforts on a national level are necessary, and these depend largely on the national policy of the country. In some countries, the government is ahead in developing means for an effective quality program. National efforts include.

Standardization: Preparation of national standards covering terminology, sampling methods, testing methods, specifications, quality management systems, and codes of practice

Certification: To attest that products comply with standards, and that quality-related activities are carried out in accordance with certain standards on quality management systems

Export inspection: Ensuring the quality of certain products for export through preshipment inspection

Legislation: Enforcement of standardization, certification, accreditation, export inspection, and other requirements through acts of parliament and legislature

National promotion: National programs to promote a general awareness of quality

Education and training: Development of the necessary knowledge and skills, as well as exertion of influence on attitudes

External Assistance: Assistance from international organizations, bilateral aid programs, transnational corporations, and other sources to shortcut the development process

Institutional infrastructure: Services offered by institutions in the areas of standardization, certification, accreditation, testing, metrology, quality consulting, and training

Professional societies: To develop the competence of quality professionals and practitioners

The steps to be taken on a national level are determined mainly by the governments of the respective developing countries. The way this is done depends on the policy of the government. In some developing countries there is a centrally planned economy, and in these we will often find a strong reliance on governmental institutions and legislation. In other countries only some basic needs (e.g., standardization, education) are met by the government. There is a growing trend among developing countries toward less government intervention and more deregulation.

STANDARDIZATION

Standardization plays a major role in promoting industrial and economic development of a country. Many developing countries have realized this and as a consequence have set up national institutions to handle the standardization activities.

Standardization refers to the process of formulating and applying standards to a specific activity. There are several types of standards:

Terminology standards: Terms used in technical and legal documents have to be clearly defined. Terminology and symbols are a means of communication.

Basic standards: Standards on units of measure are a prerequisite for trade, engineering, health care, etc. There are also other basic standards in fields like civil engineering, electrical engineering, and mechanical engineering.

Dimensional standards: By making components to certain standardized dimensions, interchangeability will be achieved.

Performance standards: Criteria reflecting the fitness for use of the products are important for consumers. These, as well as safety-related requirements, are given in performance standards.

Testing and inspection standards: Test and inspection data can differ depending on the methods used. Therefore, standards describing the equipment to be used, the procedures to be adopted and the evaluation of the data obtained are important. This also includes the sampling procedures to be used.

Quality systems standards: Industrial buyers are increasingly referring to the international series of standards for quality systems (ISO 9000) in the procurement of equipment and materials. An increasing number of developing countries have as a consequence adopted these standards as national standards.

National Standardization. Standardization activities on a national level are dealt with by a national standards body. This institution, carrying full government recognition (in many developing countries through legislation), is responsible for the development and publication of national standards, as well as for keeping them up to date. In preparing standards, the national standards body calls upon the knowledge and experience of manufacturers, users, government departments, universities, etc. This is normally done by setting up technical committees with this wide representation.

The following procedure is applicable in relation to the national standards bodies activities on preparing national standards (International Organization for Standardization 1994a, pp. 32–42):

1. Identification of standardization subjects
2. Justification of projects and assignment of priorities
3. Approval of projects and their inclusion in the work program of the national standards body
4. Development of the standards
5. Approval of the standards by the national standards body and their publications

As an example of standards preparation, the procedure used by the Standards Association of Zimbabwe (SAZ) is shown in Figure 37.4.

A checklist for identifying subjects and assigning priorities for national standardization is given in Figure 37.5.

National standards can be mandatory or voluntary. Mandatory standards are found in countries with a centrally controlled economy, while countries with a free-enterprise economy normally have voluntary standards. In most countries, however, there is a mixed or selective approach in the enforcement of national standards. This means that standards are voluntary, except those dealing with safety and health. Such standards are mandatory.

This mixed or selective approach would fit the needs of many developing countries where the situation is as follows (International Organization for Standardization 1991, p. 21):

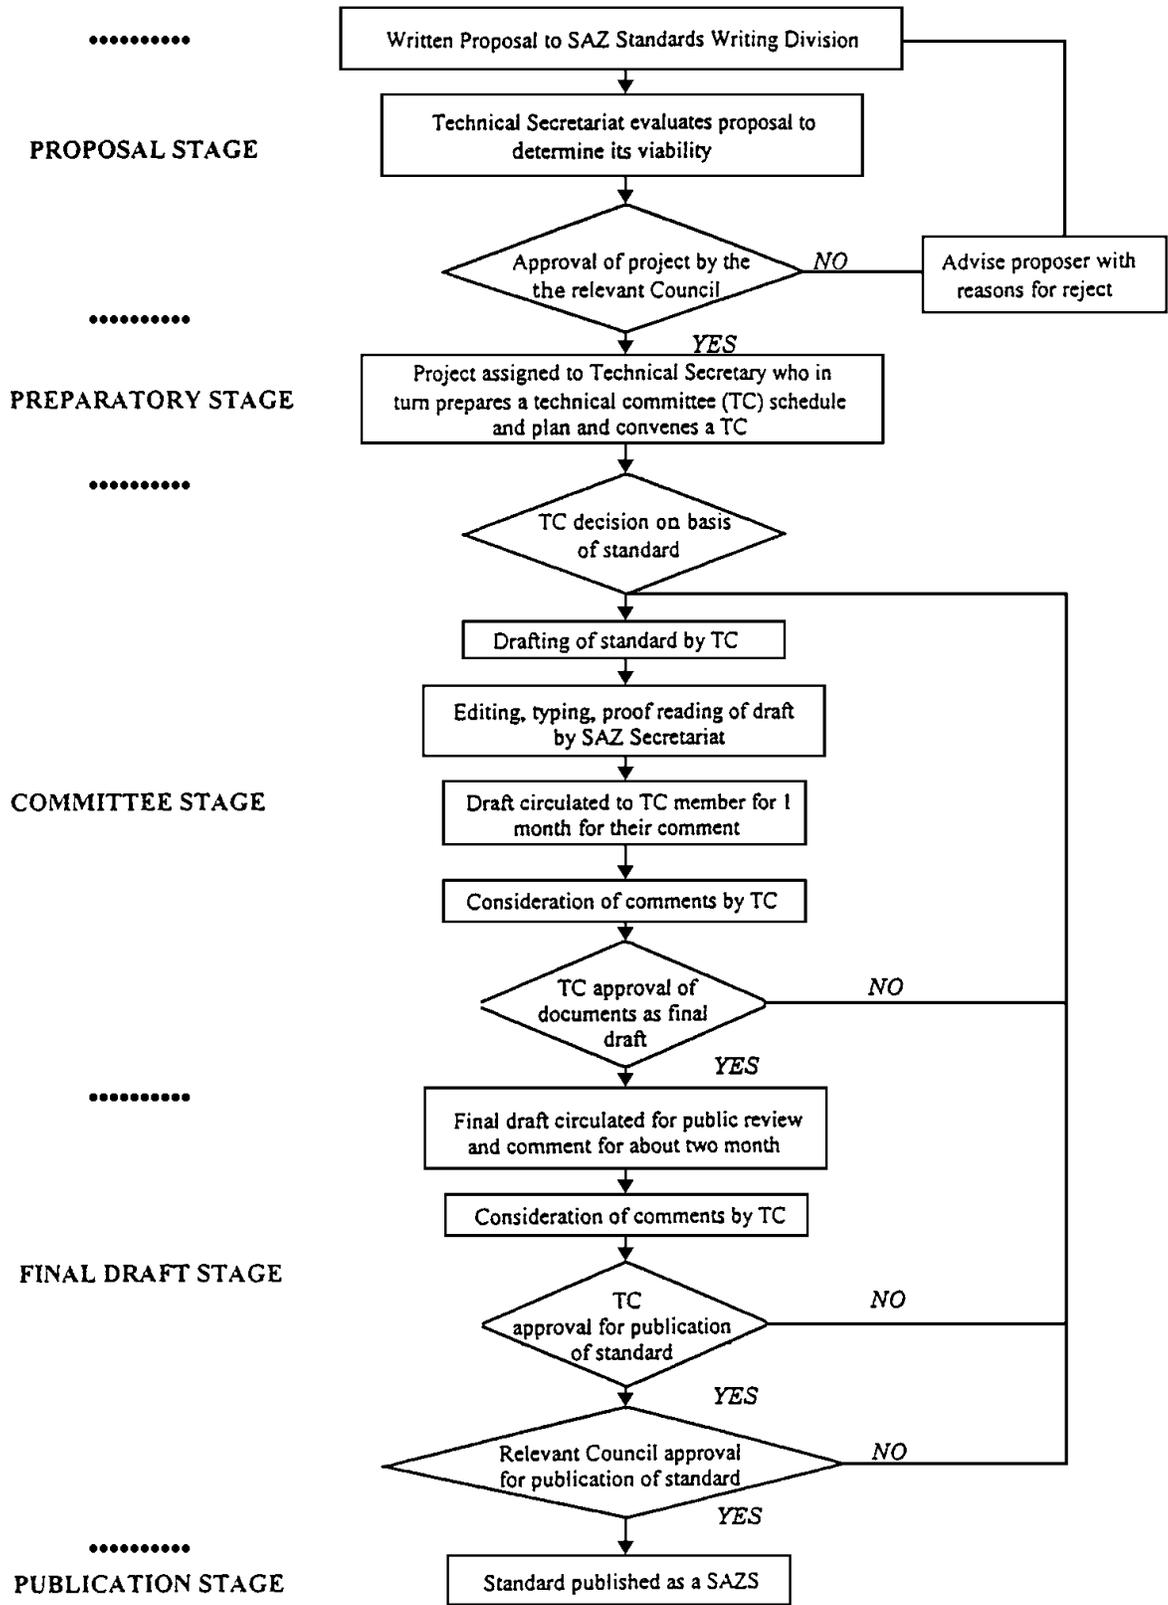
1. Low level of standards consciousness in circles involved in production and distribution of goods and services, combined with a low literacy rate in the country as a whole
2. Coexistence of modern and traditional industries
3. Small or unrecognized industries that, by virtue of their number, contribute to substantial production
4. Wide variation in manufacturing and processing capabilities
5. Uncertainty about the availability of raw materials of assured quality
6. Sporadic or low consumer demand for standard quality
7. Difficulty in ensuring an adequate enforcement mechanism
8. Need for ensuring essential health and safety protection of the consumers


FIGURE 37.4 Standardization procedure used by the Standards Association of Zimbabwe (SAZ). (*Mhlanga 1995, p. 56.*)

1. Which of the following objectives should be included in the standards?

	YES	NO
Mutual understanding	☐	☐
Health, safety, protection of environment	☐	☐
Interface, interchangeability	☐	☐
Fitness for purpose	☐	☐
Variety control	☐	☐
Others (please specify)	☐	☐

2. Which of the following aspects are to be standardized?

	YES	NO
a. Terminology symbols/signs	☐	☐
b. Characteristics	☐	☐
• Dimensional	☐	☐
• Mechanical	☐	☐
• Chemical (including microbiological)	☐	☐
• Thermal	☐	☐
• Electrical	☐	☐
c. Marketing, labelling, packaging, transport	☐	☐
d. Sampling	☐	☐
e. Testing	☐	☐
f. Others (please specify)	☐	☐

3. What is (are) the specific aim(s) of the standard? E.g.,

	YES	NO
a. Government requirements in support of	☐	☐
• Public sector procurement	☐	☐
• Legislation	☐	☐
b. International/regional harmonization	☐	☐
c. Commercial factors associated with	☐	☐
• Exports	☐	☐
• Imports	☐	☐
• Internal trade	☐	☐
d. Certification	☐	☐

4. What technical expertise is available?

	YES	NO
a. Research institutions/universities	☐	☐
b. Manufacturers	☐	☐
c. Users (consumers)	☐	☐
d. Independent personnel	☐	☐
e. Government departments	☐	☐
f. Others (please specify)	☐	☐

5. Is it envisaged that these aspects can be covered

	YES	NO
In a single publication?	☐	☐
Or in parts?	☐	☐

6. Are any of the aspects listed in 4 or 5 above covered by existing national legislation in the country? _____

   Please specify such legislation. _____

7. Are any of these aspects covered by existing

	YES	NO
a. International standards	☐	☐
b. National standards	☐	☐
c. Other specifications of written requirements?	☐	☐

8. Are any of the requirements included in standards considered to be of outstanding importance by your organization?　☐　☐

9. What is the estimated time needed to complete the project? _____

10. What liaison will be necessary with other technical committees or outside bodies? _____

11. Who will be the ultimate users of the standard (number and/or names)? _____

FIGURE 37.5 Checklist for identifying fields for the establishment of national standards. (*Source: International Organization for Standardization 1994b,* pp. 93, 94.)

Regional Standardization.   Developing countries in the same region have similarities in climate, culture, governmental policies, consumption, industrial production, etc. Therefore, there might be a need for common standards. In order to deal with these regional issues in the field of standardization, regional standards organizations have been formed.

Such regional standards organizations exist in Africa (African Regional Organization for Standardization, ARSO), in Arab Countries (Arab Organization for Standardization and Metrology, ASMO), in the Caribbean (Caribbean Common Market Standards Council, CARICOM), and in Latin America (Comisión Panamericana de Normas Técnicas, COPANT).

International Standardization.   International standards are an important means of communication in international business and trade. With the globalizing of trade, the need for international standardization increases.

There are three international standardization bodies which are most important to developing countries:

The International Organization for Standardization (*ISO*):   This a worldwide federation of the national standards bodies of some 110 countries, many of them developing countries. The mission of ISO is "to promote the development of standardization and related activities in the world, with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technological, and economic activity." This work results in international agreements which are published as international standards.

The International Electrotechnical Commission (*IEC*):   This is a body preparing international standards in the electrotechnical field. IEC and ISO have a close cooperation.

The Codex Alimentarius Commission (*CAC*):   This is a body jointly set up by the Food and Agricultural Organization of the United Nations (FAO) and the World Health Organization (WHO) in order to prepare international standards in the food sector.

Developing countries can gain by adopting or adapting international standards as national standards, as the process of standards development is time-consuming and costly. Many developing countries do not have the professional resources necessary to prepare standards in certain areas.

Adopting and adapting international standards as national standards has several advantages (International Organization for Standardization 1986, p. 5):

1. It supports export promotion

2. It creates flexibility in imports and ensures the quality of imported products, services, etc.

3. It facilitates the transfer of technology

4. It supplements the production of national standards

5. It gives national authority to the use of international standards

As international standards are providing the key to international markets, it is important to developing countries to be able to see such standards internationally established for products that are vital to their national economies. In addition, they are concerned for the safety and the health of their citizens.

A developing country may find a need for an international standard to serve one or more of the following purposes (International Organization for Standardization 1994b, p. 3):

1. For an important export commodity: to ensure equitable prices that correspond to the delivered quantity and quality and to avoid rejects due to nonconformance to different conditions of export markets.

2. For an imported product that may affect the health and safety of users or have environmental implications: to have a technically sound and universally accepted basis for government regulations to protect the consumer and the ecology.

3. For a service that is being offered in the country to local and foreign customers: to maintain an acceptable level that would ensure safety (such as in building construction and health services) and/or competitiveness with other countries that offer similar services (such as tourist services).

4. For products and components traded with other countries: to ensure ability to interact and interchangeability.

5. For information, commercial, cultural, and other types of exchange: to facilitate communication between nations.

It may be difficult for developing countries to launch and to get acceptance for proposals on international standards in fields of interest to them. In order to help developing countries to prepare their proposals in a way that will have a good chance of acceptance by other countries, ISO has published some guidelines on how to launch a standards initiative (International Organization for Standardization 1994b).

CERTIFICATION

Certification means to verify conformance with certain requirements. This can take many forms, ranging from a simple statement by the manufacturer that the product conforms to the specification to a third party certification in which an independent body verifies that the manufacturer operates in accordance with a recognized standard on quality management systems.

Certification on a national level is very often combined with standardization. This means that national standards bodies, in addition to dealing with standardization on a national level, may also perform third-party certification on a national level.

Product Certification.   This involves checking and certifying that products comply with the standards. The purpose of a product certification program is to give the buyer confidence that the product is of a certain quality or that it meets quality requirements. Such certification goes beyond the seller's assurances that the product conforms to the requirements and beyond the buyer's own verification—instead, systems operated by impartial bodies are used (third-party certification). The impartial certification body can be a governmental or nongovernmental organization. In developing countries the national standards body normally assumes this responsibility.

In developing countries there are various reasons for having a third-party certification program. One is to upgrade quality in the domestic market. Because of the shortage of goods and the absence of competition which very often prevail in developing economies, product quality is likely to be poor, and a mandatory certification system can provide a minimum quality level. A second reason is to promote exports. A certification system can be an important factor in enabling developing countries to secure access to foreign markets. A third reason is to prevent importation of products of inferior quality. Some developing countries have had the misfortune to be used as dumping grounds for unscrupulous foreign manufacturers.

A third-party certification can take various forms:

Type testing: A sample of the product is tested according to a test specification in order to verify conformance with certain specified quality requirements. The testing is carried out by the certification body or by a recognized testing institute or laboratory.

Audit testing: In order to provide for a subsequent assurance, the type testing can be followed by an audit test of samples purchased in the market place or selected from the manufacturer's production before shipment.

Batch testing: Manufactured batches are tested. This could be done on a sampling basis or 100 percent.

Assessment: Specialists from the certification body visit the manufacturer's factory in order to find out how the quality control activities are performed.

These forms can be combined into certification systems (Figure 37.6). Products that come under a certification program and have been found to comply with the standards are marked with a certification mark upon the granting of a license issued by the certification body (in most cases the national standards body). The manufacturer has to support the application with the following documents:

1. Articles of incorporation
2. Organizational chart
3. Quality control staff complement, their designations, qualifications, training courses attended, and number of hours thereof

---

System No. 1—Type testing

Type testing is a method under which a sample of the product is tested according to a prescribed test method in order to verify the compliance of a model with a specification. It is the simplest and most limited form of independent certification of a product both from the point of view of the manufacturer and the approval authority.

System No.2—Type testing followed by subsequent surveillance through audit testing of samples purchased on the open market

A system based on type testing (see System No. 1) but with some follow-up action to check that subsequent production is in conformity. Open market audit testing means a random audit testing of the type tested model from distributors' or retailers' stock.

System No.3—Type testing followed by subsequent surveillance through audit testing of factory samples

A system based on type testing (System No. 1) but with some follow-up action to check that subsequent production conforms. Audit testing of factory samples involves a regular check of samples of the type-tested models selected from the manufacturer's production before dispatch.

System No.4—Type testing followed by subsequent surveillance through audit testing of samples from both the open market and the factory

A system based on type testing (System No. 1) but with follow-up action to check that subsequent production conforms. Audit testing both of factory samples and open market samples.

System No.5—Type testing and assessment of factory quality control and its acceptance followed by surveillance that takes into account the audit of factory quality control and the testing of samples from the factory and the open market

A system based on type testing (System No. 1), with assessment and approval of the manufacturer's quality control arrangement followed by regular surveillance through inspection of factory quality control and audit testing of samples from both the open market and the factory.

System No.6—Factory quality control assessment and its acceptance only

Sometimes known as the approved firm or approved manufacturing method of certification. A system under which the manufacturer's capability to produce a product in accordance with the required specification, including the manufacturing methods, quality control organizations, and type and routine testing facilities are assessed and approved, in respect of a discrete technology. This system can be applied particularly where the specification covers a type of manufacture, possibly a material, but where the end product may take a variety of forms for which there are no particular specifications.

System No.7—Batch testing

Batch testing is a system under which a batch of a product is sample tested and from which a verdict on the conformity with the specification is issued.

System No.8—100% testing

100% testing is a system under which each and every item certified is tested to the requirements of the technical specification.

FIGURE 37.6   Description of third-party certification systems. (*Source: International Organization for Standardization and International Electrotechnical Commission 1992, pp. 156–171.*)

4. List of training courses regularly conducted by the company or other outside training courses attended by company personnel

5. Flow process diagram indicating the inspection points, frequency of inspection and key quality characteristics to be inspected at each control point

6. Brief description of manufacturing process

7. Copy or summary of management policies

8. Copy or description of test plan and specifications used by the company

9. Copy of sampling plans

10. Copy or a sample of work instructions or other related documents

11. Sample copies of frequency tables, histograms and/or statistical control charts and records of inspection/test results

12. Brief description of action taken on defectives

13. Brief description of the system for the preservation, segregation, and handling of all items

14. List of measuring and testing equipment with nominal capacities at each inspection point and final product testing together with their evidence of ownership

15. Brief description of calibration program (including frequency of calibration)

16. Brief description of equipment maintenance program

System Certification.   There is a trend to move from product certification to system certification. This means that the supplier's credibility is demonstrated by the assessment and registration of his quality system.

The assessment of the supplier's quality system is carried out by an independent certification body against an applicable quality system standard in order to establish whether the system conforms to the standard. Standards usually referred to are the international standards on quality management systems ISO 9001 and ISO 9002 (or the equivalent national standards). If the assessment shows that the supplier's quality system conforms to the relevant quality system standard, the supplier is entered into a register of certified companies. The idea is that this will indicate to the user of the register that the supplier is capable of producing a certain product or range of products. The registration is maintained by surveillance through periodic audits of the supplier's quality system, performed by the certification body. This will ensure continued conformity of the quality system with the standard in question.

In some developing countries, the national standards body has been assigned the quality system certification task. As soon as the auditing capability of the staff is developed and the necessary management structure is set up, quality system certification will be one of the major tasks of the national standard bodies in developing countries. As there is a great demand for quality system certification, many foreign (mainly European) certification agencies are operating in developing countries on a commercial basis. The certification has also become a business opportunity for local consultants. The less scrupulous ones form two organizations: one to set up the quality systems and to write the quality manuals for their clients, and one to certify that these quality systems and manuals conform to the quality system standards ISO 9001 or ISO 9002. The certification agency itself might have achieved accreditation by a body in Europe on a rather loose ground, making any of the certificates it issues of doubtful validity.

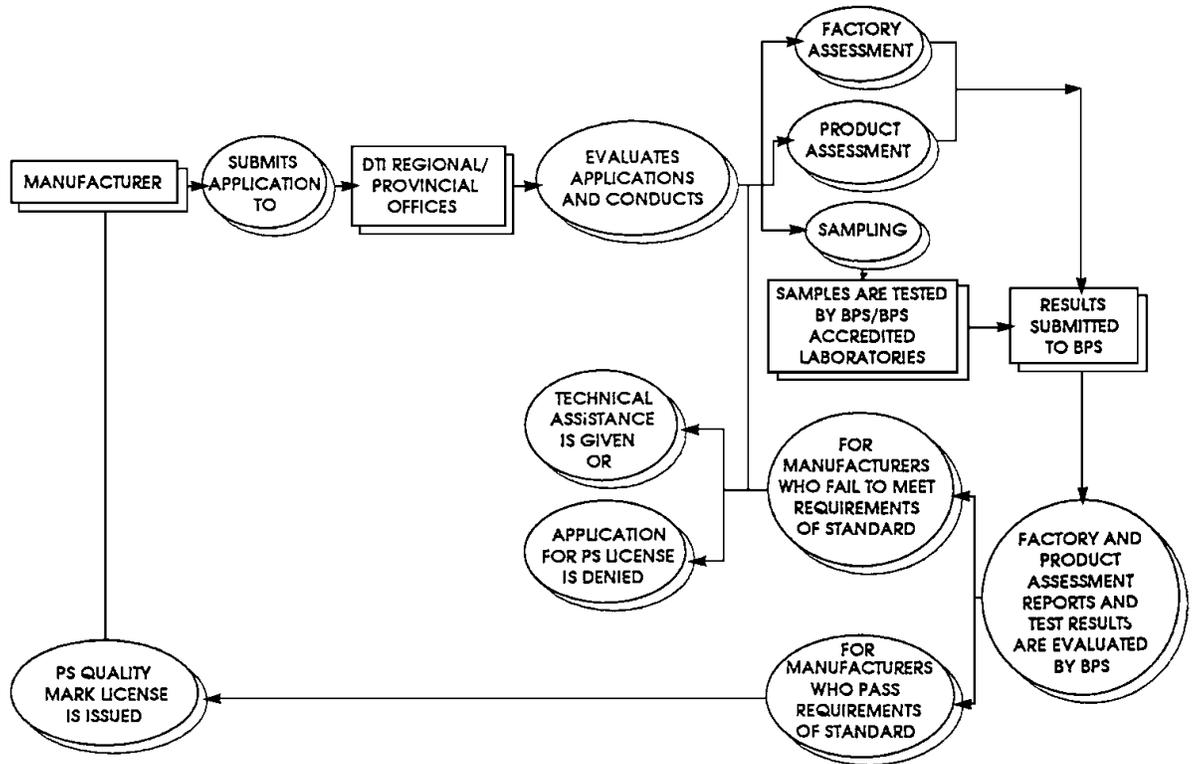
There are doubts about the validity of quality system certification, as this mainly relies on documentation in the form of quality manuals, work procedures, instructions, and records generated during the operation of the quality system. Product quality, and the customers' perception of quality, are not considered. Such doubts are more valid in developing countries compared to industrialized countries (Lal 1996a). In developing countries top management more often pays only lip-service to quality. They see the ISO 9000 certification as "some kind of magic key" which will open doors to export markets for their products. For them it is most important to obtain the formal certificate. There will be no basic change in the quality culture of the enterprise, nor will any real product quality improvements take place. The limited experience in quality management among assessors and auditors in developing countries will also create doubts about the validity of the certification.


FIGURE 37.7   Product certification procedure used in the Philippines. (*Courtesy Bureau of Product Standards, Philippines.*)

Worldwide Recognition of Certificates.   In order to encourage good practice in conformity assessment activities worldwide among the organizations that perform them, the International Organization for Standardization and the International Electrotechnical Commission in 1985 set up the Committee on Conformity Assessment (CASCO). CASCO has three basic objectives: (1) to study the means of assessing the conformity of products, processes, services, and quality systems to appropriate standards or other technical specifications; (2) to prepare international guides relating to the testing, inspection, and certification of products, processes, and services, and to the assessment of quality systems, testing laboratories, inspection bodies, and certification bodies and their operation and acceptance; (3) to promote mutual recognition and acceptance of national and regional conformity assessment systems and the appropriate use of international standards for testing, inspection, certification, assessment, and related purposes (Donaldson 1996). The guides are available from the International Organization for Standardization (see below, under External Assistance).

The worldwide growth in the certification of enterprises to ISO 9000 has led to a desire to establish a global system of mutual recognition of certificates. Therefore, on the basis of a proposal from CASCO, ISO and IEC initiated a voluntary worldwide system called Quality System Assessment Recognition (QSAR). The objective of QSAR is to ensure that ISO 9000 certificates issued to any enterprise, anywhere in the world, by any quality system certification body recognized under the QSAR program, are accepted everywhere. When QSAR has established itself, developing countries could benefit from such a worldwide recognition system in their efforts to export goods and services.

EXPORT INSPECTION

In assuring foreign buyers goods of an acceptable quality, plans for preshipment testing and inspection of products for export are used. Some developing countries have legislation dealing with export inspection. The legislation generally applies to specific commodities that are of key importance for

the national economy (coconut, coffee, cocoa, fruit, jute, rice, rubber, etc.).

As a consequence of the deregulation of the markets, the trend is to get away from compulsory systems for export inspection enforced by law. Instead the export inspection is a matter for the market forces, which means that the trading partners (the exporters and the importers) set up and agree on how to ensure the quality of the deliveries. Third-party certification is then increasingly applied.

An example of an export inspection program which has been successful in promoting export is the fish inspection program in Thailand (Suwanrangsi 1995). The Fish Inspection and Quality Control Division (FIQD), established in 1992 within the Department of Fisheries, has gained recognition in major importing countries such as Australia, Japan, Canada, and the European Union for its active role in controlling the performance of the seafood export industry.

The Thai fish inspection program involves plant inspection and preshipment inspection. The plant inspection, carried out two to four times a year, covers the condition and maintenance of construction, equipment, processing operations, plant hygiene, and personnel. The preshipment inspection includes sampling of batches to be delivered. Sensory and microbiological assessment, as well as testing for contamination, toxicology, etc., are performed according to the requirements of the importing country. FIQD also provides consultancy service and training to the seafood industry in matters related to quality.

LEGISLATION

National standards bodies in developing countries have been established by acts of parliament or legislature. Such acts, normally called "standards acts," stipulate the role of the national standards institute in promoting standardization throughout the country. Provisions related to the enforcement of standards are sometimes incorporated into some of these laws; for example, foods acts or certification mark acts.

The standards act may also deal with weights and measures. In some countries such standards are covered by a separate weights and measures act, which also deals with the testing of weighing and measuring equipment to ensure that it is fit for use in trade.

There may also be legislation on export inspection, which is the case for certain items in some developing countries.

NATIONAL PROMOTION

In an increasing number of developing countries, national programs for promoting a general awareness of quality have been launched with the involvement of government agencies and trade and consumer organizations. The national programs usually have the following components:

High-level recognition: Support from ministries and important national organizations is granted. Even the head of state may be involved.

Publicity: Public media such as newspapers, magazines, radio, and television are used.

Conferences, seminars, and other meetings: Speeches are given by political leaders, industrialists, quality professionals, etc.

Slogans: Slogans such as "Quality first" are disseminated through posters, pamphlets, stickers, badges, etc.

Logotype: The campaign has a common emblem, displayed on posters, flags, pamphlets, etc.

Awards: Deserving companies and individuals are recognized through awards, which are presented with great publicity.

Quality month: The promotional activities may be concentrated in a particular month.

National Quality Awards.   Promoting quality among enterprises by means of a national quality award program has in recent years become an important factor to improve the competitiveness of

the industrial sector in many industrialized countries. Experience shows that these programs stimulate improvements of quality and productivity to an extent that goes beyond the effects of ISO 9000. The awards criteria have become a yardstick for enterprises that allows them to assess their own situation and to guide their improvement efforts.

National quality awards have also been launched in some developing countries, e.g., Argentina, Brazil, Colombia, India, Republic of Korea, Malaysia, and Philippines (Stephens 1995). In most cases, either the Malcolm Baldrige National Quality Award or the European Quality Award has served as a model in the development of the setup and the awards criteria.

In some developing countries, the responsibility for the national quality award is assumed by a governmental organization, in others by a foundation financially supported by the private sector. The latter is the case in Argentina and Brazil. The National Quality Award in Argentina was established by a legislation passed by the Argentinean parliament. The administration of the award is delegated to a private foundation (FUNDAPRE, the National Quality Award Foundation), funded by member companies and by the government (Bertin 1996).

In India, the Rajiv Gandhi National Quality Award, named for the late prime minister of India, was launched in 1991. The award is promoted by the Indian Government and administered by the Bureau of Indian Standards. The presentations are made by the prime minister. A list of the award criteria and the point allocations is shown in Table 37.1.

There are four awards, consisting of one for large-scale manufacturing units, one for small-scale manufacturing units, one for service sector organizations, and one for best overall. In addition, there are six commendation certificates each for large-scale and small-scale manufacturing units: metallurgical, electrical and electronic, chemical, food and drug, textile, and engineering industry and others. The objectives of the award are stated as follows:

- Encouraging Indian companies to make significant improvements in quality for maximizing consumer satisfaction and for successfully facing competition in the global market as well.

- Recognizing the achievements of those companies which have improved the quality of their products and services and thereby set an example for others.

- Establishing guidelines and criteria that can be used by industry in evaluating their own quality improvement efforts.

- Providing specific guidance to other organizations which wish to learn how to achieve excellence in quality, by making available detailed information on the "Quality Management Approach" adopted by award winning organizations to change their cultures and achieve eminence.

TABLE 37.1 Criteria of the Rajiv Gandhi National Quality Award in India

Criteria	Marks
Leadership	100
Policies and strategies	100
Human resource management	50
Resources	100
Processes	150
Customer satisfaction	200
Employees satisfaction	50
Impact on society	100
Business results	150
Total	1000

EDUCATION AND TRAINING

A key to quality upgrading is education and training, which involves developing necessary knowledge and skills, as well as influencing attitudes. In developing countries, it is necessary to direct activities of this kind not only toward manufacturers and service providers but also toward consumers; consequently, the activities are very far-reaching. The difficulties are aggravated by the normally high illiteracy rate in these countries.

National Level.   Education and training in the quality field can be dealt with in different ways within a developing country:

Educational Institutions.   Quality management topics are to an increasing extent included in the curricula of engineering universities and institutes, particularly in the more industrialized developing countries. The courses offered deal mainly with the more trendy tools, such as statistical process control, quality function deployment, benchmarking, and ISO 9000. Topics related to top management are rare. The courses are taught by professors who have limited experience in industrial work and management. There is a limited supply of locally developed textbooks.

Under a project of the European Union and with the involvement of three European universities, an undergraduate course on total quality management has been developed at the Indian Institute of Technology in New Delhi (van der Wiele 1996). The course has a modular basis with a content according to Figure 37.8. Each module includes case studies from Indian industry. The course was designed to meet the following objectives:

- Present an overall view of quality fundamentals for engineering graduates of all disciplines
- To present the international developments in the field of total quality management

---

Module I. Fundamentals   (6 lectures)

General introduction (definitions, evolution etc.). Contributions from quality gurus. Major conclusions and a general framework for understanding TQM. Examples of companies. Tools and techniques. Costs of quality.

Module II. Human Resource Management   (8 lectures)

General framework. Attitude, value system, and behavioral pattern. Motivation models. Team concept. Human resouce development. Quality circle. Quality education and training. Employee empowerment.

Module III. Tools and Techniques   (12 lectures)

Significance. Seven QC tools. Pareto analysis. Process control chart. Seven management tools. Just-in-time. Quality function deployment. Statistical process control. Process capability. Tolerances and interference. Quality and maintenance.

Module IV. Systems and Procedures   (8 lectures)

Quality system structure. Quality-related standards. Certification, testing, registration, and accreditation. Quality manual. Quality information systems. Quality audit. ISO 9000.

Module V. Implementation   (7 lectures)

Quality strategy as a competitive tool. Customer-supplier chain. Quality policy deployment. System strategies and tactics. Leadership. Motivational elements. Breakthrough improvement. Continuous quality improvement. Quality awards and self-assessment. Benchmarking. Employee empowerment. Implementation barriers. Impact on society.

FIGURE 37.8   Content of undergraduate course on total quality management given at the Indian Institute of Technology. (*Courtesy of Indian Institute of Technology, New Delhi, India.*)

- To create an awareness of the major factors in evolution on the quality front
- To expose the students to the important tools and techniques of quality management
- To emphasize the role of standards in maintaining and improving quality
- To appreciate the role played by human factors like motivation, leadership, and teamwork in sustaining quality
- To imbibe the principles of quality and apply them to achieve personal improvement

Courses and Seminars Offered by Associations, Institutes, and Other Organizations. In countries that have reached a higher level of industrialization, courses and seminars are offered by national institutions for standardization, productivity, etc. and by professional associations (e.g., manufacturers' associations, national quality societies), as well as by consultants. Some countries are active in inviting foreign lecturers. As a consequence of the great interest in ISO 9000 certification, the majority of courses offered are in this field (e.g., implementation of ISO 9000, preparation for ISO 9000 certification, quality system auditing). International consulting and registration firms (mainly European-based) offer lead assessor training that can lead to registration by the International Register of Certified Assessors (IRCA).

Meetings and Conferences. An important activity of a national quality organization is to hold meetings and conferences at which practitioners can exchange ideas and experiences. Countries with a more developed industrial sector generally have a quality association that is active in this way. Such organizations are the Chilean Association for Quality (ASCAL), the China Quality Control Association, and the Philippine Society for Quality Control.

Self-Instruction. Independent study of books and journals can provide considerable knowledge in the quality management field, particularly for managers and engineers. In many developing countries there is, however, a shortage of such literature, owing to the lack of foreign exchange, a national language with limited readership, etc. Some national quality organizations publish a journal or newsletter as a means of promoting the professional development of their members.

In-House Training Programs. Successful enterprises in industrialized countries have adopted a strategy that includes a massive in-house training program with the objectives of changing everyone's attitudes and giving new skills and knowledge. In these enterprises training in quality is provided for everyone regardless of function and level. Such training starts with top management and then works its way down the organization, level by level. This kind of massive training is rare in developing countries. In some larger enterprises, training in various narrow concepts and tools is provided.

On-the-Job Training. On-the-job training is the principal method of training workers and inspectors, even in developing countries. Instructions are given by the supervisor or a more experienced inspector. The result depends on both the technical ability and the ability of the instructor to instruct and motivate the participants. In general, these abilities vary more in countries that have a limited industrial tradition.

International Level. Developing countries also have opportunities for training on the international level by sending trainees to more industrialized countries. International organizations such as the United Nations Industrial Development Organization (UNIDO), the International Organization for Standardization (ISO), and the Asian Productivity Organization (APO) organize quality training programs for developing countries. (For information on these programs consult the International Trade Centre and the International Organization for Standardization at the addresses given under References.)

The United Nations Development Organization, in cooperation with the Government of Japan (Ministry of International Trade and Industry, MITI) and the Japanese Association for

Overseas Technical Scholarships (AOTS), organizes a 5-week training program on Quality Improvement of Industrial Products every 2 years. The structure of the program is given in Figure 37.9. The program, intended for quality managers and production managers, focuses on problem-solving.

Since 1973, the government of Sweden has been sponsoring training programs in the field of quality for developing countries. A 7-week course entitled "Total Quality Management" is held in Sweden twice annually, and a 3-week top management seminar entitled "Quality Leadership" is held once annually. The training programs include lectures, case studies and study visits. The content of the theoretical training sessions of the "Total Quality Management" course is listed in Figure 37.10. The training programs in Sweden have been attended by quality professionals and managers from some 80 countries in Africa, Asia, Europe, Latin America, and the Caribbean. (Address information for the Swedish International Development Agency is given under References.)

EXTERNAL ASSISTANCE

External assistance plays a significant part in the industrial and economic growth of developing countries by making it possible to shorten the process of development. There are various forms of assistance.

Assistance from International Organizations.   There are international organizations providing assistance to developing countries in the field of quality. Some of them work worldwide (mainly within the United Nations system), others work on a regional basis. Significant organizations of this kind are:

European Union (EU).   EU offers financial support to development projects in developing countries. Address:

Rue de la Loi 200	Telephone: +32 2 2991111
B-1049 Brussels	Telefax: +32 2 2950138
Belgium	Internet: http://europa.eu.Int

Food and Agriculture Organization of the United Nations (FAO).   FAO has a mandate to raise levels of nutrition and standards of living, to improve agricultural productivity and the conditions for rural populations. The organization is involved in land and water development, plant and animal production, forestry, fisheries, economic and social policy, investment, nutrition, food standards and commodities and trade. Address:

Viele delle Terme di Caracalla	Telephone: +39 6 52251
00100 Rome	Telefax: +39 6 52253152
Italy	E-mail: webmaster@fao.org

International Organization for Standardization (ISO).   ISO is a worldwide federation of national standards bodies in more than 100 countries, with the objective to promote standardization and related activities worldwide. Within ISO there is a committee on developing country matters (DEVCO) with the aim of assisting developing countries and being a forum for the discussion of all aspects of standardization in this group of countries. In the program for developing countries (ISO 1995), ISO/DEVCO has identified six elements: identification and accommodation of standardization needs in developing countries, preparation and publication of development manuals, training, participation in ISO standards committee meetings, development of international standards needed by developing

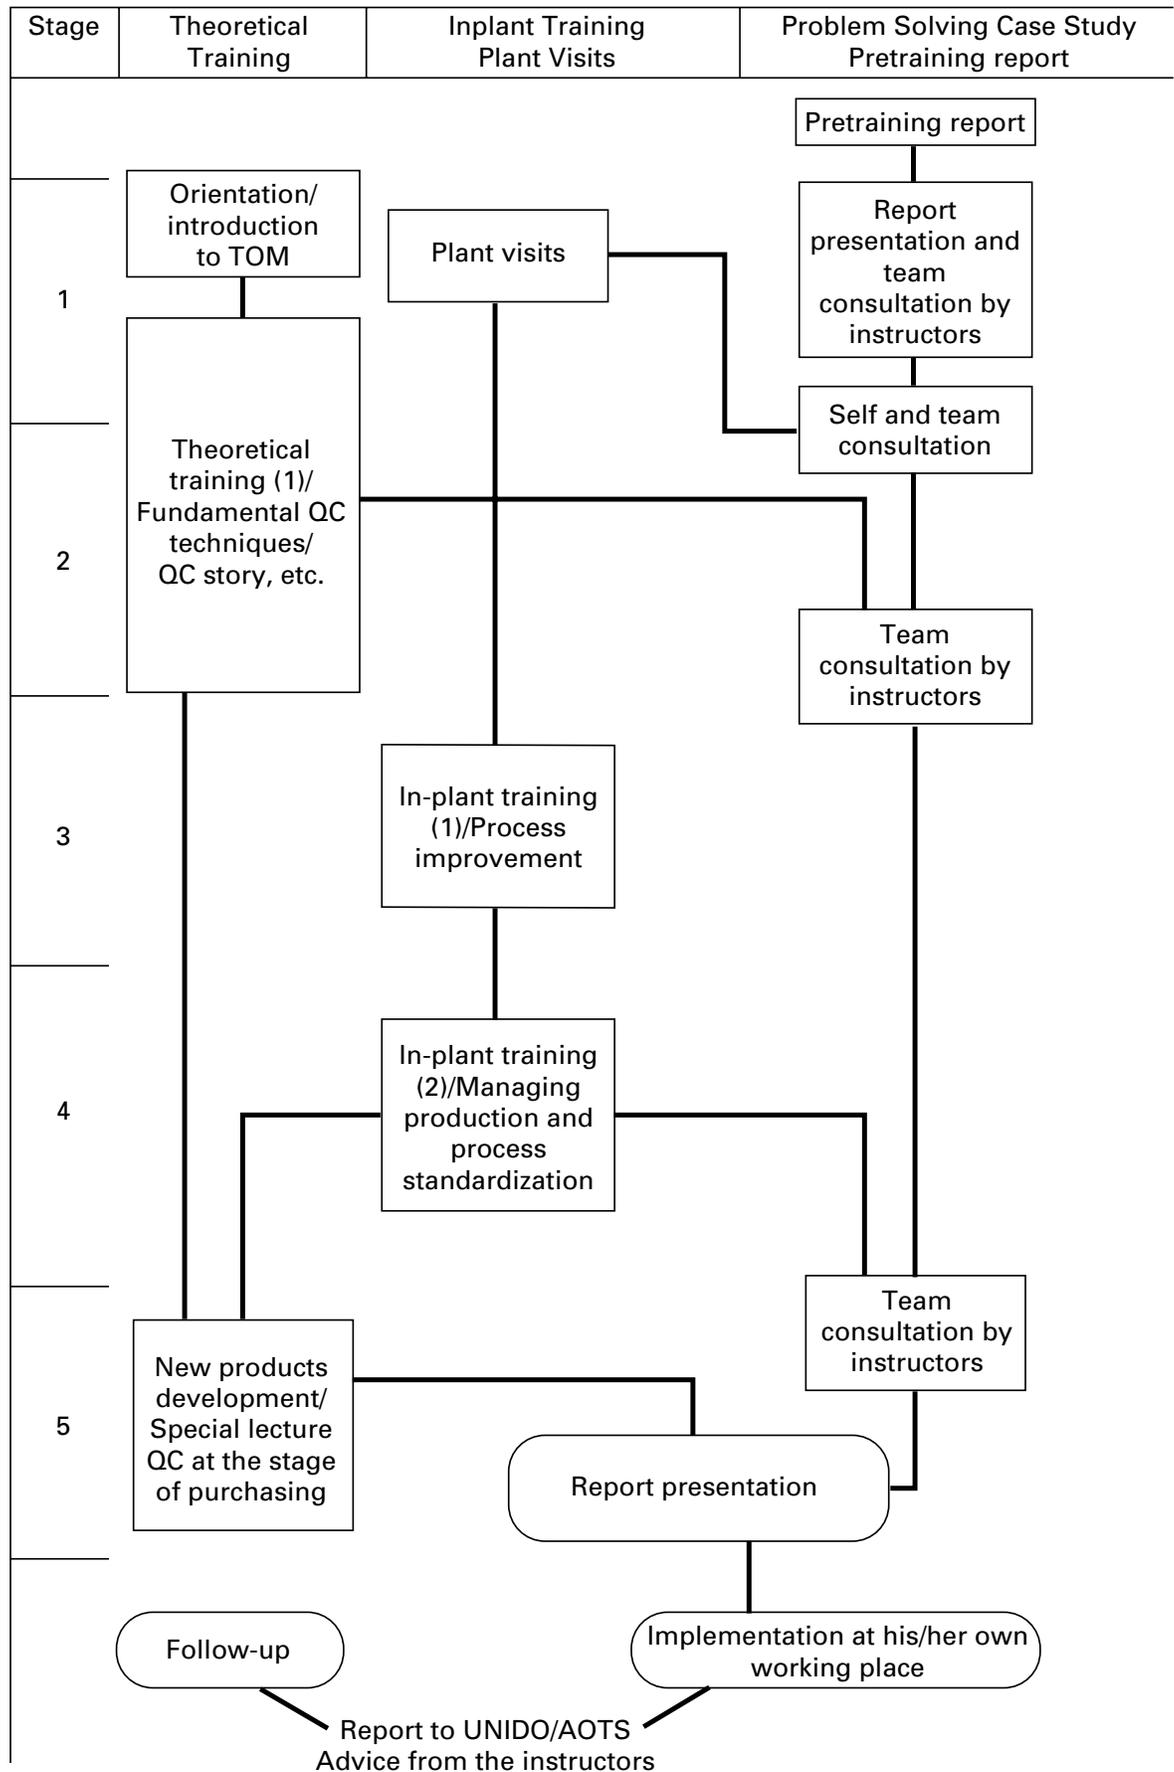
Stage	Theoretical Training	Inplant Training Plant Visits	Problem Solving Case Study Pretraining report


FIGURE 37.9   Structure of training program on Quality Improvement of Industrial Products held in Japan. (Courtesy UNIDO, MITI, and AOTS.)

Introduction: Quality; the quality function; quality management; role of upper management; quality planning; the concept of total quality; developments in the quality profession; profitability and quality; quality strategies; terminology

Statistical tools: Basic concepts, the statistical tool kit; methods of summarizing data; probability distributions; process capability; tools for process studies; control charts; acceptance sampling; point and internal estimates; tests of hypotheses; transformations of data; regression and correlation analysis; design of experiments

Metrology: Measurement technology; error of measurement; calibration control

Inspection: The nature of inspection; statistical tools in inspection; automated inspection; inspection accuracy; inspection workplace; inspection feedback; inspection by operator; inspection planning; planning of incoming inspection; planning of process inspection; planning of final inspection

Reliability and dependability: Dependability concepts; reliability requirements; failures and failure mechanisms; reliability prediction; fault tree analysis (FTA) and safety analysis; failure mode and effects analysis (FMEA); reliability determination by testing; reliability growth and screening; reliability verification; maintainability requirements, prediction and testing; availability requirements and testing; maintenance support conditions; environmental testing in general

New-product quality: Product phases and development programs; forms of early warnings, design reviews; the concept and definition phase; the preliminary design and development phase, the final design phase; the pilot production phase; series production, marketing and installation; use and maintenance phase; project management for new product quality; new-product planning

Quality specifications: Purpose and content; setting requirements; revisions; standards

Supplier relations: Supplier relations; purchase documents; supplier selection; joint quality planning; activities in the supplier's plant; incoming inspection; supplier surveillance; supplier certification; complaints; supplier quality improvement; single-source suppliers

Manufacture of quality: Manufacturing planning; nature of process; providing capable process; providing capable instruments; process control; self-inspection; inspection feedback to production; process improvement; traceability; quality responsibilities on the factory floor; automated manufacturing

Customer relations: Customer; field intelligence; complaints; marketing; product safety and liability; consumerism; government regulation of quality

Quality assessment: Why assessment?; standing in the marketplace; customer-focused quality analysis; quality culture; assessment of quality activities; using quality awards criteria; quality auditing; costs of poor quality; quality data, benchmarking

Quality audit: Quality audit concept; product quality audit; process quality audit; systems quality audit; total quality audit (quality surveys)

Economics of quality: Quality and economics; quality and income; quality costs; user's costs; life cycle costing

Quality data: Basic concepts; in-plant quality data; usage data; quality cost data; reports on quality

Improving quality: Control versus breakthrough; need for quality improvement; quality improvement sequence; obtaining information; project identification; diagnosis; remedies; follow-up and feedback; organizing for improvement; resistance to change; training in quality improvement; seven tools

Human factors in quality control: Controllability; theories of motivation; human resource management practices; role of management; role of work force; role of teams; quality motivation for managers; training; inspection accuracy

Quality leadership: Recognized champions versus potential champions; strategic quality management; quality strategies; role of upper management; quality policy; quality objectives (goals); implementing total quality

Quality system: Quality systems terminology; the systems concept; systems requirements and standards (ISO 9000); the quality manual; importance of ISO 9000

Organization for quality: Basic concept; quality work elements; evolution of the quality organization; organization for acceptance; organization for prevention; organization for improvement; organization for coordination; organization for assurance; role of the quality department

Quality consulting: Efficiency of the quality function; studies of the efficiency of the quality function; evaluation; report; who carries out the evaluation?

Developing countries and quality: Situation in developing countries; industrial development and quality; national efforts for quality; standardization; certification; export inspection; legislation; national promotion; education and training; external assistance; institutional infrastructure; national quality society

FIGURE 37.10 Content of theoretical training sessions of the total quality management course given in Sweden.

countries, documentation and information systems. ISO also organizes regional courses and seminars related to the ISO 9000 standards. Address:

P.O. Box 56	Telephone: +41 22 749 01 11
CH-1211 Geneva 20	Telefax: +41 22 733 34 30
Switzerland	E-mail: central@isocs.iso.ch

International Trade Centre UNCTAD/WTO (ITC).   ITC works with developing countries and economies in transition to set up effective trade promotion programs for expanding their exports and improving their import operations. This includes assistance in the quality management field in order to improve product quality and competitiveness in international markets. Services given are advisory missions, consultancy, development programs, research, publications, etc. ITC operates computer databases, including "Qualidata," which covers information on export quality management, and "Qualicontacts," containing worldwide data on quality-related institutions. Address:

Palais des Nations	Telephone: +41 22 730 01 11
CH-1211 Geneva 10	Telefax: +41 22 733 44 39
Switzerland	E-mail: itcreg@intracen.org
	Internet: http://www.unicc.org/itc/

United Nations Development Programme (UNDP).   UNDP normally plays the chief coordinating role for operational development activities undertaken by the whole United Nations system. The UNDP activities focus on six priority themes: poverty elimination and grass roots development; environment and natural resources; management development; technical cooperation among developing countries; transfer and adaptation of technology; and women in development. Address:

One United Nations Plaza	Telephone: +1 212 9065000
New York, NY 10017	Telefax: +1 212 9065001
USA	

United Nations Industrial Development Organization (UNIDO).   UNIDO is the specialized agency of the United Nations aimed at supporting and promoting industrial development in developing countries in order to overcome these countries social and economic difficulties and to achieve a greater stake in the global market. UNIDO's quality, standardization, and metrology program provides multidisciplinary services in areas such as total quality management, just-in-time manufacture, statistical quality control, and business strategies. Address:

Vienna International Centre	Telephone: +43 1 211310
P.O. Box 300	Telefax: +43 1 235156
A-1400 Vienna	E-mail: omaizza-neto@unido.org
Austria	Internet: http://www.unido.org

World Bank.   The World Bank Group comprises five organizations. Two of them, the International Bank for Reconstruction and Development (IBRD) and the International Development Association (IDA), provide loans to developing countries for development projects. Address:

1818 H Street, NW	Telephone: +1 202 4771234
Washington, DC 20433	Telefax: +1 202 4776391
USA	Internet: http://www.worldbank.org

World Health Organization (WHO).   WHO is the United Nations directing and coordinating authority on international health work. The organization has a wide range of functions including pro-

motion of technical cooperation; improving nutrition and environmental hygiene; improving standards of teaching and training in the health, medical, and selected professions; establishing standards for biological and pharmaceutical products. Address:

20, Avenue Appia   Telephone: +41 22 7912111
CH-1211 Geneva 27   Telefax: +41 22 7910746
Switzerland   E-mail: postmaster@who.ch

Bilateral Assistance.   A great deal of the external assistance to developing countries is through bilateral aid from industrialized countries. In this way, quality experts have assisted in various developing and training programs.

An example of this kind of assistance is a 3-year program founded by the U.S. Agency for International Development (USAID) to help enterprises in Egypt with ISO 9000 implementation and certification. A similar program for the countries in Southern Africa is funded by the Norwegian government. The Swedish government funds training programs in quality management organized in developing countries. The Japanese MITI (Ministry of International Trade and Industry) is active in assisting developing countries in Southeast Asia in total quality management development.

Assistance from Transnational Companies.   External assistance may also take the form of collaboration with foreign manufacturers to obtain benefits such as technical know-how in joint ventures, import of plants and equipment, or consultant service. This kind of assistance is vital to developing countries.

INSTITUTIONAL INFRASTRUCTURE

Industrial enterprises require access to an infrastructure of institutions able to render a wide range of services for instance, in the areas of standardization, certification, accreditation, testing, metrology, quality consulting, and training. Developing countries that are in the process of industrializing must also provide for development of such an institutional infrastructure.

National Standards Body.   In most developing countries, a national standards body is in operation primarily to provide services in standardization, certification, testing, and metrology. Unlike standards bodies in the West, national standards bodies in developing countries are usually governmental agencies established by law and founded by their respective governments. Because of the importance of standardization to both the public and private sector, some developing countries restructure their national standards bodies as joint public/private sector bodies. In the early stages of industrial development some form of government support is needed. A balanced representation of all groups interested in standardization should be considered: industry, trade, consumers, professional associations, the government.

If an integrated approach is used, the list of tasks of national standards bodies includes (International Organization for Standardization 1994a, p. 11):

- The preparation and promulgation of national standards

- The promotion of the adoption and application of national standards at all levels in the country

- The promotion of standardization as a technical activity and an integral yet distinct function of management in the country

- The promotion and, if necessary, provision of third-party guarantee of the conformity of products through a national product certification program

- The promotion of quality in industry and services and, eventually, the provision of third-party

certification of quality management systems implemented by industrial firms and service operators

- The provision of means for collecting and disseminating information on standards and related technical matters both nationally and internationally
- Supporting export promotion programs by providing information on the standards and regulations of export markets, promoting quality by testing products, and certifying their conformity to export specifications
- Protecting the consumer, particularly for safety and against health hazards
- Supporting through standards the efforts undertaken to safeguard the environment from hazards related to products and processes
- Safeguarding the country against the dumping of inferior quality goods as well as unsafe and ecologically hazardous goods
- The promotion of metrology as a necessary adjunct to standardization
- The coordination, for the benefit of the country, of standardization and related activities carried out at various levels: company, national, regional, and international
- The promotion and, if necessary, operation of an accreditation system for testing and calibration laboratories, to promote the precision of their results and enhance confidence in their work
- Undertaking tests for industry
- Offering technological advice to both government and industry
- Organizing training in standardization and related matters
- Conducting investigations to quantify the benefits of standardization with subsequent dissemination of information

The national standards bodies have not traditionally provided any services to industry in the fields of quality consulting and training. In consequence of the great interest for ISO 9000 certification and registration, an increasing number of national standards bodies in developing countries have started offering training in areas related to ISO 9000, such as quality systems implementation and auditing.

The mission of a national standards body is given in Figure 37.11.

In most countries the standards bodies are governed by a council which is responsible for working out policy guidelines, as well as for approving standards. The drafting of standards is supervised by technical committees representing manufacturers, users, university-affiliated institutions, research centers, etc. Usually, there are technical committees in particular fields, such as electrical, mechanical, and civil engineering, chemicals, and textiles.

The staff of a national standards body is headed by a chief executive officer or director, who is usually in charge of departments for standardization, certification (sometimes called quality control or quality assurance), metrology, laboratory services, information, and administration. The organizational structure of a fairly well-developed national standards body is given in Figure 37.12.

National Quality Council. With the increasing awareness of the fact that quality is an important element behind the economic growth of a country, the emerging necessity of having a national institutional infrastructure for the following activities is growing more and more apparent (Lal 1996b, p. 167):

Creating awareness about quality and its economic benefits including administering the national quality award

Promoting new concepts in quality management

Training in quality-related subjects

BPS MISSION STATEMENT

We at BPS, in partnership with other organizations, are committed to contribute through standardization to national economic and social development by helping industries raise the quality and competitiveness of their products and by fostering consumer and environmental protection, and to serve our clients with the quality of service that is attainable with our resources.

RENATO V. NAVARRETE

Director

22 March 1993

Accreditation of certification bodies

Registration of certified auditors for quality systems

These activities should not be assigned to governmental agencies only, although governments have to take a major initiative in these areas. They should be autonomous, free from bureaucratic control, and set up in close cooperation with the private sector.

The Quality Council of India is an example of such a council. It is an autonomous body composed of about 10 members from governmental departments and about 20 members from industrial and trade organizations, academic institutions, consumer associations, certification bodies, quality award-winning companies, etc. The chairman is nominated by the prime minister. The structure is shown in Figure 37.13.

PROFESSIONAL SOCIETIES

A national quality society can play an important role in promoting quality nationwide, both in developing and in industrially more developed countries. Quality societies or associations are being formed in an increasing number of countries. Some of the national societies offer individual membership only and some offer institutional membership only, but most offer both.

Some societies are very active, for example, the Argentine Institute of Quality Control (IACC), the Brazilian Association of Quality Control (ABCQ), the Chilean Association for Quality (ASCAL), the China Quality Control Association, the Institute of Quality Control Malaysia, and the Philippine Society for Quality Control (PSQC). These societies organize conferences and seminars, conduct training programs, and distribute information (newsletters, journals, etc.).

A case in point is the Philippine Society for Quality Control, founded in 1969. At the end of 1996 it had 300 institutional members and 100 individual members. The mission of PSQC is phrased as follows: "We are an internationally recognized organization highly committed to promote quality as a culture and a way of life in our industries, government, academe, non-government organizations and communities. We lead and influence the transformation of the Philippines into a world class country by being proactive in the practice of total quality management." The values are phrased: "The organization is continuously striving for excellence. This is to be achieved through: respect and concern for people, continuous improvement, customer orientation and teamwork."

PSQC's objectives are

- To promote quality awareness and practices in both the private and public sectors through seminars, conferences, publications, and awareness campaigns
- To promote the development of members in quality leadership and technology
- To link with international organizations for updates in recent trends and the latest technologies

PSQC's programs and activities are

- To organize luncheon dialogues and symposia, seminars, and training programs
- To organize a National Quality Forum during the National Quality Month in October
- To disseminate quality information and updates about PSQC through quarterly issues of the society's newsletter, "Q…Point"

- To establish links with government agencies in promoting quality practices
- To coordinate "ugnayan" (the Filipino word for "linking") with host member companies for plant tours and sharing of their quality programs and success stories
- To form Youth Quality Chapters in universities to increase youth involvement and participation in making quality a way of life
- To administer the selection of the Philippine Quality Award winner every year

The term of office is 2 years, but an election is held every year for nine and six members alternately, to allow for smooth transitions and prevent a complete change in the composition of the board. The trustees elect officers from among themselves every year. They subsequently form working committees from the rest of the membership to help carry out the programs for the year. The immediate past-president is the 16th member of the board as an advisor.

PSQC is a member of the regional organization Asia-Pacific Quality Control Organization (APQCO). Another regional organization of national quality societies is the Latin American Organization for Quality (OLAC). These regional organizations regularly organize regional conferences.

CONCLUSION

The so-called developing countries are in various phases of economic and industrial development—some have just started with manufacture, whereas others are almost fully industrialized. No matter which phase a country is in, the quality of the goods and services provided is important to its economic growth. Quality management in a broad sense will ensure that goods and services are fit for domestic use, reduce the waste of scarce resources, and facilitate the export of national products.

It is of great importance that developing countries use appropriate methods in quality efforts. Simple basic techniques will in most cases give a better result than currently fashionable methods (to which too much attention is often paid). Before methods are selected, the actual needs have to be determined. This seemingly obvious point, however, is often overlooked. The focus should be shifted from a method-oriented to a more result-oriented approach, with increased emphasis placed on studies of established facts. Such an approach will provide a better basis for successful development.

There is an obvious need for extensive studies on how to deal with quality in developing countries on both a national and a company level and on the relations between the two levels. Models and plans for different levels of industrial development, different industrial structures, different branches of industry, etc. should be worked out. This is an important international undertaking.

ACKNOWLEDGMENT

SECTION 38
QUALITY IN WESTERN EUROPE

Tito Conti

INTRODUCTION

Europe is composed of many different nations, cultures and languages. From whatever point of view you consider it, its differences are easier to pinpoint than its similarities. The current move toward economic and political integration—a long and difficult process—should eliminate the remaining pockets of economic and social backwardness and boost the continent's political and economic strength, while maintaining legitimate differences and the specific cultural identity of each nation. Quality, which is a cultural issue first and a technical issue second, is no exception as far as diversity is concerned. There is no such thing as European quality. Significant differences exist among and even within the various countries. The quality profiles of the nations vary enormously, too. Germany, for example, has a solid reputation for product quality; many Northern European countries provide excellent service quality. Other countries offer outstanding quality in specific sectors: France and Italy are typical examples. France is famous for its *haute couture* and its food and wines, while Italy has a reputation for design, fashion, and goldwork. But despite these great differences, over the last 10 years, Europe has made up a great deal of ground in relation to the United States of America and Japan. In the second half of the 1980s, large corporations still employed the services of non-European specialists to plan their Total Quality Management (TQM) strategies. Today, halfway through the 1990s, both the corporate sector and the leading quality consultants—a small minority, but this is the situation everywhere—stand up well to comparison with the United States and even with Japan.

In discussing quality in Western Europe, this section provides a brief overview of the main development trends and then looks at a specific and highly important issue: the impact of the Single Market on the quality culture (the Single Market is the term normally used in Europe to refer to the market formed by the 12 original members of the European Community, which has gradually extended to the Free Exchange Zone and continues to expand as new member states join what is now called the European Union). At the level of the individual nations, only Germany, France, and Great Britain are analyzed separately, since they represent three typical examples of the evolution of quality in Europe after the Second World War and thus cover the main trends in the other nations. The country-by-country analysis ends with a brief summary of distinctive developments in other West European countries. This section then looks at the European quality organizations, which have played an important part in recent quality developments, and discusses Europe's quality awards. The final portion of this section discusses environmental quality.

QUALITY DEVELOPMENT TRENDS IN EUROPE AFTER THE SECOND WORLD WAR

In Western Europe as in other areas of the western world, from the 1950s to the 1970s, quality was considered a priority issue mainly in defense, aerospace, telecommunications, electronuclear energy and energy in general, chemicals, and other high-technology sectors. An indication of the level of interest in quality disciplines (specifically, in statistical quality control) was the formation of national quality associations in many European countries during the early 1950s. In the area of consumer durables and consumer goods in general, which were enjoying a period of high demand, a capacity for innovation and the ability to produce large volumes at low costs were the main priorities. Healthy market performance meant staying more or less in line with the typical (and often mediocre) quality standards of the relevant price/performance class, which, given the lack of specific competitive stimuli, tended to remain stable. Certain niches, brands, or even entire geographical areas stood out for the high quality and reliability of their products, but as a rule, higher quality positioned a product in a higher price class compared with products offering similar performance. Countries like Germany, for instance, had a reputation for superior product quality, especially in niche markets (e.g., luxury automobiles, electric home appliances), but since this quality stemmed from high professional skills and craftsmanship, product prices were usually higher. (See Quality in Germany below.)

For the strategic sectors in the first group, quality, reliability, and safety were essential. Price was a secondary variable. Many suppliers financed R&D work for their commercial productions with the margins on their military sales. On the other hand, these sectors occupied a position of strategic importance for Europe during the period concerned: the defence sector in relation to the cold war, the others in relation to postwar reconstruction and creation of the infrastructures needed for new growth. Taken together, these considerations explain the development of a quality culture and quality practices predominantly based on the specific characteristics of this group of sectors.

The first characteristic is the contractual relationship between the supplier and the customer. The supplier provides goods for a specific customer, who stipulates requirements in a contract, in as precise and as clear a form as possible. The supplier undertakes to provide what the contract requests, and therefore regards quality as conformity with predefined specifications and standards. This produced a quality culture based on the concept of standards conformity and fulfillment of specifications. The focus was on execution (engineering and production) rather than on goals, which had already been set. This was a "reactive" approach to quality: the customer orders; the supplier provides what has been ordered—and (if possible) nothing more, since any extra is not paid for.

The second characteristic of this first group of sectors is that quality and reliability requirements are generally very high. Preventing failures is essential. The focus on ensuring reliability meant that engineering techniques improved. Progress was slower in production, where the quality and early-life reliability levels requested were often achieved not through process improvements but through final-product testing and screening (prolonged testing, run-ins, burn-ins), which raised costs significantly.

As product quality requirements rose, producers acquired greater skills in technical quality disciplines geared to technology and the product. Among customers, the 1960s witnessed a continuous increase in the number of inspectors appointed to approve products and plants. (See Quality in Great Britain, which discusses the role of the British Ministry of Defence).

Quality took a major step forward with the move from inspection to preventive assessment of suppliers' quality systems. Once again, the development originated in the defense field, following the introduction of NATO's APAQ standards (1968). In similar fashion, the U.K. BS 5750 standard (1979) was drawn up on the recommendation of the Ministry of Defence, to replace the endless series of second-party audits with third-party certification (Hutchins 1995).

At the beginning of the 1980s, therefore, the quality culture and quality practices in Europe were closely associated with the concept of conformity with standards or previously defined specifications. Table 38.1 summarizes the situation of quality standards during 1980.

In the second half of the 1970s, however, word had begun to spread about the success achieved by Japan with a "proactive" approach that perceived quality as a competitive factor. Doctor Juran's article "Japanese and Western Quality: a Contrast" (Juran 1979) was a revelation in many quarters. Large companies operating in highly competitive international markets were a particularly receptive audience. In the early 1980s, these companies began to experiment with total quality, often with little success in the first instance. For a number of years, the standards-based quality culture and the new concept of continuous improvement, customer focus, and process control evolved separately: two converging tributaries, the temperature, speed, and composition of whose waters are so different that they flow side by side without mixing. At this point, the EC Council began examining the question of the technical barriers inside the Single Market.

THE CREATION OF THE EUROPEAN SINGLE MARKET AND ITS IMPACT ON THE EVOLUTION OF THE QUALITY CULTURE

The European Community (EC) Council Resolution Of May 1985. On May 7, 1985, the EC Council adopted a resolution regarding technical harmonization and standardization which was designed to bring about the rapid elimination (by the end of 1992) of the technical barriers that, together with physical and fiscal barriers, were obstructing the creation of the Single Market. The EC strategy, known as the *nouvelle approche,* was based on the following principles:

1. Limitation of compulsory technical regulations to the essential issues of security and protection of health and the environment.

2. Harmonization of member states' voluntary technical standards, through discussions among the national and European standardization bodies. Implementation of specific measures by the Council to provide guidance for these bodies and strengthen their role.

3. Rapid definition of a testing and certification strategy to permit mutual recognition of certifications.

4. Acceptance of a manufacturer's declared standards conformity once that manufacturer's quality system is certified as compliant with European quality assurance standards.

TABLE 38.1 Quality Standards

	Market sectors	
Type of standard	Strategic (defense, etc.)	Commercial
Product	Defined by customer	Defined by a market which was sometimes indifferent to quality
Quality system and processes	Developed through cooperation within the sector; widely available and widely applied	Not generally available or applied

At this point, however, work on the ISO 9000 standards (published in 1987) had reached an advanced stage.

With the approach of January 1, 1993, and the official launch of the Single Market, the European political system made the pleasant discovery that a regulatory tool intended for worldwide application was about to be introduced, paving the way to elimination of technical barriers in Europe (McMillan 1994). The European Standardization Committee (CEN) immediately incorporated the ISO 9000 standard into the European standards with the name EN 29000 (now EN 9000) and initiated an emergency procedure to complete work on the remaining standards (EN 45000). For national governments, which apart from a few notable exceptions had until then lent a very half-hearted ear to the messages on total quality coming from various sectors of private industry, the ISO 9000 standards presented quality in a formulation that was much closer to their way of thinking. The simplicity of certification and mutual recognition had enormous appeal, especially for those with no previous experience of quality, who tended to overestimate the potential of the certification approach, hailing it as a sort of magic wand for the development of quality in Europe.

In this period, the European Foundation for Quality Management (see below) was set up, for the specific purpose of focusing the attention of senior executives from business and state administrations on the question of total quality. Despite the EFQM's high-level sponsors (the chairmen of 14 leading European companies), the interest it attracted in political circles and the media was small in comparison with the interest fueled by certification. The EC allocated abundant funds to the national standardization bodies, to be used, rightly, for the rapid harmonization of standards across Europe. Less justifiably perhaps, these funds helped to spread a standards-based quality culture, which was clearly out of step with the times.

Ratified by the 1987 Single Market Act, the 1985 Resolution of the EC Council would have unforeseen effects on the evolution of quality both in and outside Europe.

Fears of "Fortress Europe."   In 1987, the Malcolm Baldrige Award was launched. For the next few years, the TQM model used by the award was the center of U.S. attention, and many companies adopted it as a self-assessment guideline, even though they were not competing for the award itself. The introduction of the ISO 9000 standards therefore went almost unnoticed in the United States. Nevertheless, the Malcolm Baldrige model provided for product and service quality—the key issue of the ISO 9000 standards—in category 5. It was not until 1990 that the excitement in Europe about the ISO 9000 standards began to arouse the interest of the United States. At this time, Europe's sights were firmly set on the 1993 deadline, fueling suspicions in non-European political and economic circles that construction of a "Fortress Europe" was the ultimate goal. The ISO 9000 standards and the growing demand for preventive certification of the conformity of suppliers' quality systems with those standards resembled nothing if not a bulwark of that fortress.

In May 1990, the ASQC invited European quality specialists to attend its congress, as did the Juran Institute and a number of other bodies, in an attempt to find out what lay behind the European craze for ISO 9000. This was followed by a general rush to the ISO 9000 camp in North America, too, a trend that could be justified from a commercial point of view. It is less easy to explain when one considers the content of the standards. After a decade of total quality and continuous improvement, it is strange, to say the least, that quality assurance—an essential issue, but only one aspect, indeed a preliminary condition, of the wider theme of total quality—should have attracted such enormous attention.

The reaction in Japan was less extreme. The ISO 9000 standards were analyzed in detail (Kume 1990) and compared with current practice. Without doubt, Japan grasped the commercial significance of certification, as well as the value of adopting the criterion of ISO 9000 conformity in contractual relations, especially in geographical areas where partnership between customer and supplier is difficult to achieve. Its verdict on the ISO 9000 standards as such was favorable, with the proviso that the concept of continuous improvement should be integrated into the standards approach.

Midterm Effects of the Emphasis on ISO 9000 and Certification.   The political focus on the ISO 9000 standards and certification has had positive and negative repercussions for

quality in Europe. The effects on the process of market unification, which was the main goal, are positive. As far as the effects on the development of quality itself is concerned, it is too soon to draw conclusions, but a brief analysis is possible.

The main benefit is the rapid spread of basic quality assurance know-how. Huge numbers of small to medium enterprises, operating mainly in domestic markets or in fields that are still unexposed to international competition, have had their attention drawn to quality system certification by industrial customers, distributors, and clients in the public sector. Other operators have been involved in an indirect way, often through sectoral associations. Without doubt, had the need to remove technical barriers within the Single Market not been such an urgent priority, the number of companies reached by the quality message would have been on a far smaller scale.

The reverse of the picture is that the emphasis on ISO 9000 and certification has distracted attention away from competitive quality for too long; certification is an important requirement, but it is a precompetitive requirement. Moreover, this "distraction" appeared at a critical time, just when total quality concepts were beginning to make headway in corporate culture. A groundless antagonism frequently developed between the two approaches, which can only be explained as the result of political intervention in quality issues (in many European countries, state economic intervention was a significant factor during the period considered) and the appetizing business potential of certification.

Unfortunately, the quality organizations jumped on the bandwagon, too. Certification was the sole focus of interest of many national quality associations for years. The EOQ congresses at the end of the 1980s were dedicated almost entirely to standards-based quality [see The European Organization for Quality (EOQ) below]. No decisive change occurred until 1992, when the EOQ took active steps to redress the balance with TQM. The European Foundation for Quality Management, which was set up in 1988 to promote TQM, has played an important role in re-establishing an equilibrium, most notably with the launch in 1991 of the European Quality Award.

Table 38.2 illustrates the singular attention to certification in Europe.

TABLE 38.2 ISO 9000 Certifications Awarded in Europe

Country/region	1989	January 93*	March 95*	December 95*
Austria		101	667	1,133
Belgium		180	1,226	1,716

The 1990s: Setting a New Course.   Around 1994, European and national government bodies began to set a new course. After extensive consultations, in 1994 the Directorate General III (DGIII) of the European Commission (responsible for internal market and industry) published a working paper entitled "A European Quality Promotion Policy." This document stated that, with the completion of the regulatory phase designed to create the correct operating conditions for the Single Market, the Commission intended to launch a new phase of promotion and support to enable business enterprises in any part of Europe to pursue their goals within a balanced European competitive environment. The paper listed the following strategic objectives:

- Satisfaction of the expectations of consumers and of the community in general
- Development of human potential
- Respect for the environment
- Prudent use of resources
- Efficient and effective enterprise management
- The ability to create jobs, in particular through creativity and innovation

The strategies outlined in the paper are largely derived from TQM strategies. Three main groups of measures are identified—development of human resources, improvement of production structures, and development of a European quality image—which are intended to support TQM strategies in business and in state administrations.

The European Quality Promotion Policy document was endorsed by the European Union's Industry Council in November 1996.

In 1995, the European Union promoted the following initiatives: a European Quality Award for small to medium enterprises to flank the current Award, which is open to companies with more than 250 employees, and an annual European Quality Week (to be held the second week of November). These initiatives are organized by the two European quality organizations, the EOQ and the EFQM, under the umbrella of the European Quality Platform (see below).

COUNTRY-BY-COUNTRY ANALYSIS

Quality in France.   Many large French companies were nationalized in the immediate postwar period (Renault in 1945 for example); others were nationalized during the early 1980s. The trend has been reversed since the mid-1990s. The decline in quality generally associated with nationalization—which many European countries have experienced—has not been seen in France. Many state-controlled French companies have been leaders in quality in Europe during the 1980s and 1990s: Renault is a case in point, its leadership exemplified by the success of the Espace automobile and the Formula I engine. This is probably a result of the high quality of managers trained in France's *grandes écoles,* which provide the country's major corporations with approximately 80 percent of their management recruits (the management schools such as the Ecoles des Hautes Etudes Commerciales, and the scientific schools, e.g., the Ecoles Polytechniques) (Gogue 1988).

The key elements of the French approach to quality from the mid-1940s to the mid-1990s are as follows:

1. The central role of the State in promoting quality, as a result of its dominant presence in the economy (the above-mentioned nationalizations are the most extreme manifestation of this). State intervention appears to have been beneficial, again very probably due to the high quality of management (in this case, the quality of managers in the state administration, which is superior to that of other European countries).

2. The deliberate focus on the regions and, in particular, on small to medium enterprises (SMEs). This has stimulated dynamic territorial activity and created a flourishing bottom-up movement.

3. The particular characteristics of the French Quality Award, which was introduced in 1993: The award is for SMEs (companies with fewer than 500 employees) and is based on a two-tier bottom-up selection procedure, from regional to national level.

This is the background to the development of quality in France following the formation in 1957 of the French Quality Association (AFCIQ), a particularly significant event (Dragomir and Halais 1994).

In 1975, the Ministry of Industry set up an Office for Industrial Product Quality and Standardization (SQUALPI). In 1978, the Loi Scrivener consumer protection law was passed. In 1980, the French Association for Standardization (AFNOR) published the NF X 50-110 quality management and assurance standard, which was abandoned in 1987 with the introduction of the international ISO 9000 standards. Also in 1980, the AFCIQ and a number of other groups instituted the "Industrie et Qualité" Award.

1981 was proclaimed Quality Year by the Ministry of Industry; the following year, together with the Ministry for Higher Education, the Ministry of Industry created the "Club Enseignement-Qualité" (Quality Training Club).

In France as in other European countries, the 1980s witnessed a proliferation of quality associations. However—and this is another positive element that distinguishes France from other nations—in 1991 these groups merged into the French Quality Movement (MFQ). Jean-René Fourtou, the chairman of a major French company, Rhône Poulenc, was appointed president of the MFQ.

In 1984 the French government drew up a first program of measures to improve quality in French industry. A far more complete, wider-ranging second program covering quality, certification, safety, and training was launched in 1993. Initiatives included the introduction of an environment mark, a food mark and a new Quality Award.

Measures taken to involve the Regions included the Quality Train in 1985 and the "Tour de France" in 1987. A second, more incisive Tour was organized in 1993 to mark the introduction of the new Quality Award, with an average of 2000 businesses taking part in each stretch.

The Prix Français de la Qualité (PFQ, French Quality Award) was launched in 1993 by the Ministry of Industry and the MFQ (which runs the award). A particularly interesting feature of the French scheme is that although it is related conceptually to the European Quality Award (EQA), it is geared to small- and medium-sized businesses and operates at two levels, regional and national (*Prix Français de la Qualité* 1994). Companies wishing to apply for the award must first compete successfully at the regional level in order to qualify at the national level. (In the first year alone, approximately 1000 companies competed for the 22 regional awards. Thirty-six regional winners then went on to compete for thenational prize, which was awarded to one company); a further three won a special mention (Qualité en Mouvement 1993).

The high level of participation in the regional awards reflects the strong French focus on SMEs. These companies usually find it difficult to take part in national awards, let alone European awards: For them, the regional level is the natural starting point. Companies that win regional awards have already acquired a certain degree of experience, self-confidence, and determination and find it easier to qualify at national level. In 1995, the French model was taken as the reference by the two European organizations, the EOQ and the EFQM, when they were asked by the EU Commission to plan a European Award for SMEs. And in fact, this Award is organized at a third level, after the regional and national prizes.

To conclude, within the general European quality scenario, the French situation is notable for the stronger, more dynamic presence of the State, at both central and regional levels. With a few rare exceptions, most notably in the automobile sector, the response of the business community has been less forceful. Progress in product and service quality does not as yet appear to match the efforts of central and local government.

Quality in Germany.   Although the concepts of scientific management and Taylorism came to Germany, as to other countries, with widespread industrialization, they developed through the filters of the German manufacturing culture, which was strongly rooted in the guilds and in the skills training

and apprenticeship systems. The guilds had established precise quality standards for their members and for the training of artisans and shopkeepers. These standards, typically based on a 3- to 4-year apprenticeship, still constitute the basic model today. Awareness of the merits of this system and the consequent determination to defend its values meant that German industrialization developed on the basis of the skills of the country's workers. This is the reason for the "craftsmanship" of much of German industry, even in medium to large organizations; routine tasks are performed by low-skilled labor (often temporary immigrant workers), while highly skilled experts always play a key role in guaranteeing quality.

While Germany's large and, above all, its medium-sized companies retain a highly skilled, craftsmanlike approach, its small businesses (with fewer than 10 employees), which represent approximately 12 percent of gross domestic product (GDP) and employ about 16 percent of the workforce, are still heavily influenced by the imprint of the guilds. They account for more than 40 percent of apprentice training (Schlötel 1988).

Another significant factor in the rationalization of the German industrial system, which has had considerable benefits for quality, is the great emphasis on standardization. The Deutscher Normenausschuss (DNA), the German standards committee which drew up the Deutsche Industrienorm (DIN) standards, was formed in 1926. The DNA has always been a positive embodiment of the typical German industrial policy, in which the intervention of the State has tended to converge with the interests of the private sector, producing great competitive advantages for the economic system as a whole. The DIN standards apply German rationality to the industrial system in order to optimize overall benefits for consumers and manufacturers. They have played a leading role in the creation of standards, not only in Germany, but also in Europe and worldwide.

Another important organization is the VDE Pruf-und-Zertifierungsinstitut (Test and Certification Institute), which was formed by the Verband Deutscher Elektrotechnicker (VDE) in 1971 from a test laboratory that had existed since 1920. The VDE quality and safety mark for electrical products is granted in accordance with rules that for the most part have become DIN standards. The VDE mark is regarded as a guarantee of high quality and safety for the consumer, in and outside Germany.

A further step forward in the rationalization of the industrial system was the creation of the Rationalisierungs-Kuratorium der Deutschen Wirtschaft (RKW, Board for the Rationalization of the German Economy), which coordinates the activities of all the various rationalization bodies. The RKW is another example of broad cooperation among social and economic groups for the common good (Lerner 1995).

The traditional high quality of German products is also linked to another distinctive feature of the system, its trademarks and quality marks. The use of the trademark to guarantee product quality stems from the guilds. On the German market, Fugger, Welser, and Henkel's Zwilling Factory in Solingen were familiar names to everyone, and their products were automatically accepted without any form of inspection. Paradoxically, it was a defensive move by the British Parliament (the Merchandise Marks Act of 1887) that fueled awareness of the quality of German products outside Germany. People began to associate the "Made in Germany" mark with high quality, specifically quality in terms of above-average reliability and solidity (and often weight!).

Frequently, this higher quality and reliability was and still is coupled with a premium price, which the purchaser looking for a superior product is willing to pay. The premium price is usually the consequence of higher costs, as a result of overdimensioning and higher skilled labor content. As a result, German products tend to be regarded as niche products, offering craftsmanlike quality and reliability. Many of these niche markets are highly sophisticated, covered by a large number of small and medium high-tech enterprises, which are often worldwide market leaders (Simon 1996).

As far as quality marks are concerned, the Reichs-Ausschuss für Lieferbedingungen (RAL) was set up in 1925. Another broadly held private-public concern, the RAL ensures that product and service quality marks are properly used. Today, it also supervises use of the environmental mark created by the Federal Ministry of the Interior, to guarantee product environment-friendliness (Schlötel 1988).

Another guarantee of product quality is the Stiftung Warentest, a product testing foundation founded in 1961, which conducts systematic tests on different competitors' products and publishes the results in *Test* magazine. Its findings are usually reported by the media and used in advertising and are therefore an extremely significant factor in consumers' purchasing decisions.

In Germany, therefore, the emphasis on product quality predominates. Quality has been the main focus of German industry to date, and will probably continue to be so for the foreseeable future. Nevertheless, the risk of problems emerging in relation to other industrial systems that have had greater success in combining quality with efficiency and resolving the apparent conflict between quality and large-scale production should not be underestimated.

In this connection, German industry has been slow to grasp the importance of Quality Management, first at the level of quality assurance and later at the level of Total Quality Management. Its leadership in technical quality seems somehow to have overshadowed the development of a systemic, integrated vision of quality. As far as the ISO 9000 standards are concerned, Germany has made up rapidly for lost time: by 1995 approximately 10,000 companies had obtained certification. The absence of a strong military production sector and the corresponding focus on the market could be the reason for the relatively low importance previously attached to quality system standards, which are essential factors in the customer-supplier relationship in the military, nuclear, and space industries. Comparison with the situation in Britain supports this theory.

Germany has only just moved into the age of TQM; it remains to be seen whether its recovery here will be as rapid as it was in the ISO 9000 area. Greater problems could well emerge, given the enormous importance that corporate Germany attaches to professional skills. A strong sense of profession creates a strong functional identity (people who work in the R&D field—or in production, etc.—take pride in their specific skills). This makes it more difficult to achieve the interfunctional integration at process level that is vital to optimize costs and times together with quality. Similar difficulties could arise in attempting to obtain significant improvements, which always require interfunctional groups. Combining efficiency and quality is the challenge that many German companies will be facing in the next few years.

The Deutsche Gesellschaft für Qualitat (DGQ) has had an important role in spreading the quality culture in Germany. It was founded in 1952 and has been a full member organization of the EOQ since the latter was formed. In 1995 it had more than 6000 members, of whom about 25 percent were corporate members and 75 percent individual members. The DGQ is based in Frankfurt and has approximately 60 full-time employees. Its main activity is education and training, with approximately 1500 courses per year, attended by more than 30,000 people. These figures refer to 1993, when 7500 diplomas were awarded to participants at courses that have become *de facto* qualifications on the labor market. The DGQ also has a research unit, which conducts applied research jointly with business and universities.

This brief review of the development and current situation of quality in Germany cannot end without mention of Walter Masing, entrepreneur, lecturer, and quality pioneer in Europe, who was a cofounder and the first president of the European Organization for Quality. In addition to the many honors received from national associations and universities, in 1996 Dr. Masing was awarded the EOQ gold medal, a tribute that had previously been given only to Dr. J. M. Juran.

Quality in Great Britain.   The main characteristic of the British approach to quality in the period from the early 1970s to the mid-1990s is certainly the great emphasis on standards-based quality and certification. This is not to say that more advanced aspects of quality have been neglected; indeed, Britain was one of the first European countries to introduce the new TQM concepts, especially among large companies operating in highly competitive fields. But in Britain's divaricate vision of quality, certification has certainly predominated, at least at the quantitative level and in terms of image. With more certifications than the rest of Europe put together (see Table 38.2), during the period in question the United Kingdom has been the symbol and reference model for supporters of the standards-based approach to quality. The divergence between this view and the TQM view, a typical trend in Europe from 1987 to 1995, has assumed fairly extreme proportions in the United Kingdom, which can be taken to exemplify the phenomenon. The excessive emphasis on standards-based quality in Britain is probably the reason why the TQM vision has evolved as a counterreaction rather than as a complementary development. The emphasis on standards is itself the outcome of the crucial economic weight of large customers and, in particular, of the Ministry of Defence, the great champion of standards, which, through

its procurement contracts, controlled approximately 10 percent of the products manufactured in the United Kingdom when the Defence Standards for Quality Assurance were introduced in 1973 (Hutchins 1995).

It was toward the end of the 1970s that an approach to quality based on the experience of companies operating on highly competitive open markets, and geared to customer satisfaction and continuous improvement (as opposed to the customer-driven view geared to obtaining products compliant with specifications), began to emerge. This new vision sprang both from the direct experience of British industry and, indirectly, from the experience of U.S. business, which at that time was beginning to come under severe competitive pressure from Japan. This antagonism has created a situation in which, on one hand, the standards-based view has focused so single-mindedly on quality control and assurance that it has often lost sight of the customer; on the other, the TQM vision has sometimes been taken to such an extreme that it has lost sight of the fundamental need to ensure product and service quality through rigorous monitoring of every phase in the life cycle. Although this divergence obviously has no legitimate basis, it has developed nonetheless and has had a negative impact on quality development in every European country.

The phenomenon can be analyzed when discussing the development of quality in Great Britain, since it has acquired such significant proportions there. The split was formalized in 1992, when the British Quality Association (BQA, formed in 1981 to handle quality in the corporate sector) separated from the Institute of Quality Assurance (IQA). Founded in 1919 and granted its present title in 1972, the IQA was a Full Member Organization of the EOQ for both bodies. Officially, the purpose of the separation was to create a new body with the characteristics required by the government to run the new British Quality Award, which is based on the European award and therefore has a strong TQM content. The organization of the award was thus assigned to the BQA, which changed its name to the British Quality Foundation. But although, formally speaking, the division appears to have come about for contingent reasons connected with the award, it was in fact the last act in a deliberate distancing of the new groups that support the TQM approach from the historical nucleus that had promoted quality assurance for so many years. It is a false ideological distinction, which is bound to be a not insignificant obstacle to the correct growth of the quality culture in Europe.

With the loss of its branch that handled quality in the corporate sector, the IQA has abolished the clause that limited membership to professionals and now also welcomes corporate members. To date, quality assurance remains its chief mission, but the association has explicitly acknowledged the need to cover the entire spectrum of issues from control to quality assurance and total quality management.

The BS 5750 Standards and Certification Fever.   A comparative analysis of the development of quality concepts in the United Kingdom and in Germany in the postwar period reveals similarities between the United Kingdom and the United States on one side, and Germany and Japan on the other. Here is a possible explanation, based on a plausible interpretation of the facts, which at the very least merits further historical investigation. Like the United States, Britain was one of the victors of the Second World War; like the United States, it regarded defense as a top priority, partly in response to the Cold War. Like the United States at world level, the United Kingdom at European level had the strongest military defense industry, with the Ministry of Defence playing a key role. The strong emphasis on conformity with specifications, an essential requirement in this type of contractual relationship, could hardly fail to have a decisive impact on the development of the quality culture. Whereas the military commitments of Germany, like those of Japan, were no longer of a level to make the respective ministries of defense key "accounts" of industry. In Germany and Japan, industry was driven, first, by the needs of postwar reconstruction and later by the desire for expansion on the international marketplace, and therefore tended to regard quality as competitive added value for customers rather than as conformity with standards. These similarities should not be taken too far, however: Japan has tended to set its sights on high-volume markets and therefore on process-based quality, at minimum costs; Germany has concentrated on niche markets with high added value, where quality may involve higher costs. But certainly in both countries the approach to quality has been driven by the need to boost market share rather than to comply with standards and specifications.

The United Kingdom's particular focus on standards-based quality dates back to 1968 and the Raby report. The Ministry of Defence formed the Raby Committee to resolve the problem of inspections, which had grown out of all proportion, revealing all their intrinsic limitations in assuring the quality of purchased products. The Raby report led to the creation and approval in 1973 of the Defence Standards for Quality Assurance, based on NATO's AQAP standards (Allied Quality Assurance Publications).

During the same period, a number of other large organizations in both the public and the private sectors, including the Central Electricity Generating Board and a number of automobile manufacturers, had developed their own standards for auditing the quality systems and processes of their suppliers. Multiple audits thus began to be a serious problem for many companies. In 1979, the BSI published the BS 5750 standard, which was immediately adopted by the Ministry of Defence (Hutchins 1995) and, after some initial difficulties, by an increasing number of organizations and businesses. This was the start of the certification phenomenon in the United Kingdom, which would have significant repercussions on the history of quality, not just in Britain, but throughout Europe.

In 1987, when the ISO 9000 standards (which were based on the BS 5750 standards) were introduced, the number of certified operations was approximately 7000; in 1993, it had risen to approximately 19,000, and by the end of 1995 to approximately 53,000 (see Table 38.2).

It was not until 1994 that the first detailed critical reviews of Britain's attitude to certification were conducted (as opposed to the criticisms regularly made by the opposing group). The SEPSU report (SEPSU 1994) commissioned by the Royal Society and the Royal Academy of Engineering and, in the same year, a report by the BFQ put the spotlight on the following problems:

- In many cases, BS 5750 (or ISO 9000) certification is wrongly seen as an almost miraculous event, which makes companies automatically capable of generating quality, instead of as a first step toward competitive quality.

- Certification is unrelated to customer satisfaction; it has effectively shifted attention away from product quality and customer satisfaction.

- The certification business has led to the creation of a surplus of certifying bodies (more than 40 in 1995), and this has certainly lowered average quality. Significant inconsistencies exist among the approaches of these bodies, because of their number and the shortcomings of the National Accreditation Board (NAB).

- The economic support of certification provided by the State has encouraged a marketing-type approach by ISO 9000 consultants.

- High demand for consultants to help prepare companies for certification has led to a decrease in the quality of the service offered and to a tendency to sell standard solutions for situations and needs that vary widely.

- There is a general tendency to neglect specific technological and sector characteristics.

The rapid growth of the certification business in Britain has been amplified by the creation of extensive consultancy opportunities abroad as certification fever has spread to Europe and the rest of the world. These opportunities have been fueled by Britain's image as a leader in certification, which is leveraged, at times deservedly, at other times less so, by British certification bodies and consultancies, and by the fact that English is so widely used around the world. Consultancy work and certification of both companies and assessors outside the United Kingdom has reached huge proportions, generating a captive market and stimulating a desire to exploit demand by extending standards and certification to pathological levels (the creation of TQM standards, for example).

The most significant step taken by the British government to promote standards and certification was the publication of the "Standards, Quality and International Competitiveness" white paper and the simultaneous launch of the National Quality Campaign, to promote the BS 5750 quality assurance system standards in British industry. From 1983 to 1989, the Department of Trade and Industry spent around £19 million in a series of quality initiatives (Lascelles and Dale 1989). The fact that in 1983, when the need for research into the competitive dimension of quality as introduced by the Japanese had already become evident, a major national campaign focused on promotion of standards

and certification is symptomatic. To quote David Hutchins: "It seems that rather than discover why the approach did not provide a remedy for a worsening of Britain's competitive position with regard to the Far East, the advocates [*of the campaign*] were saying that all that was necessary was the same medicine but with a larger spoon." (Hutchins 1995.)

Today, halfway through the 1990s, it is still too soon to draw any conclusions about the effectiveness of such a massive drive toward standards and certification. The impression is that the results in terms of improvements in products and services and increased productivity are well below expectations. Britain is certainly the most important test bench as far as certification is concerned, since no other nation has achieved a similar scale. We can only hope that in the United Kingdom and the rest of Europe, the artificial separation between quality assurance and approaches that put the emphasis on the customer and continuous improvement can be resolved, in the interest of European industrial competitiveness, with a global vision based on a correct balance of all the various elements. (Signs of a move in this direction are already beginning to emerge.)

The Citizen's Charter.   In the area of government services for citizens, the British Government was one of the first in Europe to introduce systematic quality promotion schemes, as part of its program of privatization of government services. It has since been imitated by other European governments with the wave of privatizations in the 1990s.

In the 1980s, the U.K. government introduced significant reforms in the way public services were organized and run. These reforms addressed the problems of efficiency and effectiveness in central government, local government, and the National Health Service.

The first objective was to abolish bodies that filled no useful function. Those remaining were divided into two categories: those to be privatized, and those to remain in the public sector. In 1994 almost 1 million jobs passed to the private sector. Moreover, in areas where the public sector continued to be responsible for the provision of a function, an assessment was made of whether government should provide the function directly or through the private sector. The purpose was evidently to improve efficiency through competition.

The Citizen's Charter is designed to ensure that citizens receive adequate standards of service, irrespective of the provider. Basically, the idea is to create a competitive situation wherever possible, as a precondition for achieving quality. And since the focus is on services for the public, the government wishes to guarantee that the quality made possible by competition is actually produced. In cases where competition cannot be created, action is being taken—including incentive schemes— to guarantee the required quality.

The Citizen's Charter was launched in 1991. It is a 10-year rolling program of improvements to public services, based on the following principles (Hilton 1994):

- To set and monitor standards for services and to publish performance results
- To provide openness and full information about how services are run and what they cost
- To provide choice wherever possible
- To make services available equally to all who are entitled to them
- To provide courtesy and helpfulness
- To put things right
- To improve value for money

Special charters are planned for each of the main public services. By 1994, 38 sectors had published charters, including central and local government, schools, universities, hospitals, police services, rail services, prisons, tax collection, and the regulated utilities: gas, electricity, water, telecommunications.

A charter mark scheme has been devised as recognition for organizations that, in the opinion of users, deliver outstanding service. The earnings of those who run the services are in part performance-related.

The Citizen's Charter has been running for a number of years, and assessments of its success are many and varied. Once again, the results have been lower than expected: It is difficult to change peo-

ple's attitudes, especially in the state administration. Nevertheless, some admirable improvements have been achieved, for example in the Post Office: in 1989–90, 78.1 percent of first-class letters were delivered on the next working day after mailing. This figure rose to 89.8 percent in 1991–92 and to 92 percent in 1993–94.

One significant merit of Britain's Citizen's Charter is that it has led to the introduction of similar schemes by other European governments, giving fresh stimulus to a sector that is traditionally extremely static. This is why the Charter is discussed at some length here, despite the fact that, in terms of real quality of public services, a number of northern European countries could justifiably claim superiority.

Notes on Other Countries.   Although detailed descriptions of every West European country are not possible here, a series of comments and clarifications are provided to complete the picture.

We can begin with Switzerland, which has a well-deserved reputation for the quality of its manufactured goods (e.g., wristwatches, large electromechanical equipment, chemicals) and its services (e.g., banking and tourism). Switzerland was one of the first countries in Europe to institute a national quality system certification organization (the SQS, formed in 1983) and it has one of the highest certification rates. Many of its manufacturing companies and service providers pursue TQM strategies.

The Netherlands also has a long-standing quality tradition and was one of the first countries to introduce certification (1982). The Dutch Quality Foundation dates back to 1953 and was a founder member of the EOQ. In 1984, the Dutch government launched the first national quality program, intended primarily for SMEs, which form the backbone of the country's economy. A second program, introduced in 1988, provided 50 percent government funding for more than 100 projects designed to promote quality principles and methodologies within the corporate sector. Dutch universities also play a significant role. Finally, mention should be made of the Dutch Quality Award (which is based on the European Award but introduces a number of interesting differences). The Award is run by the Dutch Quality Institute, which was set up in 1992.

Scandinavia, too, woke up to quality issues in the 1980s. In 1984, Sweden instituted the first TQM chair, at the University of Linköping. In 1990, the Swedish Quality Institute was formed to run the Swedish Quality Award (1992), which is based on the Malcolm Baldrige model. In the business world, the wave of privatization at the beginning of the 1990s encouraged the spread of TQM. Certification is also strongly promoted, especially in Denmark. All three Scandinavian nations pay particular attention to the quality of services, most notably in health care, and to environmental quality. Sweden takes a special interest in customer satisfaction issues, at both the academic level and in practical applications. It was the first country to introduce a national customer satisfaction observatory, the Swedish Customer Satisfaction Barometer (SCSB), which was created in 1989 and was the model for the American Customer Satisfaction Index formed in 1994. The SCSB monitors customer satisfaction in a number of industries and individual corporations within those industries. It has five objectives:

1. To compare industries
2. To compare individual firms with the industry average
3. To make comparisons over time
4. To predict long-term performance
5. To answer specific questions

Germany also has a Customer Satisfaction Index, which was created in 1992. Research is currently underway to assess the possibility of introducing a European customer satisfaction index.

Certification also has an important place in Ireland and Italy. The situation in Italy (whose national certification body, the AICQ, was one of the five founder members of the EOQ) merits a brief comment. In the corporate world, the various sectoral associations (for the mechanics industry, electronics, chemicals, etc.) effectively control certification in their respective sectors, even though the market is open to anyone wishing to enter the certification business. It is obviously in these associations'

interests to keep certification quality high; moreover, since assessors are frequently recruited from the ranks of those who have spent their working life in the particular sector, they are able to assess the factors that really count, and avoid the bureaucratic approach adopted by assessors who are familiar with the standards but not with specific processes. This combination of factors has tended to keep the level of certification relatively high in Italy, compared with countries where the business aspect of certification tends to predominate.

THE EUROPEAN QUALITY ORGANIZATIONS

The European quality organizations have been a major contributing factor to the rapid growth of interest in quality over the years. So a specific section is dedicated to them here. Readers wishing to examine in greater detail the issues discussed here, which are necessarily touched on only very briefly, should refer directly to these bodies. Two major organizations operate at the European level, the EOQ and the EFQM; the bodies active at the national level are usually the member associations of the EOQ and in some cases the organizations that run the awards.

The European Organization for Quality (EOQ).   The European Organization for Quality is the federation of the European national quality organizations. Its aims are specified in the following mission statement:

> To facilitate the exchange of information and experience of quality theories and best practices across Europe, in order to enhance the competitiveness of the European economic system, with special attention to small and medium enterprises; to promote the growth of quality in public services and the educational system.

To accomplish these missions the EOQ:

• Promotes and coordinates the activities of its member organizations and all working units

• Organizes annual congresses, seminars, and forums

• Publishes the journal *European Quality*

• Participates in and contributes to projects at European level

The EOQ was founded in 1957 by the national quality organizations of France, the Federal Republic of Germany, Italy, The Netherlands, and the United Kingdom as the European Organization for Quality Control (EOQC). Since then, membership has expanded to other national quality organizations, as shown below. By 1996, thirty-one national quality associations had become Full Member Organizations (FMOs) of the EOQ.

Date	*Country*
1961	Denmark, Sweden
1962	Norway
1963	Czechoslovakia
1966	Yugoslavia
1970	German Democratic Republic
1971	Portugal
1972	Hungary
1974	Belgium
1976	Turkey

Date	Country
1979	Austria, Greece
1980	Ireland
1989	Iceland
1991	The former Union of Soviet Socialist Republics becomes Russia and the Federal Republic of Germany incorporates the former German Democratic Republic
1992	The former Yugoslavia splits into separate states; Slovenia is the first of the new states to enter the EOQ
1993	Croatia and Estonia; the former Czechoslovakia splits into the Czech Republic and the Slovak Republic
1994	The former Yugoslavian Republic of Macedonia
1995	Latvia
1996	The Ukraine

In 1989, the EOQC changed its name to European Organization for Quality (EOQ), to take account of the new developments in quality concepts after quality control: quality assurance, quality management, Total Quality Management.

One of the outstanding characteristics of the EOQ in its early years was its policy of accepting organizations from all over Europe, West and East, in a period when the continent was deeply divided. Promoting exchanges of experience between quality specialists within the two extremely different economies was considered of greater importance than the political divisions on the two sides of the Iron Curtain. This was demonstrated to the world when an Annual Congress was organized in Czechoslovakia as early as 1969 and when a Soviet citizen was elected President in 1978.

The EOQ is governed by Swiss law. Its General Secretariat is located in Bern, Switzerland, and is currently composed of three people. This low number is a significant indication of the difference between the EOQ and other quality organizations, such as the ASQC. Whereas the latter is a national association (covering the entire U.S. territory, although it is a highly decentralized organization consisting of territorial divisions), the EOQ is a federation of national associations (the Full Member Organizations). The EOQ reflects the political organization of Europe, a continent composed of separate sovereign states, which are gradually moving toward economic integration and partial political unification (among the 15 member states that make up the European Union and other states that will gradually join the EU), without to date at least overriding the absolute preeminence of each country's national identity. Similarly, within the EOQ, the national quality associations tend to maintain their specific prerogatives and dedicate most of their attention and resources to national initiatives. The limited proportion of resources that go to the EOQ (to cover membership fees and the participation of their representatives at the meetings of the statutory bodies, committees/sections, and workgroups) enables the federation to provide harmonization, coordination, and leadership on special strategic initiatives of European significance or on operations for which a centralized organizational approach improves efficiency by enhancing synergies among the various bodies.

The prevalence of the FMOs' national activities over the European activities conducted by the EOQ is confirmed by staff figures. If the staffs of the 31 national organizations are added together, the total is approximately 250 people, compared with 3 at the EOQ General Secretariat. The national bodies also rely on the work of many volunteers. The EOQ executive organs feel, however, that the central structure should be strengthened to take account of the expansion of activities at the European level fueled by the growing economic and political integration of the EU.

Table 38.3 lists the FMOs of the EOQ, showing their individual and corporate members.

Structure and Activities. The decision-making organ of the EOQ is the General Assembly. It consists of the representatives of the Full Member Organizations, the members of the Executive, and the

N.A.=not available.

General Secretariat. The General Assembly meets twice a year: at a summer session during the Annual Congress and at a winter session. The Executive is composed of the President, the Immediate Past President and four Vice Presidents. The activities of the EOQ are conducted through:

• The Annual Congress
• The official EOQ journal, the *European Quality Journal*
• The Committees and Sections
• The Unit for the Registration and Qualification of Quality Professionals
• The Evolution of Quality Working Group

The Annual Congress. Held every year since 1957, the EOQ Congress is hosted by the member countries on a rotating basis. The first Congress, chaired by Walter Masing, was held in Paris in 1957. The Congress calendar has already been drawn up until 2005 (1997: Trondheim, Norway; 1998: Paris; 1999: Spain; 2000: Hungary; 2001: Turkey; 2002: United Kingdom; 2003: The Netherlands; 2004: Bulgaria; 2005: Italy).

The Congress is usually held in the month of June; every other year it ends with the election of a new president and Executive.

The European Quality Journal. The *European Quality Journal* is the EOQ's official journal. A bimonthly magazine, it was introduced in January 1994, when it replaced the *EOQ Journal.* The journal is owned by the EOQ and published by European Quality Publications, J. & M. Kelly. Its editorial position is decided by an Editorial Board consisting of the Editor, the Secretary General, and another EOQ representative. The journal also has the support of an Advisory Board of United States and Japanese as well as European experts. The journal is a managerial rather than technical publication; it is intended for managers in general, in every type of organization, public or private, profit-making or not, and for the academic world.

The Committees and Sections. The number of committees and sections has varied over the years, depending on requirements and on individual FMO availability to chair new groups. In 1995, the following sections were operational: Automotive, Pharmaceutical Industry, Construction Industry, Consultancy, Healthcare; the following committees were operational: Education and Training, Dependability, Glossary, Statistical Methods, Software, Human Factors in Quality Management, Environmental Quality, Service Quality.

The Unit for the Registration and Qualification of Quality Personnel. The Unit runs the Harmonized Scheme for the Qualification and Registration of Quality Personnel, which was introduced by the EOQ in January 1994 as a means of establishing high standards for the training and qualification of quality personnel throughout Europe and paving the way toward mutual recognition of all the relevant professional figures. As of 1996, the EOQ Scheme identifies three categories of quality personnel: the Quality Professional, the Quality System Manager, and the Quality System Auditor. The Scheme is based on the training experience of a number of FMOs, who in 1991 decided to launch a process of harmonization in order to create a common scheme. It has also been adopted by the FMOs who were not involved in its planning and has thus become the official EOQ Scheme. If it is accepted by the relevant bodies, it will also become the European Scheme. Today, the Scheme is run by the EOQ in line with the requirements of the EN 45013 and ISO 10011 standards. The EOQ therefore acts as a *de facto* accrediting body and will officially be recognized as such if the Scheme is integrated into the European system. The EOQ's FMOs act as certifying bodies for professional figures in their respective countries. Under EU rules, this function is not confined to the FMOs but may also be performed by other bodies that meet the requirements specified in the relevant EOQ document. Nevertheless, the FMOs are the EOQ agents in their respective countries and guarantee correct application. Figure 38.1 illustrates entry requirements and the certification process.

The Evolution of Quality Working Group. This group monitors and, when possible, anticipates the evolution of quality theories and practices, in order to help keep Europe at the forefront of developments. One of the reasons behind the formation of the Group in 1994 was the realization that, over the years, quality had developed in a one-sided manner in Europe and within the EOQ itself, with the result that the organization was in danger of losing the leadership envisaged by its vision and mission statements, and confirmed by its history. After 1987, quality system certification based on the ISO 9000 standards had become the key issue in Europe and in the EOQ Congresses. High demand for certification had created new opportunities for the national quality associations, which were able to offer their experience in quality training and launch new activities in the area of assessor certification. This increase in activity not only boosted the importance and visibility of the national organizations, it also led them to enlarge their structures, with the result that technical structures gradually came to prevail over professional skills. More and more time was spent resolving problems related to budgets, expansion, internal organization, and competition with other groups attracted by the new business opportunities. Specialist, professional issues were neglected or, often, not even perceived. Developments in the field ofTotal Quality Management were relegated to the sidelines in the FMOs and consequently in the EOQ, because of the overwhelming priority given to certification.

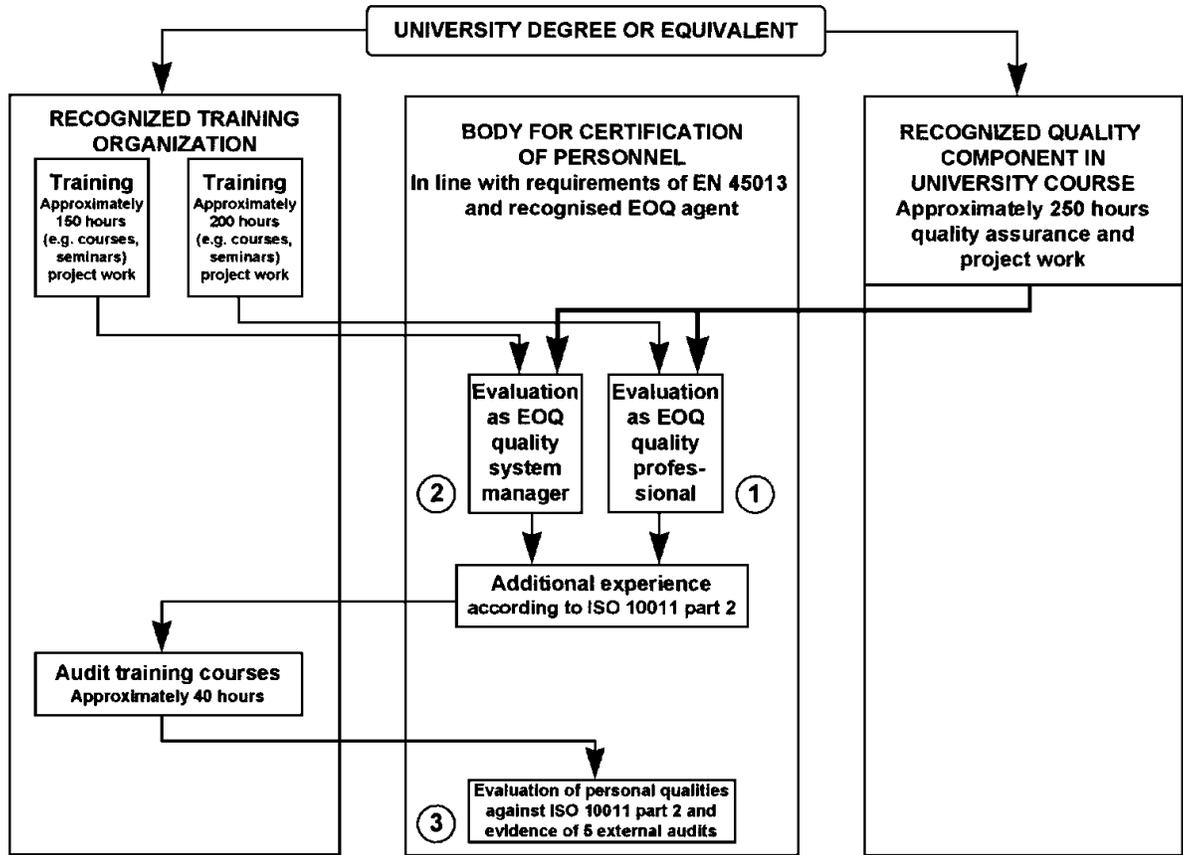
The Evolution of Quality Working Group was set up to provide the EOQ with an observatory that would identify and analyze major trends in quality as distinct from specific issues—albeit legitimate ones—of contingent concern, business opportunities of interest to certain groups or the latest fads.


FIGURE 38.1   The EOQ harmonized scheme for the registration and certification of quality personnel (1 = quality professional, 2 = quality system manager, 3 = quality auditor).

The Group is therefore a point of reference for the EOQ and the FMOs, providing support in making the correct decisions and avoiding the pitfalls of fashion. It meets about three times a year and organizes an annual forum to discuss a theme of particular current interest. It also provides support for the FMO that hosts the EOQ Annual Congress, helping to choose the main theme for debate, select speakers, and assess the articles received in response to the call for papers. It also examines the key themes in the papers, before discussion by the Executive.

The European Foundation for Quality Management (EFQM).   By the 1980s, the new quality messages had spread to many European companies and many quality managers had experienced their benefits at firsthand. The main difficulty was how to involve top management and line management in general. Sensitive to this problem, the quality associations attempted to draw the attention of corporate chairmen and chief executives on one hand and politicians on the other to the new quality issues, but with little success.

In 1987, the chairman of N.V. Philips Gloeilampenfabrieken, the Dutch electrotechnical and electronics multinational, contacted 13 other major European companies (14 EFQM founder companies) with an idea for the creation of a European body to stimulate corporate interest in Total Quality Management, which was seen as a major strategic factor in the recovery of Europe's industrial competitiveness. The 14 chairmen assigned their quality strategy managers to analyze the project. The result was a proposal to set up an organization that would be complementary to those already operating in the quality field. If the strong point of the existing associations was the know-how and experience of quality managers and quality experts and their weak point was the lack of top management participation, then a highly visible, direct top management presence would be the goal of the new organization. On September 15, 1988, the chairmen of the 14 companies met in Brussels to sign a

letter of intent for the formation of the European Foundation for Quality Management. The Foundation was formally constituted the following year, on October 19, in Montreux (Switzerland), again in the presence of the fourteen chairmen. The Policy Document approved in Montreux set out the vision, missions, and objectives of the EFQM. Specifically, the Foundation's missions were as follows:

- First, to support the management of Western European companies in accelerating the process of making quality a decisive influence in achieving a global competitive advantage
- Second, to stimulate and, where necessary, support the participation of all segments of the Western European community in quality improvement activities and to enhance the quality culture.

For the first five years, the EFQM was directed by a Governing Committee consisting of the chairmen of the founder companies. The policies drawn up by the Committee were transformed into initiatives by an Executive Committee composed of the chairmen's representatives and implemented by a staff headed by a Secretary General. An Advisory Board of representatives of the Executive flanked the Secretary General during the intervals between the meetings of the Executive Committee. In 1994, EFQM membership conditions were changed, with the only distinction now being between Regular Members (public or private companies, or governmental bodies) and Associated Members (nonprofit organizations). Correspondingly, the Governing Committee and the Executive Committee are elected from among the members. The Foundation's official headquarters are in Eindhoven (Netherlands), but since 1992 the 20-strong staff headed by the Secretary General has operated from the EFQM Representative Office in Brussels.

In 1996, the EFQM had approximately 500 members.

EFQM Activities.   The main activities of the EFQM are as follows:

- *Recognition:*   Covers management of the European Quality Awards (by far the most important activity).
- *Services for managers:*   The Annual EFQM Representatives Meeting, the Quality Management Open Days, seminars, common interest days, working groups, etc.
- *Communication:*   Publication of the *Quality Link* newsletter and monographs.
- *Education, training, and research:*   Organization of the annual Learning Edge Conference and other activities.
- *Winners' conferences:*   The conferences at which the winners of the awards illustrate their paths toward excellence for the benefit of other European companies. The conferences are organized by the local EFQM members.
- *Award-related training activities:*   Training for award assessors and company internal assessors.

In the main countries in which the EFQM operates, local activity groups have been formed to translate documents and coordinate the national group of award assessors.

The Annual Forum.   This is the EFQM's main public event. The first Forum was held in 1989 in Montreux, the second in 1990 in London, and the third in 1991 in Paris. Since 1992 (Madrid), the Forum has also included the European Quality Award presentation ceremony. The Forum has been held in Turin (1993), Amsterdam (1994), Berlin (1995), Edinburgh (1996), Stockholm (1997), and Paris (1998).

Although the presentation of the Award is a key highlight, the Forum offers an intensive schedule of events of great interest to large numbers of European managers: papers by European corporate chairmen and CEOs and workshops on carefully selected issues. The Forum is also the venue for the annual meeting of the Foundation's Governing Committee.

The EFQM 2000 Program.   In 1996, the EFQM reviewed its vision and missions and launched a long-term program.

The Foundation's new *vision* is

> To be a leading organization, recognized on a global basis, for the development and promotion of a consistent approach to Total Quality Management as the vehicle for the achievement of business excellence in European organizations.

Its *missions* are

- To stimulate and support the participation of organizations throughout Europe in improvement activities leading to excellence in customer satisfaction, impact on society and business results.
- To support the managers of European organizations in enhancing the role of Total Quality as a decisive factor in achieving a global competitive advantage.

Under the EFQM 2000 program, the Foundation's *objectives* are as follows:

1. For the European Model for Business Excellence to be recognized as the key strategic framework for managing an organization and identifying improvement opportunities, regardless of the nature and size of that organization.
2. For the European Quality Award and Prizes to be recognized internationally as major achievements, and the winners to be acknowledged as role models of business excellence.
3. To provide membership satisfaction, through value-for-money services.
4. For the philosophy, methods, tools, and techniques of Total Quality to be accepted as a key element of education and training in Europe, at every level.
5. To establish constructive relationships with the national quality organizations, the European Organization for Quality, and the European Union.
6. To operate on a sound financial basis.

The EFQM has set itself a membership target of 800 by the year 2000.

The European Quality Platform.   Given the complementarity between the EOQ and the EFQM, on September 1, 1994, the two organizations created the European Quality Platform as a means of optimizing the overall benefits for Europe of their activities. The Platform's vision reads as follows:

> The European Quality Platform is the leading body in relation to communication and coordination in the field of quality matters throughout Europe.

> The European Quality Platform serves and supports the European Commission and all private and governmental organizations in Europe in their attempt to promote quality at all levels and in all sectors.

The Platform comprises a Board with three representatives from each of the two organizations, which meets at regular intervals, a permanent link between the EOQ and EFQM Secretaries General and, primarily, a range of joint activities. Leadership of these activities is always handled by one or another of the organizations, but planning and supervision are conducted jointly by special Steering Committees. From 1994 to 1996, the Platform's joint activities were as follows:

- Creation of the new European Quality Award for Small to Medium Enterprises
- European Quality Week
- Preparation of a book illustrating case studies of TQM strategies developed by European companies.

These three activities were part of the programs of the European Commission (DGIII) and therefore received Commission funding. The Platform's future plans involve activities in education and training, publication of information about quality, and promotion of Professional Quality Figures.

THE EUROPEAN QUALITY AWARDS

The European Quality Prizes and the European Quality Award (EQA) were launched in 1991 by the EFQM, with the support of the EOQ and the European Commission. The EFQM is responsible for their management and funding. To receive a prize, an organization must "…demonstrate that its approach to Total Quality Management has contributed significantly to satisfying the expectations of its customers, employees, and others who have an interest in it, over a number of years.…" Since the candidates do not compete against one another, but are assessed separately against a predefined level of excellence, a number of prizes can be awarded in the same year. The "best of the best" receives the European Quality Award. Originally, the awards were intended for large or medium-large business organizations. In 1996, a separate award was introduced for public service providers. An award for small to medium enterprises (SMEs) will be introduced in 1997 (see notice of brochures about the awards under References).

If the applicant is an independent company, the sole condition for eligibility is that at least 50 percent of its activities over the previous 5 years must have been conducted in Europe. If the applicant is part of a larger organization, the following conditions must also be met: (1) the applicant must have a unique company name and its own unique brands; (2) the applicant must have more than 250 employees (from 1997 on, this will no longer be a condition; 250 employees will be the dividing line between the awards for large organizations and SMEs); (3) output supplied to the parent company must be less than 50 percent of total output; (4) the applicant must perform a sufficiently broad range of business functions (European Quality Award).

The following companies won European Quality Awards from 1992 to 1995 (the first company in the list for each year is the Award winner, the other companies are Prize winners):

- 1992: Rank Xerox Ltd.; BOC Ltd., Special Gases, Industria del Ubierna SA, UBISA, Milliken European Division.
- 1993: Milliken European Division; ICL Manufacturing Division (now D2D).
- 1994: D2D (Design to Distribution); Ericsson SA, IBM SEMEA.
- 1995: Texas Instruments Europe; TNT Express (UK) Ltd.
- 1996: Brisa-Bridgestone Sabanci Tire Co. SA; British Telecommunications plc; Netas, Northern Electric Telekomunikayson AS.
- 1997: SGS Thomson; British Telecommuncations plc; TNT UK Ltd.; Netas, Northern Electric Telekommunikayson AS. 1997 was also the first year of the European quality award for small/medium enterprises: Award winner: Beksa. Prize winners: Gasnalsa, Gas Natural de Alava; DiEU; ABB Semiconductors; DD Williamson; Prec-Cast Foundry Ltd.; Landhotel Schindlerhof.

The EQA timetable is approximately as follows: submission of preliminary application data (information about the company and fulfillment of eligibility criteria), end of January; submission of final Application Document, beginning of March; site visits, June; announcement of the award winners, October/November.

A team of five to seven assessors, headed by a senior assessor, is assigned to each application. After the application is examined separately by each member of the team, the senior assessor calls for a "consensus meeting" to reach qualitative agreement (on strengths and areas for improvement) and quantitative agreement (on scores). The resulting "consensus report" is then presented by the senior assessor to the EQA Jury, which examines all the consensus reports and selects the applicants which will receive a site visit. After the visits have been completed, the EQA Jury meets to reach its final verdict. The number of assessors involved in the process varies, depending on the number of applicants.

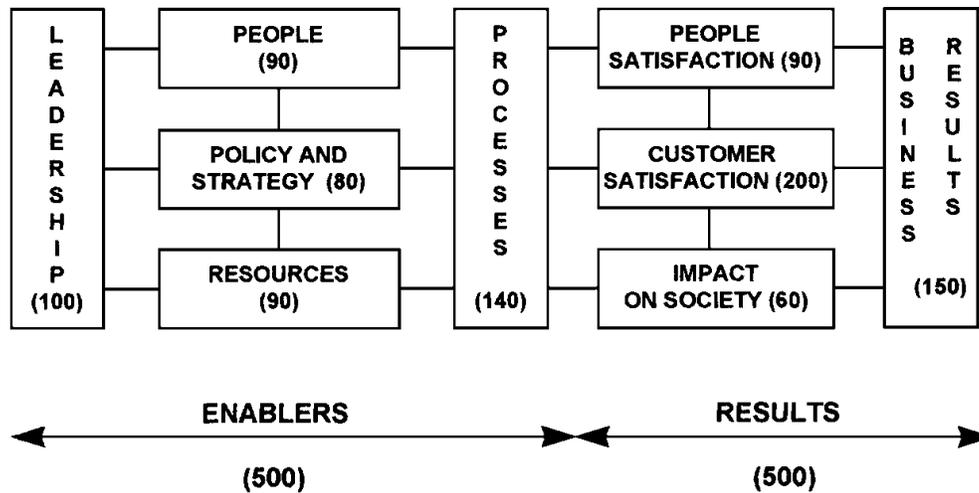
The EQA is based on the model in Figure 38.2. The model expresses the concept that *customer satisfaction, people (employee) satisfaction* and a positive *impact on society* can be achieved through *leadership* as the driving force behind *policy and strategy, people management,* and management of *resources* and *processes,* and that this leads ultimately to excellence in *business results.* The clear division between *enablers* and *results,* with a 50 percent weighting attributed to each of the two blocks, is the distinguishing characteristic of the EQA.


FIGURE 38.2 The European Quality Model, with weights.

THE EUROPEAN ENVIRONMENTAL MANAGEMENT SYSTEM

The world's first set of environmental management system standards, BS 7750, was drawn up by the British Standards Institute (BSI) in 1992. Clearly, in becoming the first body to establish an environmental standard, the BSI was able to capitalize on its years of experience in quality system standards (BS 5750 and, later, ISO 9000).

At the European level, the first Resolution of the EC Council in this field, passed on December 3, 1992, expressed the view that a preventive guideline geared to the market economy in the area of environmental protection could benefit industrial competitiveness and should be adopted wherever possible. The following year saw the publication of EC Ruling 1836/93 on the voluntary compliance of industrial companies with a community eco management and auditing scheme designed to raise the environmental efficiency of industrial operations. In preparation for the introduction of the scheme, the Ruling provided a set of legislative, technical, and managerial guidelines covering the development of "environmental management systems" within companies, the implementation of the necessary audits, and information for the public. The Eco Management and Audit Scheme (EMAS) became operational in 1995. By 1996, therefore, three systems existed: the BS 7750 standard, the EMAS, and the ISO 14000 standard, the final draft of which was approved in Oslo in June 1995. The formal standard is due to be published by the ISO in the second half of 1996 (Kiesgen 1995).

Though similar in many ways, the three systems contain basic differences in emphasis. The ISO standard is considered to be the least prescriptive, because of the compromises introduced to make it internationally acceptable. The EMAS standard is regarded as the most demanding. Many observers in Europe believe that EMAS registration should be the ultimate goal and that both the BS 7750 and the ISO 14000 standards should be regarded as staging posts. However, the CEN (the European standardization body) is examining the possibility of narrowing the gap between the EMAS and ISO 14001, leading ultimately to the adoption of the ISO standard.

The approach of the environmental efficiency certification system for industrial operations outlined by the EU Ruling is similar to that adopted for quality system certification in relation to the free circulation of goods within the Union. The EMAS registration roadmap is as follows (Mullins 1996):

1. Adopt an environmental policy. This must be a corporate policy designed to ensure:

- Compliance with the relevant environmental regulations
- A commitment to continuous improvement

2. Conduct a site environmental review. The aim is to identify the site's environmental impact and relevant issues.

3. Develop an environmental program. The program should be set out in accordance with the company's environmental policy and the outcome of the site environmental review.

4. Set up an environmental management system.

5. Perform an environmental audit using EMAS, BS 7750, or ISO 14001 criteria. The frequency of the audit depends on the specific business, but it must be performed at least once every 3 years.

6. Prepare an environmental statement for publication. The aim is to ensure that all interested parties are aware of the environmental impact of the site and the company's environmental management policy.

7. Validation. An accredited environmental verifier scrutinizes the company's environmental policy, program, management and audit procedures, to ensure that they meet EMAS requirements.

SECTION 39

QUALITY IN CENTRAL AND EASTERN EUROPE

Robert E. Hoogstoel

OBJECTIVES OF THIS SECTION

This brief survey of quality as experienced in central and eastern Europe has two principal objectives:

1. To review the history of the region, especially with respect to how quality has been managed
2. To identify the forces now at work which may affect the way quality is managed in the future

RECENT HISTORY OF CENTRAL AND EASTERN EUROPE

Central and Eastern Europe Defined. In this section, "central and eastern Europe" signifies the area of Europe whose countries, in the period beginning in the years following World War II proclaimed themselves socialist or communist under single-party rule. This includes the countries which were allied with the Soviet Union (U.S.S.R.)—Bulgaria, Czech Republic, the German Democratic Republic, Hungary, Poland, Romania, and Slovakia—or were actually incorporated into it as socialist republics—Belorus, Estonia, Latvia, Lithuania, Ukraine. It also includes socialist countries that stood apart from the U.S.S.R.—Yugoslavia and Albania. And, because of its decisive influence in quality as in other matters in this region, we include Russia, then at the center of the U.S.S.R. This is not a complete list, nor have we tried to anticipate the emergence of new countries in the region as the result of negotiation or civil war. For a discussion of quality the list will suffice; it contains the most industrialized and therefore the most influential countries in the region regarding quality.

Recent History. It is good to remember that the recent history of this area, both economic and political, is a turbulent one. The experiences of self-rule before 1989 were brief and scattered. In the

countries that were the remnants of the Austro-Hungarian Empire or Prussia, self-rule was limited to the period following the end of World War I, in 1918. Those newly independent countries were Austria, Hungary, Poland, Czechoslovakia, Yugoslavia, and the Baltic states of Lithuania, Latvia, and Estonia. Self-rule for them effectively ended with the rise of Nazi Germany, beginning around 1935. After that there was occupation, World War II, and more occupation. Soon after the end of World War II in 1945, with the exception of Austria, all of them, plus eastern Germany, became communist, under the rule of various national Communist Parties, most dominated by the Soviet Union through economic and military agreements enforced by military power. All told, there was little over a decade to develop democratic forms, too short a time to establish democratic traditions. Further, during the 40 and more years before 1989, the experience with market-based economics in central and eastern Europe was limited to black markets, transactions outside of state control, and condemned and punished as criminal.

It is this common history and the challenges which that history poses that bind these countries with respect to quality. Each of the countries, whatever the new form of organization toward which it is tending, aspires to create products—goods and services—which can compete in the world marketplace. And each must find a way to create the environment in which that aspiration can be fulfilled.

Political and Economic Organization under Communism.

This part of Europe is in transition. Rather than speculate where each will be in the future, it is perhaps more fruitful to look backward and examine the common factors which today affect the state of quality in this region.

For over 40 years (longer in the case of Russia), the region was governed under a political-economic model dramatically different from that of the Western countries. The model and the consequences of its implementation created the climate for industrial quality. The features of the model profoundly affected the management of quality. The habits of management and thought left behind still affect quality management. Some of the features and their effects were

- *The economy was centrally planned.* Smith (1976) discusses some of the effects in Russia of commitment to plans issuing from the top of the political hierarchy and promulgated downward. There was pressure on managers to "meet the plan." Fearing retribution for failing to make the plan, and motivated by a system of bonuses for meeting the plan, managers throughout the economy resorted to all manner of shady schemes to either meet the plan or be certain that blame for failure to do so was attributable elsewhere. These distortions led to unrealistic plans, which in turn led to increasing shortages of materials throughout the economy, with which managers had to deal with increasingly creative dishonesty.

- *In effect, the state was the only customer.* Regarding consumer goods, this meant that huge central agencies represented the needs and wishes of the general population. There was no direct customer input to the design of goods or delivery of services, and no effective feedback of product experience in the field. The consumer had to accept what was available and suffer with the quality (Smith 1976).

- *Orientation was toward production volume. The central plan required commitment to numerical production quotas.* The most obvious shortcut to meeting the plan (or to exceeding it and achieving production stardom) was to shortcut quality. Khrushchev (1970) describes his investigation of an epidemic of failing automobile tires. He found that the factory had, at the request of a visiting commissar of transport, reduced the amount of reinforcing wire at the edges and of cording under the tread. This action was motivated by a wish to meet the plan and save material. Unfortunately, it was uninformed by the technical requirements of an automobile tire. Although the incident took place in 1939, it was typical of the problems that continued to plague industry under the communist system.

- *Much of the industrial production was committed to military purposes.* The military, as the preferred customer, always enjoyed direct input in the factories, and had either their own "closed" plants or plants for mixed civilian-military production. High priority for the military meant consequent low priority for the remainder of the economy. The practical effect was a two-tier system of quality. The first tier was occupied by military goods; the second tier by everything else.

- *The plan committed the state to heavy-industrial development.* In the earliest days of communist rule in Russia, this policy was based on the objective to convert an agrarian economy into an industrial one. The policy outlasted the need and became an end itself, promoted for propaganda purposes (Smith 1976). This has left the entire region with gigantic factories unable to react to rapidly changing market demands and rapidly changing technology.

- *There was little or no private ownership of property.* The most apparent effect of public ownership was the disregard for maintenance evident in decaying public works of all sorts—factories, apartment blocks, sewer systems, and so on. One expert in the region (Behrman 1998) has observed that "where the owner is 'everyone,'…no one feels responsible for maintenance." A related effect was the perfecting of a notoriously poor work ethic, summed up in the workers' joke: "We pretend to work and they pretend to pay us."

Effects of the Political and Economic Organization. Implementation of this system and its plans and goals involved cultural changes on an unprecedented scale. Motivation was presumably based on the common good, not the good of the individual, but this motivation was never sufficient. At least one Western student of the Soviet Union (Figes 1997) has observed that communism was bound to fail because it sought to achieve the impossible: the transformation of human nature.

From the start, state coercion played a large role in moving plans forward. There was state control of information and cultural affairs, reflected in censorship of publications unfriendly to the state and punishment of dissident behavior. At the factory level, authoritarian management prevailed.

Information control had many adverse implications for quality. The reactor explosion at Chernobyl in 1986 dramatically revealed some of these. Before the accident, it was government policy to conceal from the general public accidents at nuclear power stations and to forbid publication of "information about the unfavorable ecological impact of energy-related facilities on operating personnel, the population, and the environment." This contributed to widespread complacency when the accident occurred. Further, in 1985, a newly appointed minister of energy further impeded exchange of information and reduced the ability to anticipate and prepare for reactor accidents by abolishing the central coordinating body of the ministry. Most obviously, when the accident occurred, the authorities failed to alert the immediate population and the people who lived downwind of the accident, resulting in extensive unnecessary exposure to radiation (Medvedev 1991).

By 1995, among children in the affected area, the incidence of thyroid cancer was reported to be 285 times the preaccident rate (Crossette 1995). Medvedev (1991), a Russian expert in nuclear power, condemns generally the government's control of information with these words in the preface to his account of the Chernobyl disaster: "…Chernobyl demonstrated the ignominious failure and the sheer insanity of the administrative-command system."

On a less frightening dimension, the concentration of economic information and decision making in the hands of a few resulted in widespread ignorance of microeconomic and financial concepts, contributing also to poor preparation for life in a market economy.

Quality Management—1945 to 1990: State Quality Control

Council for Mutual Economic Assistance (CMEA). During the communist period, most countries in the area, under the leadership of the Soviet Union, formed a trading alliance—the Council for Mutual Economic Assistance. Among other matters of mutual concern, the alliance cooperated on the approach to industrial product quality. Between 1971 and 1980, the CMEA introduced programs to promote economic integration among CMEA countries. One requirement for success was the development and adoption of a wide variety of uniform quality standards.

Unified System of State Quality Control (USSQC). The approach to quality was based on a Russian model established in 1978, known as the Unified System of State Quality Control. Under USSQC, quality control was a function of the central government, involving the coordination of economic planning (including planning for quality control at all levels of the economy). USSQC is described in detail by Egermayer in the fourth edition of this Handbook (Egermayer 1988).

In practice, the most widely adopted function of these state QC systems was product certification, according to three quality categories or grades: highest—products whose quality reaches or surpasses the highest quality level of comparable domestic or foreign products; first—products whose characteristics satisfy the requirements of currently valid technical standards; and second—products whose characteristics do not satisfy current requirements and are of poor quality. [These categories probably correspond to those described earlier by a metalworker in a Russian steel factory, as reported by Smith (1976): first, for the military; second, for export; and third, for "common" domestic use.]

Details varied from country to country, but "highest" and "first" grade products generally carried an approval stamp of certification from a national laboratory.

Although there were official reports of general improvement in product quality as a result of this system, Egermayer (1988) reported that implementation of product certification in the CMEA countries was "not uniform, and certification results [were] not internationally valid."

Price premiums and penalties were awarded to factories, according to the outcome of product certification tests of the factory's product. These incentives were supposed to provide strong motivation and promote the interests of manufacturers in the achieving product certification and improving product quality. In fact, the effects were slight.

USSQC included direct quality control at the worker level, based on three principles: (1) The majority of errors committed by an employee on the job can be prevented, (2) every employee is responsible for the quality of work done and therefore is obliged to control it, and (3) every employee should know the exact job duties and must be given all facilities to accomplish them. As implemented, the system evolved to include worker certification for self-inspection, financial bonuses for attaining such certification, and measures of workers' quality performance.

This system was adapted to various national cultures, appearing as "Fehlerfrei Arbeit" (failure-free work) in the German Democratic Republic, "DO-RO" (shorthand for "good work" in Polish) in Poland, and so on.

The USSQC approach fit comfortably with the Soviet ideals of centralized planning and control. However, evidence is scarce of competitive results attributable to the system itself.

More on the Two-Tier System.   Some military goods were—and continue to be—successful, even in the export market. Russian rockets are an example. The rockets are now in great demand for launching commercial communications satellites. The rockets appeal to commercial customers not because of leading-edge technology (which they don't have), but because of high reliability in service, low initial cost, and ease of maintenance. These characteristics are traced to simple and rugged design, typical of many Russian military products (Broad 1996).

The story is different for consumer goods, whose reception in Western markets has been cool at best. For example, automotive products, such as Lada (U.S.S.R.), Yugo (Yugoslavia) and Daccia (Romania), and farm tractors, such as Belorus (U.S.S.R.) and Ursus (Poland), were unable, despite dramatic price advantage, to overcome their quality deficiencies in competition with Japanese and Western products.

USSQC could not achieve the stated objective of a high rate of quality improvement. The structure of incentives always favored military goods, never consumer goods. Furthermore, the system described was at complete odds with the social conditions existing in the factories. First, standards for consumer goods were technical standards, established centrally, at a great social distance and with little input from the consumers who would actually use the products involved. Second, the contribution of metrology depended largely on the appropriateness of the standards used. If the standard were not appropriate—for example, for lack of input from the consuming public—it mattered little how precisely and accurately the product was measured or how high the product scored against standard. Beyond that, the environment of chronic shortage of material and parts meant that managerial energy was concentrated on making production quotas, not on quality. Finally, emphasis on inspection was in sharp contrast to the Western experience in recent years. In the West, industrial managers have learned that it is futile to "inspect in" quality. Dependence on product inspection as a means for quality attainment has been generally abandoned in favor of control of the process by which the product is made.

Evidence of poor quality results is plentiful in technical literature from former CMEA countries, in periodicals and general literature, and in accounts of contemporary travelers. Hedrick Smith's "The Russians" (1976) and "The New Russians" (1990) treat the matter of productivity and quality as part of his studies of the Russian people.

How It Worked.   Juran (1994) summarized the Soviet approach to quality management in consumer goods with an example:

Consider a product such as shoes. A planning ministry decided what shoes to produce (styles, sizes, quantities, schedules, etc.), a production ministry made plans to produce the shoes, dividing the work among the various production facilities, a marketing ministry planned for the distribution and sale of the shoes, and the consumer bought the shoes at a retail outlet—perhaps a shop or a store at his or her place of work. The standardization ministry was responsible to create appropriate quality standards. (In fact that ministry, faced with the need for large numbers of standards, itself had a quota for the production of standards.) The enforcement branch of the standards ministry provided inspection at the factory. The factory's income depended in part on the quality level as determined by the inspectors. It was illegal to ship substandard goods.

Under this system, if a consumer discovered a defect in a pair of shoes, he or she complained to the manager of the shop where they were purchased. That complaint had to work its way up through the hierarchy of the marketing ministry—consumer to store manager to local office of the marketing ministry, then up the chain in that ministry to a minister, then into the production ministry hierarchy—say "production" to "light industry" to "shoes" and finally to the factory where the shoes were made. The process took months, and by that time the complaint might have undergone some amazing distortion along the way (see also Kamm 1995). Whether relief of the problem resulted, indeed, whether the information was of any use at all by that time, is questionable. Thus was the system in practice deprived of two vital elements of effective quality control: rapid and direct feedback on deviation from standard; and the direct input of the customer.

One characteristic of consumer commerce in the Soviet era, noted by virtually all writers on the subject of the Soviet Union's consumer marketplace, was the absence of customer orientation on the part of sellers—shop personnel and retail service providers—and the powerlessness of consumers to stimulate a change. In fact, the very word "customer" within the communist system had a whiff of the counterrevolutionary about it and was better not mentioned. The famously stoic Russian shoppers, and their counterparts throughout the region, simply bore up—stood in long lines, suffered shabby treatment at the hands of shop clerks (who, in turn, had to go out and suffer the same when they did *their* shopping), withstood the disappointment of limited selection of goods and poorly stocked store shelves—and carried on as best they could.

USSQC, its predecessor systems, and the ideology which brought them forth had 70 years in Russia and more than 40 years in the other countries of CMEA to pervade the economic systems in which they were embedded. A system so pervasive over so long a period of time cannot be easily abandoned, even now that the economies have begun a transition to something other than communism. Remnants of the system remain in the mind. The leaders of the former CMEA countries will have to assess the system, identify the parts which contribute to competitive quality, and identify and discard the parts that do not.

QUALITY MANAGEMENT TODAY AND TOMORROW

The Forces at Work.   Today, there are numerous forces at work which are sharply changing the course of quality management in central and eastern Europe.

- *Local appearance of Japanese and Western goods:*   In newly opened markets, Western products—manufactured goods, foodstuffs, even services—began to appear. They were at first too expensive for most people to afford. But their presence often created a new standard of comparison with local products.

- *Availability for purchase of Japanese and Western goods in the local market place:* With the shift to a market economy, quality standards were determined in the marketplace, not in the committee rooms and laboratories of the standards organizations. Survival of local products required action which would bring quality to levels which are competitive in the world market. The introduction of Western automobiles produced a rapid decline in marketability of those made in the region. For example, when the German Democratic Republic (East Germany) and the Federal Republic of Germany (West Germany) joined, the West German government agreed to exchange East German marks for West German at the rate of one for one. The citizens in the east who had substantial savings were suddenly enriched. Many, attracted by the superior quality of the newly available Western automobiles, bought one. The Trabant and the Wartburg, two mainstays of the East German roads, went out of business.

- *The need and desire to compete at home against Western imports:* Governments in the region know that high import tariffs to protect local industry against these imports can only be a temporary remedy. In the long term, local industry must make competitive products or suffer loss of business.

- *Need and desire to sell high-value goods on the international market:* Governments know that the key to long-term economic health is vigorous participation in the world market. World competition requires products of world-class quality.

- *Joint ventures with international corporations:* Joint ventures are proving to be effective vehicles of technology transfer in market-oriented management, including quality management.

Many successful international corporations, attracted by the market potential and the availability of a well-educated work force at low cost, have been rushing into the region for some years. They have formed local partnerships, joint ventures, and other commercial relationships which involve local people directly with foreign (Western and Asian) quality approaches, standards, and procedures, as well as with foreign goods and services. Such companies as ABB, General Electric, General Motors, Hewlett-Packard, Honda, and Toyota bring more than investment in modern physical plant; they bring business systems, including quality systems, which have been developed over decades, and which have enabled them to create products whose quality ranks among the best in the world.

An example is the introduction of Coca-Cola into Romania, described by Nash (1995). At the end of 1991, 2 years after the overthrow of the Ceacescu regime, Coke had no presence in the country. By 1994, as many as 25,000 kiosks and other small retail shops started or maintained their business because of Coca-Cola. In an interview, an economic advisor to the president of Romania said he viewed the arrival of multinational firms such as Coca-Cola as vehicles for transferring organizational and managerial skills. Coke's decision to develop local suppliers has meant that the manufacturers of bottles, plastic cases, and labels have all begun to experience Western-style quality standards and concepts.

In Moscow, within 5 years of opening in 1990, the McDonald's restaurant on Pushkin Square had become the company's busiest in the world. To achieve this, McDonald's had to develop extensive local supply of ingredients to their standards, and to train an army of servers to the company's service standards. Perhaps more significant in the long run is the emulation of the McDonald's model by another Russian restaurant, Russkoye Bistro, which presents traditional Russian food items in the same format and employing the same quality approach—fresh ingredients and good service at relatively low prices (Specter 1995).

Viewed from the local perspective, involvement in these management systems may be viewed in two ways: as an encroachment on local culture and autonomy to be resisted, or as first steps on the road to competitive quality, an opportunity to be embraced. In fact, there is evidence that each view has its adherents. The most reliable predictor of this is age, older people being likely to resist, younger ones to embrace. The older one was at the time of the shift from the old system to the new, the more difficult was the transition, hence the more likely the case for resistance. (This phenomenon is nothing new or strange, nor is it unique to the case of the change of system being discussed here. Millions of words have been written on the subject of a variety of cultural changes and the indi-

vidual behaviors they stimulated, from agricultural economy to industrial, from manual labor to machine-assisted labor, from manufacturing economy to service, and so on.)

Lorber (1993) tells of being offered advice when he took the post as manager of Hewlett Packard's new office in Prague. He was told to "forget the older people; work with the young ones." "How old is old?" he asked. His friend responded that after the age of 25 it's too late. That seemed a bleak viewpoint, but it is true that younger employees had a far easier time of adjusting to the conditions of the marketplace than those who had made their careers accommodating themselves to a different economic and political structure. The older employees require much help to learn and apply the new concepts.

Total Quality Management, Customers, and Democratic Traditions.   The concept of Total Quality Management (TQM) developed in the context of market economics and democratic tradition. In a market-based economy, the identity of the customer can be made clear, and the producer is free to use all means to ascertain (and even to influence) the customer's needs. In a centrally planned economy, decisions as to who is the customer and what are thecustomer's needs are hidden from view. The customer being the very foundation stone of TQM, the formerly planned economies seeking to establish TQM will need to restore respectability to market transactions and the word "customer," and train participants in market business basics.

Democratic tradition affects the flow of information. TQM depends on the free exchange of information within an organization. Lacking an environment which encourages such free exchange, TQM is not achievable. Where the political system discouraged free exchange, its participants must be trained to overcome the habits of guarded exchange.

TQM Criteria—The Ideal.   The principal goal of TQM is to attain competitive (or world-class) quality. The criteria of the Malcolm Baldrige National Quality Award provide a widely accepted definition of comprehensive quality management. The Baldrige criteria support a model which includes:

1. Success measured in terms of delighted customers, empowered employees, higher revenue, and lower operating costs

2. Attainment of success through management processes which include quality planning, quality control, and quality improvement

3. Organizational infrastructure on which these processes depend, including a documented quality system, customer-supplier collaboration in partnerships, involvement of everyone in the organization in the quality effort, measurement and information systems for key business variables, and education and training of all in the organization, when and as required

4. A foundation of the quality effort which includes strategic planning and management to the plan, hands-on leadership by top executives, and a focus on customers, their wants, and their needs.

These elements of the Baldrige model provide a framework for assessing an organization's ability to progress toward TQM.

TQM Criteria in Practice

Delighted Customers.   In the old regime, the concept of customer was alien, even subversive. Likewise, "consumer" had no currency. In Poland's Popular Encyclopedia of 1982, consumer was defined only in terms of the biological food chain (Lanigan and Bielska 1994). Habits of thought and behavior toward customers (or consumers), leftover from times of the single supplier and chronic shortages, still often reveal themselves in brusque customer treatment.

To delight customers, one must first recognize that customers exist and that commercial success depends on how well the customers are served. Where employees have operated in state monopolies for all of their careers, there is no reason to expect them to behave appropriately when they are suddenly thrust into the open market. This is not so different from the situation in the West, where it is not uncommon for workers who never face an external customer directly, let alone employees who

have no experience with the concept of customer, to believe that they have no customers themselves. This state of belief is one of the first hurdles for organizations to overcome in establishing an approach to quality.

It will be necessary to educate all employees—managers and workers alike—whether they deal directly with external customers or exclusively with internal ones, to view those to whom they supply product and service as customers in the commercial sense, as a means to encourage a sense of partnership in the interest of the ultimate external customer, the one who buys the finished product or service.

In Poland, the author encountered an example that typifies the changes that will come with the shift to market orientation. An assembler of automobile components, a division of a major automobile maker, provides more product for other auto makers than to its parent company. The managing director has gone so far as to separate assembly operations by floor according to customer (which also reduces the probability of confusing one customer's parts for another's), and to identify these areas by prominently displaying each customer's logo on the exterior of the building and in its designated assembly area within the building.

Empowered Employees.   In 1994, the director of a Polish factory reported that in the past, each fax message from his plant had required an authorizing management signature. Although he had announced a policy change which eliminated that signature requirement, some employees still climbed the stairs to his fourth floor office to ask for his signature. They were too accustomed to the old rules to feel comfortable ignoring them and adapting themselves to the new ones. Those employees lacked a sense of empowerment.

Employee empowerment means three things. First, that the employee is in a state of self-control, that is, able to know what is expected, know current performance as measured against those expectations, and adjust the process to bring actual performance into line with expectations. Second, the employee is able to make recovery, i.e., has freedom, within limits, to make things right when things go wrong. Third, the employee has the opportunity to participate in planning and improving the work. Key conditions of empowerment are (1) information which is both timely and accurate, (2) trust among the workers and managers, and (3) motivation to act in the interest of quality.

In a visit to a multiplant Polish manufacturing company, in plant visits and classroom meetings, it was common to be asked how to get accurate and timely information—from customers, from suppliers, from workers, from managers. Some groups asked how to get people to tell the truth. From the managers, this had the flavor of getting people to admit error. The workers seemed to suggest they were blamed for things they couldn't control. Questions like these are consistent with the formality of relationship between workers and managers and between layers of management which is, to Western eyes, extreme, and which could only impede the free flow of information within the company. (It is worth noting here that when a group of Polish supplier executives visited a progressively managed factory in Connecticut, they remarked favorably on the informality and apparent ease of communication between managers and workers.)

The questions are also consistent with the history within the company of not sharing information. This failure to share information dates from the communist period, when information was charged with political significance. Where financial information is involved, the situation is compounded by the fact that financial and cost information have never been available in a form that is useful in making decisions in the market setting. Further, there is also a history of punishing people who provided unwelcome information—a practice known in the West as "shooting the messenger." This was common during the time when the survival and promotion of managers was tied to meeting production goals, and when reporting bad news likely implicated the messenger as a barrier to meeting the goals.

As to trust, it has been frequently noted that the history of the past 50 years has seriously eroded trust in the former communist societies. Often enough, this lack of trust is reinforced by the fact that some former Party functionaries still hold positions of influence in companies that are still state-owned.

As to motivation, judging from the frequent questions on the subject directed to the author by employees and managers in Poland, there is a belief that (1) the quality effort will require more work from employees and (2) the employees should receive payment for that extra work. (Our view is that quality is an important part of every employee's job. To separate "quality work" from "normal work" is artificial and will damage the quality effort.)

Developing a remedy for these conditions will take time and patience. The management of such a company (and this one is probably typical) must first be aware of the conditions, recognize the conditions as a problem, recognize and agree on the causes of the problem, and begin setting a strategy to remove the causes. It will take education and, above all, continuous demonstration by the management at all levels that it is not only safe to participate and to share information, but that it is important for the future of the organization and the job security of everyone to do so.

For many companies enduring this transition, employee participation does not fit easily with the traditional management style. But participation is vital if they are to become as effective as they can be. This will require skilled leadership and facilitation as teams are set in motion. There are a number of basic skills in which managers will need to be trained, including finance, motivating people, identifying and valuing customers, sharing information, etc.

Employee empowerment also requires capable processes. In factories, this brings into question the ability of the existing manufacturing technologies to consistently meet the quality goals which they are supposed to meet. The problem of capability became acute in factories which were run for years without updating or even proper maintenance. This was typical throughout the automobile industry in the East.

Reduced Costs and Increased Profits. There is a more fundamental negative effect of inadequate process capability than the effect on potential employee empowerment. It is the effect on the unit cost of product—especially as the result of rework. For example, in the paint shop of one automobile factory, to paint a body in a popular metallic finish required three passes through the paint booth, with an enormous amount of hand rubbing between passes.

In an extreme case, an automobile factory in Yugoslavia was in such disarray that, as a visiting consultant reported to the author, one finished car on the assembly line had wheels loose to casual touch, another had a blue front seat and a brown back one, and all the cars emerging from the paint booth had so much airborne debris in the paint that they "looked like Brillo pads." A shortage of funds—for power lug-nut wrenches, for sufficient inventory of seats, for air filters in the paint drying booth—was offered as the common cause for all of these and other production woes. But the consultant noted that a major contributor was the absence of consistent management and supervision in the plant. In a perverse application of "worker democracy," a work group was always at liberty to replace by majority vote any supervisor with which it disagreed. Any supervisor attempting to improve production in his area became an immediate candidate for replacement. (For these and a variety of other reasons, the company was unable to market a minimally acceptable product. The company slid quietly into industrial history not long after the consultant's visit.)

Getting Started. Providing executive and managerial leadership in this quality effort is a challenge which should not be underestimated. When the transition to a market economy began, there was little experience within these countries in managing for other than production quotas. It is an encouraging sign that many managers show interest in learning what they should do to manage for quality.

If executives and managers agree on the goals on which the Baldrige criteria are based, other elements of the Baldrige model provide guidance as to *what* the organization requires to accomplish those goals—quality processes and adherence to them, infrastructure elements, and the foundation of planning, leadership, and customer focus. The matter of *how* to provide these supporting elements is more difficult. All of these elements are likely to be very different from anything the managers have experienced before, and the foundation of planning, leadership, and customer focus is probably equally novel in their experience. It must be remembered, after all, that even in the Western setting, examples of the companies conducting themselves according to the Baldrige criteria are not so common.

When the transition to a market economy began, these countries had no tradition of relationship with or dependence on a customer. The concept of customer delight and the rest must have seemed meaningless, if not absurd. There was in the West a fair amount of skepticism, if not outright pessimism, about the prospect of rapid change.

Today, there are many hopeful signs that the changes can be made. The experience of Coca Cola and McDonald's, mentioned above, are examples. Milbank (1994) reports rapidly rising exports from the region, especially from Poland, the Czech Republic, and Hungary. This rise in exports is

enabled by dramatic improvements in quality, made possible, in turn, by financial and technical help from Western partners. Three Hungarian companies are presented as examples—a printing and packaging company, a liquor distiller, and a frozen food company—all competing successfully outside their home country.

We have stated, from the customer's viewpoint, some of the things that must change to improve quality and its management in the region. There is growing number of companies that are making those changes happen. Only time will tell how fast the changes proceed and when they will be pervasive enough to put the region as a whole on a secure path to full participation in the world marketplace.

SECTION 40

QUALITY IN THE UNITED STATES

J. M. Juran

THE BACKGROUND

The economy of the United States of America (U.S.) rests mainly on a base of numerous autonomous producers and marketers of goods and services. These autonomous companies are characterized by:

1. A high concentration of industry in relatively few companies. The number of companies runs to over a million, but the top 1000 companies account for most of the goods and services produced.

2. A high degree of private ownership of these large companies. Normally, a large company will have thousands of owners, no one of whom owns more than a few percent of the company.

3. A "professional" management. The companies are run by professional managers—persons who consider their lifetime career to be that of managing. These managers become the real power in the company, since the owners are too numerous. In addition, under the prevailing legal system of boards of directors, the managers usually dominate the board. The managers and the concept of professional management are among the main strengths of the U.S. economy.

The features of autonomous companies and professional managers to run them have a considerable impact on how quality is managed. Within the flexibility permitted by the "anarchy of the marketplace,"

each company determines which products it will make or stop making, what quality policies it will employ, and so on. Innovation plays an important role throughout, owing to the rather unusual industrial history of the country.

The early European colonists faced the problems and opportunities associated with exploiting the natural resources of a huge land mass. An innovative spirit was developed in the early agricultural days, and carried over when the nation industrialized. Self-reliance and risk-taking emerged as respected traditions. These traditions then raised entrepreneurship and individualism to a state of respect. The resulting companies tended to organize in ways which assigned responsibility to individuals rather than to teams. The tradition of self-reliance also stimulated job mobility. In the U.S., workers, engineers, and managers tend to change jobs more often than their counterparts in other countries. The concept of a lifetime career has usually been viewed as being associated with a trade, a union, or a profession rather than with a specific company.

Early Systems of Managing for Quality.
Late in the eighteenth century, the colonists broke with their European rulers and established an independent United States. The domestic economy was unified by the laws governing movement of goods in interstate commerce. These laws avoided the obstacles inherent in the national boundaries then prevailing in Western Europe—passports, customs offices, import duties, and so on—that have plagued the countries of Europe for centuries. The absence of such barriers enabled the United States to become a unified common market and contributed to the speed with which the country emerged as an economic superpower.

As the colonies began to industrialize, they generally followed the craftsmanship concept which prevailed in their European country of origin. Apprentices learned a trade and qualified to become craftsmen. Achievement of quality was one of the essential skills learned by the apprentice. A major force for assuring quality of product was the village form of society in which the craftsman met face-to-face with the users. In a shop of any size, the master carried out a form of product inspection and process audit which provided added quality assurance. Alternatively, the master delegated this function to an inspector.

When the Industrial Revolution of the mid-eighteenth century was exported from Europe to the United States, the colonists again followed European practice. Many craftsmen became factory workers, and many masters became factory foremen. Quality was assured as before—by the skills of the craftsmen supplemented by supervisory audit or by departmental inspection.

The Taylor System and Its Impact.
Late in the nineteenth century many American companies broke sharply with European tradition by adopting the Taylor system of "Scientific Management." The basic concept was the separation of planning from execution. This separation made possible a considerable increase in productivity and was a major contributor to making the United States the world leader in productivity. (For elaboration, see Juran 1973.)

The Taylor system also included some adverse side effects. It dealt a crippling blow to the concept of craftsmanship. In addition, the new emphasis on productivity had a negative effect on quality. To restore the balance, the factory managers created a central Inspection department headed by a chief inspector. The various departmental inspectors were transferred to the new department over the bitter opposition of production supervisors. In due course, the inspection departments grew into broad-based organizations called variously Quality Control, Quality Assurance, Quality Management, and so on. These organizations evolved quality-oriented specialties such as quality engineering and reliability engineering.

The central activity of these quality-oriented departments remained that of inspection and test—separating good product from bad. The prime benefit of this activity was to reduce the risk that defective products would be shipped to customers. However, there were serious detriments:

This central activity of the quality department helped to foster a widespread belief that achievement of quality was the responsibility of the quality department.

In turn, this belief hampered efforts at eliminating the causes of defective products–the responsibilities were confused.

As a result, failure-prone products and incapable processes remained in force and continued to generate high costs of poor quality.

What emerged *de facto* was a concept of managing for quality somewhat as follows:

Each functional department carried out its assigned function and then delivered the result to the next function in the sequence of events.

At the end, the quality department separated the good product from the bad.

For defective product which escaped to the customer, redress was to be provided through customer service based on warranties.

By the standards of later decades, this concept of prime reliance on inspection and test was unsound. However, it was not a handicap if competitors employed the same concept, and such was usually the case. Despite the deficiencies inherent in this "concept of detection," American goods came to be well regarded as to quality. In some product lines, American companies became quality leaders. In addition, the American economy grew to superpower size. Some of this growth was achieved in ways which had implications for quality:

Entrepreneurs were on the alert to create sales in various ways: e.g., bring new, improved products to market; create additional production capacity to eliminate shortages. (Elimination of shortages also eliminates an inevitable cause of poor quality.)

Managers were willing to invest in facilities to improve productivity. Some of those investments (e.g., in machines, tools, instruments) improved quality as well.

The United States became a leader in the concept of a "professional" approach to management, involving extensive training for managers and specialists.

The growing number of quality specialists developed numerous new methods and tools specifically oriented to managing for quality. However, use of these methods was limited by the prevailing functional organization forms and, especially, by upper management's limited understanding of how to manage for quality.

WORLD WAR II AND ITS IMPACT

During World War II, American industry was faced with the added burden of producing enormous quantities of military products, many of which made use of new, sophisticated technology. However, the basic system of managing for quality remained unchanged. Each function carried out its responsibility and delivered the result to the next function in the sequence. At the end, inspection and test separated the good from the bad.

The military clients secured their quality assurance largely by additional inspection and test. Not until well after World War II did they evolve a concept of mandating the quality system to be followed by contractors.

A part of the American grand strategy during World War II was to shut off production of many civilian products: automobiles, household appliances, entertainment products, and so on. A massive shortage of goods developed amid a huge buildup of purchasing power. It took the rest of that decade (the 1940s) for supply to catch up with demand. In the interim, the manufacturing companies gave top priority to meeting delivery dates, so that quality of product went down. (Quality always goes down during shortages.) The habit of giving top priority to delivery dates then persisted long after the shortages were gone.

During this progression of events, the priority given to quality declined significantly. In addition, the leadership of the quality function became vague and confused. What emerged was a concept in which upper management became detached from the process of managing for quality. (For elaboration on the impact of World War II, see AT&T 1989, Grant 1991, Juran 1991, Wareham and Stratton 1991.)

THE JAPANESE QUALITY REVOLUTION AND ITS IMPACT

Following World War II, the Japanese embarked on a course of reaching national goals by trade rather than by military means. The major manufacturers, who had been largely involved in military production, were faced with converting to civilian products. The chief obstacle to selling these products in international markets was a national reputation for shoddy goods, created by export of poor-quality goods prior to World War II.

The Japanese adopted a variety of strategies for improving their quality. (See generally, Section 41, Quality in Japan.) In the judgment of the author, several of those strategies were decisive in creating a successful revolution in quality.

The upper managers personally took charge of leading the revolution.

They trained all levels and functions of the hierarchy in how to manage for quality.

They trained the specialists in statistical process control.

They undertook quality improvement at a continuing, revolutionary pace.

They provided means for the work force to participate in control and improvement of quality.

In the early postwar period, the affected American companies logically considered Japanese competition to be in price rather than in quality. Their response was to shift the manufacture of labor-intensive products to low-cost areas, often abroad. Then, as the years unfolded, price competition declined while quality competition increased. However, the American companies generally failed to recognize these trends or to heed the warning signals. In 1966, the author sounded an alarm at the annual conference of the European Organization for Quality Control:

The Japanese are headed for world quality leadership and will attain it in the next two decades because no one else is moving there at the same pace. (Juran 1967)

During the 1970s and 1980s, numerous Japanese manufacturers greatly increased their share of the American market. A major reason was superior quality. Many industries were affected: automobiles, consumer electronics, steel, machine tools, and so on. Some research quantified the quality differences. [See Juran 1979 (color television sets); also Garvin 1983 (room air conditioners).]

RESPONSES TO THE JAPANESE QUALITY REVOLUTION

The most obvious effect of the Japanese quality revolution was a massive export of goods to the United States. These goods were welcomed by consumers because of their superior quality along with their competitive and even lower prices. However, these same goods did much damage to other sectors of the American economy:

The affected manufacturing companies were damaged by the resulting loss of sales.

Workers and their unions were damaged by the resulting "export of jobs."

The national economy was damaged by the resulting unfavorable trade balance.

Some of the American companies' responses to the Japanese invasion had no relation to improving American competitiveness in quality.

Block the Imports. Some of the affected companies tried to respond by reducing or eliminating the imports. They urged legislators to establish restrictive import quotas and tariffs. They urged criminal prosecutions on the grounds of violation of laws against "dumping," (selling below cost, or at "less than fair value"). They filed civil lawsuits on the grounds of unfair trade practices. They appealed to the citizenry to "Buy American."

These responses did not arouse broad sympathy among the buying public. Influential journalists, economists, legislators, and others pointed out that restriction of imports generates serious side effects: Buyers are deprived of better values; restriction invites retaliatory restriction; companies have no incentive to become more competitive; and so on. (For some case examples in which import restrictions damaged the very industries they were intended to protect, see Levinson 1987.)

Reduce Costs.   Some companies viewed the problem as one of price competition, arising from the low wage rates then prevailing in Japan. Such companies responded by moving their production to low wage areas, including locations overseas. These actions often did reduce labor costs but did not solve the main problem which was competition in quality.

Give Up.   Still other companies concluded that to become competitive in quality required expenditures (in product design and process facilities) which would not yield adequate return on the investment. These companies either sold out or otherwise went out of business.

> During the 1960s, there were over 30 American-owned companies making color television sets. By the early 1990s there was only one.

INITIATIVES TO IMPROVE QUALITY

By the end of the 1970s, the American quality crisis had reached major proportions. It attracted the attention of the national legislators and administrators. It was featured prominently in the media—it was regularly "on the front page." It forced many chief executive officers (CEOs) to become involved in managing for quality.

During the 1980s, a great many American companies undertook initiatives to deal with the quality crisis. These initiatives were largely focused on three strategies:

Exhortation.   Some consultants proposed a sweeping solution by exhorting the work force to make no mistakes—to "do it right the first time." This simplistic approach was persuasive to those managers who, at the time, believed that the primary cause of their company's quality problems was the carelessness and indifference of the work force. The facts were that the bulk of the quality problems had their origin in managerial and technological processes. In due course, this approach was abandoned but not before it generated a lot of divisiveness.

Training in Statistical Methods.   During the 1980s, many American companies undertook to train company personnel in application of statistical methods to quality problems. The term "Statistical Process Control" (SPC) became the popular label for this training.

While SPC is a useful tool, most companies assumed it to be the panacea claimed by its advocates. The companies lost precious years before learning that leadership in quality comes from multiple strategies, no one of which is a panacea. To make matters worse, the training was done before the companies had identified their quality problems and defined their quality goals. In a sense, the personnel were trained in remedies before the diseases were known.

> Eastman Chemical Company, when relating its approach to managing for quality (it became a 1993 winner of the Malcolm Baldrige National Quality Award), stated that it had trained 10,000 of its personnel in SPC. However, many trainees lacked the opportunity to apply the training, so much was forgotten. (Eastman Chemical Co. 1994)

Quality Improvement, Project by Project.   One of the consulting companies, Juran Institute, Inc., created and published a series of videocassettes titled "Juran on Quality Improvement," (Juran 1980). These were tested by many companies. Some achieved notable quality improvements

while others did not. The decisive variable was the extent of personal leadership provided by the upper managers. By the end of the 1980s, the improvement process described in those videocassettes had become the basic model for the process of continuous quality improvement adopted by most companies.

Results of the Initiatives of the 1980s.   In retrospect, the quality initiatives of the 1980s were deeply disappointing. Most fell well short of their goals. Some produced negative results—the companies lost several years of potential progress. The poor results were due mainly to poor choice of strategies and to poor execution of valid strategies. In turn, these were largely traceable to the limitations of leadership by upper managers who lacked training and experience in managing for quality. In the minds of some observers, the lessons learned during the 1980s were chiefly *lessons in what not to do.*

THE ROLE MODELS

During that same disappointing decade of the 1980s, a relatively few company initiatives achieved stunning results. Such companies attained quality leadership—"world-class quality"—and thereby became the role models for the rest of the American economy.

The role models were few in number. They included the winners of the Malcolm Baldrige National Quality Award plus other companies that had achieved similar results. Together, they made up only a tiny part of the economy. Yet there were enough of these companies to prove that world-class quality is attainable within the American culture—"They did it, so it must be doable."

The successes achieved by the role-model companies stimulated great interest among upper managers and others who sought to learn how such stunning results had been achieved. The role models were quite willing to share information about the strategies they had used to achieve those results. In addition, steps were taken to share the lessons learned through company visits, conferences, publications, and so on.

LESSONS LEARNED—THE CORE STRATEGIES

Each role-model company is different. In groping for ways to attain world-class quality, each serves as a laboratory, testing out various strategies, adopting some, modifying others, rejecting still others. In this sense each role-model company is unique. Yet despite differences among the role-model companies, analysis shows that their strategies have much in common. There is *a core list of strategies* which were widely adopted by most of the role models. These core strategies, some of which are listed below, deserve careful study—they are a body of *lessons learned,* a list of the key strategies which enabled the role models to achieve those stunning results.

Customer Focus.   All role models adopted the concept that the customer has the last word on quality. Adoption of this concept then led to intensified action to identify: who are the customers, internal as well as external; what are the needs of customers; what product features are required to meet those needs; how do customers decide which of the competing products to buy; and so on. (For elaboration, see Section 3, The Quality Planning Process.)

Many quality problems of the past have been traced to failure to meet the needs of *internal* customers. As a result, customer focus is increasingly being extended to include internal as well as external customers.

A widespread example has been product designs which designers "threw over the wall" to be produced, sold, and serviced by internal customers—other company departments.

The concept of customer focus has led to broader use of the concept of participation. This minimizes the damage done when planners are unaware of (or indifferent to) the problems their plans will create

for their customers. It provides early warning—those affected are able to point out, "If you plan it that way, here are the problems we will face." The participation concept is also being extended to supplier relations, a popular label being "partnering."

Upper Managers in Charge.   One element present in all successes, and absent in most failures, was the personal involvement of the upper managers. In effect, the upper managers took charge of quality by accepting responsibility for certain roles, including:

> Serve on the Quality Council
> Establish the strategic quality goals
> Provide the needed resources
> Provide quality-oriented training
> Stimulate quality improvement
> Review progress
> Give recognition
> Revise the reward system

Many upper managers resisted such additions to their own workload. Their preference was to establish broad goals and then to urge their subordinates to meet the goals. However, the lessons learned from the role models are that *the above roles are not delegable*—they must be carried out by the upper managers, personally.

Strategic Quality Planning.   The role models recognized that the new priority given to quality requires enlarging the business plan to include quality-related goals. These goals are then "deployed" to identify the needed actions and resources, to establish responsibility for taking the actions, and so on. The resulting plans parallel those long used to meet goals for sales and profit. A common name for this concept is Strategic Quality Planning. (For elaboration, see Section 13, Strategic Deployment.)

The Concept of "Big Q."   The role models grasped the concept that managing for quality should not be limited to manufacturing companies and manufacturing processes. It should also include service companies and business processes. This concept broadens the area under the "quality umbrella." (For details, see Table 2.1 of Section 2.) Some companies call this broader concept "Big Q," in contrast to the traditional concept which they call "Little Q."

Cost of Poor Quality.   Cost of poor quality (COPQ) consists of those costs which would disappear if everything were perfect—if there were no errors, no waste, no field failures, and so on.

As upper managers were drawn into managing for quality, they learned a good deal about COPQ. Some of what they learned came as surprises.

> *Relation to Big Q:*   Many upper managers had assumed that COPQ consisted of the cost of running the quality department, or alternatively, the costs of deficient factory goods and processes. It is now widely accepted that COPQ should include costs traceable to deficiencies anywhere—deficiencies in Big Q.
>
> *COPQ is huge:*   In the early 1980s, the author estimated that in the United States, close to a third of the work done consisted of redoing what had been done before. Depending on the nature of the industry, COPQ consumed between 20 and 40 percent of the total effort. Translated into financial terms, the sums are staggering. Translated into other terms, the effects are equally staggering: delays in getting new products to market or in providing service, damage done to customer relations, damage to internal morale, and so on.

Higher quality costs less: Many upper managers have long believed that to attain higher quality requires increasing the costs. This belief is often valid as applied to "higher quality" in the sense of better product features to increase sales. The belief is seldom valid as applied to "higher quality" in the sense of less errors, less redoing, fewer field failures, and so on. In these latter cases, higher quality almost always costs less, and often a lot less.

Upper managers who have become deeply involved in managing for quality have gained new insights relative to COPQ. They came to realize that high COPQ presented an opportunity for cost reductions, at a higher return on investment than virtually any other managerial activity. (For additional discussion, see Section 8, Quality and Costs.)

Quality Improvement.   Without exception, the role models went extensively into quality improvement—most of the stunning results came from projects to improve quality. These projects extended to all activities under the Big Q umbrella. They reduced costs, raised productivity, shortened cycle times, improved customer service, and so on.

Quality improvement required special organization. The vital few projects were carried out by multifunctional teams of managers and specialists. The useful many projects were carried out at lower levels, including members of the work force.

The role models also adopted the concept that quality improvement must go on year after year—it must be woven into the company culture. To this end, they mandated that goals for quality improvement be included in the annual business plans. They also redesigned the systems of recognition and reward to give added weight to performance on quality improvement. (For elaboration, see Section 5, The Quality Improvement Process.)

Business Process Quality Management ("Re-engineering").   A major extension of quality improvement was to the area of business processes. This extension resulted from fresh thinking relative to the multifunctional processes prevalent in functional organizations.

Figure 40.1 shows the interrelation between the typical "vertical" functional organization and the "horizontal macroprocesses" through which things get done.

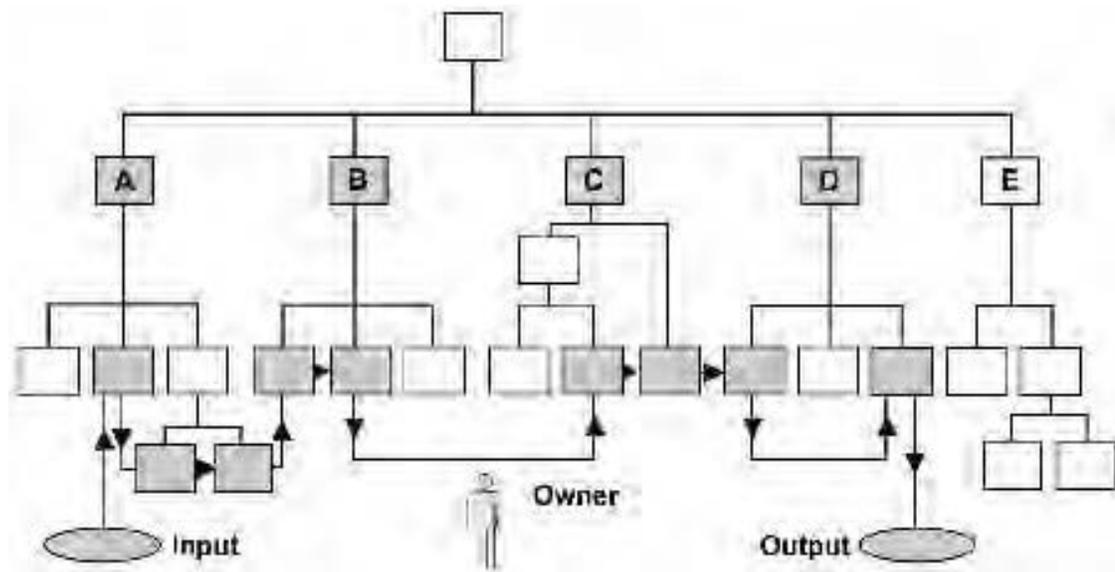
Each horizontal macroprocess consists of numerous steps or "microprocesses" which thread their way through multiple functions. Every microprocess has an "owner," but there is no clear "ownership" of the macroprocess.


FIGURE 40.1   Interrelation between "vertical" functions and "horizontal" processes. [*Adapted from Re-engineering Processes for Competitive Advantage: Business Process Quality Management, 2nd ed.* (1994). *Juran Institute, Inc., Wilton, CT, pp. 3–35.*]

The role models concluded that each key macroprocess should have an owner, and they took action to create such owners (individuals or teams). They also defined the responsibilities of an owner, including responsibility for improving the macroprocess. An important part of the "stunning results" achieved by the role models came from improvements made in the business processes. (For elaboration, see Section 6, Process Management.)

Training for Quality.   The earliest training for quality was the system of apprenticeship through which young boys became certified as craftsmen. More recently, with the proliferation of inspectors and inspection departments, there emerged training for inspectors—interpreting specifications, use of measuring instruments, and so on.

During World War II, the American government sponsored courses in statistical quality control, based on the Shewhart control chart and other tools developed by AT&T during the 1920s, (Working 1945). Following the end of the war, these courses continued to be offered by some colleges (as extension courses), by societies such as American Management Association (AMA) and the American Society for Quality Control (ASQC), and by consultants. Then, as quality departments broadened their scope, there emerged courses oriented to the functional needs of those departments: inspection and test, quality engineering, reliability engineering, and advanced courses in statistical methodology such as design of experiments and analysis of variance.

During the 1970s, there emerged the quality crisis resulting from the Japanese quality revolution. As companies tried to respond, it became clear that training for quality should not be confined to the quality department—it should be extended to all functions, and to all levels of the hierarchy. It also became clear that this extension required design of new courses, especially courses in managing for quality.

> For example, when planning a new product or process, it is usual to assign a project planner to plan for the numerous parameters: technology, finance, schedule, quality, and so on. Such planners are often experts in the technology, but seldom in planning for quality. This is known as "quality planning by amateurs." One of the remedies is to train the planners in how to plan for quality, as set out in Section 3, The Quality Planning Process.

(Some large companies extended the concept of training in managing for quality to their suppliers. They urged and even demanded that their suppliers provide training in managing for quality to the appropriate personnel).

Much of the training done during the 1980s failed to produce tangible results. The chief reasons included:

The line managers (the customers) often did not participate in the planning of the courses.

Training through exhortation (banners and slogans) was frequently counterproductive.

Training in "awareness" failed to provide employees with answers to the question "What should I do that is different from what I have been doing?"

There was overemphasis on changing attitudes and underemphasis on changing behavior.

Training in the use of tools was usually done before identifying the quality problems or setting quality goals.

Training in quality improvement consisted of training in use of statistical tools rather than by being assigned to a quality improvement team.

By the 1990s numerous course designs were available for training in managing for quality. No consensus had been reached, but three designs were in wide use:

One was based on the criteria for the Malcolm Baldrige National Quality Award.

Another was based on Deming's lectures in statistics plus his "14 points" (Deming 1986).

A third was based on the Juran Trilogy, which organizes the subject matter into three fundamental processes: quality planning, quality control, and quality improvement. (For elaboration, see Section 2, How to Think About Quality, under How to Manage for Quality: The Juran Trilogy.)

There is also a growing feeling among industrial companies that, while quality has risen greatly in importance, the national educational system has not kept up with this trend. As a result, the graduates lack knowledge of the subject, forcing the companies to fill the gap through training. Schools at all levels have begun to address this problem. In addition, some companies have set up alliances with selected schools to help redesign the curricula, provide training materials, train faculty members, and otherwise support the alliances. (For elaboration on training for quality, see Section 16, Training for Quality.)

Measurement of Quality.   Measurement of quality has long been used at the technological level. What is new is measuring quality at the business level: customer satisfaction, competitors' quality, performance of key business processes, and so on. To meet such needs may require inventing new measures as well as new methods of analysis and presentation. The need for measurement may also require creating a National Quality Index to parallel indexes already in use, such as for consumer prices, unemployment, and productivity. (For elaboration, see Section 9, Measurement, Information, and Decision-Making.)

Benchmarking.   The concept of benchmarking grew out of the need to establish quality goals based on factual analysis rather than empiricism. The approach is to discover, for the process under study, what is the best performance, whether within one's own company, or in a competitor's company, or in a completely different industry.

> For example, in one company, the best warehouse takes an average of five working days to fill customers' orders. The leading competitor takes an average of four days. A company in a different industry takes only three days. The benchmarked goal then becomes three days. There may well be a reaction "It can't be done," and this may be true as applied to the present process. However, the response is "It's being done now." So the problem is then to create (or re-create) a process which can meet the benchmark. The concept of benchmarking has been widely accepted in the United States. Progress is being made to develop data banks on what are the best known performances, and on the methods used to achieve them. (For elaboration, see Section 12, Benchmarking.)

Empowerment.   As of the early 1990s, many American companies still retained the separation of planning from execution inherent in the Taylor system of Scientific Management. Such companies were failing to make use of a huge underemployed asset—the education, experience, and creativity of the work force. It was generally agreed that the Taylor system was obsolete and should be replaced, but there was no consensus on what should replace it.

Replacing the Taylor system requires transfer of tasks from specialists and supervisors to nonsupervisory workers. The word "empowerment" has become a label for such transfer. Empowerment takes various forms, all of which have been undergoing test. The more usual forms of empowerment have included:

> *Establish worker self-control:*   This requires providing workers with all the essentials for doing good work: means of knowing what are the quality goals; means of knowing what is the actual process performance; and means for adjusting the process in the event that quality does not conform to goals. A state of self-control empowers workers to make decisions on the *process,* decisions such as: Is the process in conformance? Should the process continue to run or should it stop? Ideally, such decisions should be made by the work force. There is no shorter feedback loop.

> *Establish worker self-inspection:*   This empowers workers to make decisions on whether the *product* conforms to the quality goals. Such empowerment shortens the feedback loop, confers a greater sense of job ownership, and removes the police atmosphere created by use of inspectors.

> *Enlarge workers' jobs:*   The enlargement may be horizontal—assigning a greater assortment of tasks within the same function to reduce the monotony of short-cycle work. It may also be vertical—assigning multiple functions around the core task. A widespread example has been the training and empowerment of workers who answer telephones, to enable them to provide "one-stop shopping" to customers who call in.

Establish self-directed teams of workers: Under this concept, teams of workers are trained to conduct operations which consist of multiple functions as well as multiple tasks. The empowerment may include process planning, establishing work schedules, deciding who is to perform which tasks, recruiting new team members, maintaining discipline, and still other responsibilities formerly carried out by specialists and supervisors.

The concept of self-directed teams has been widely tested. The published results indicate that quality and productivity improve significantly. The ratio of workers to managers rises sharply. Jobs cross functional lines and become team jobs. Workers become team members. All this requires extensive training.

Because empowerment involves extensive transfer of work from supervisors and specialists to the work force, it is meeting much cultural resistance. There is also some resistance from labor unions. They sense that empowerment establishes a new communication link between management and the work force which may weaken the linkage between workers and the union.

In the view of the author, replacing the Taylor system is an idea whose time has come. It is also his view that all of the above options will grow, and that the major successor to the Taylor system will be self-directed teams of workers.

Motivation; Recognition; Reward.   To meet the new competition in quality has required company personnel to adapt to numerous changes such as:

Quality is to receive top priority.

Personnel are to accept training in various quality-related disciplines.

A new responsibility—quality improvement—is added to the traditional list of responsibilities.

The use of teams requires the personnel to learn how to behave as team members.

Generally, American companies have recognized that for such changes to be accepted, it is necessary to make revisions with respect to motivation. The companies responded by increasing the use of recognition and, to a lesser degree, by revising the reward systems.

Recognition is public acknowledgment of superior performance. The companies expanded their use of prizes, plaques, ceremonial dinners, publicity, and so on. Generally, they did this with skill and in good taste.

While recognition relates to voluntary action, the reward system relates to the mandated actions which define the job description. Here, the company responses were less sure-footed—there was no precedent on how to make the needed changes. Mostly, the companies expanded the list of parameters used annually to judge employee performance by adding a new parameter such as "performance on quality improvement." (Some companies even failed to realize that there was need for changing the reward system.)

Total Quality Management (TQM).   By the late 1980s, it was becoming clear to upper managers that competitiveness and quality leadership could not be achieved by pecking away—by bringing in this or that tool or technique. Instead, it was necessary to apply the lessons learned (from the role models) to all functions and all levels, and to do so in a coordinated way. The popular label adopted to designate that collection of lessons learned was "Total Quality Management," or TQM. (The usual Japanese term is Company Wide Quality Control.)

There has been no agreed standard definition for TQM, so communication has been confused within companies, in training courses, and in the general literature. This confusion has since been reduced by publication of the criteria used by the National Institute for Standards and Technology (NIST) to judge the applications for the United States' Malcolm Baldrige National Quality Award (Baldrige Award). NIST, Gaithersburg, MD, administers the United States Malcolm Baldrige National Quality Award.

Those criteria have been widely disseminated, NIST has filled over a million requests for application forms. While there have been relatively few applications for the award, many companies have

conducted self-audits against the criteria. In addition, as state and local quality awards have proliferated, many have used the Baldrige Award criteria as major inputs to their own list of criteria. By the early 1990s, this wide exposure had, in the opinion of the author, made the Baldrige Award criteria the most widely accepted definition of what is included in TQM.

PROGNOSIS

Until the 1980s, the prognosis for the United States was gloomy. Japanese companies had successfully invaded the American market with products which offered superior quality and value. The resulting public perception then became a force in its own right, continuing to damage those American companies who had been slow to respond.

Emergence of Role Models.   During the 1980s, the quality crisis deepened despite quality initiatives launched by many companies—most of those initiatives fell far short of their goals. The good news was the emergence of role models, discussed above, and identification of the strategies they used to become quality leaders. The job ahead then became one of scaling up—of applying those lessons learned across the entire economy, including the giant service industries—health, education, and government.

The Urge to Scale Up.   By the early 1990s, some powerful forces had converged to stimulate scaling up. The growing quality crisis had raised awareness of the subject, as did the growth of awards for quality, notably the Malcolm Baldrige National Quality Award. Self-assessment against the Baldrige criteria helped many companies to identify their strengths and weaknesses. The results achieved by the role-model companies stimulated a desire to secure similar results. The publicized "lessons learned" showed the way to get such results. The role models demanded better quality from their suppliers, who in turn transmitted those demands through the entire supplier chain. The supplier base shrank, and a major test for supplier survival was to attain world-class quality.

An additional and growing force is the increasing sophistication of American upper managers. For decades, they had been detached from the quality function—they had delegated the job of managing for quality to their quality managers. As a result, the upper managers were, in the true sense of the word, ignorant of how to manage for quality.

When the quality crisis deepened, the upper managers were forced to move in. At first their ignorance led to poor choice of strategies. But once upper managers moved in they did not remain ignorant, they learned from their mistakes as well as from the role models.

A further powerful force is waiting to emerge—the urge to "buy American." Most Americans do prefer to buy American, all other things being equal. During the 1960s and 1970s, other things were not equal, so the urge to buy American was overcome by the superior quality and value of Japanese products. We can expect the quality gap to narrow in the coming century. That will translate into growth in market share for American companies, once customer perception catches up with the realities. Some of this has happened already.

Yet another force which urges scaling up is the rise of quality to a position of prominence in the public mind. Quality has moved to center stage due to a convergence of multiple trends:

Growing public awareness of the role of quality not only in competitive trade, but also in other fields such as national defense

Pressure from consumer organizations for better quality and more responsive redress if products fail

Fear of major disasters and near disasters arising from quality failures

Growing concerns about damage to the environment

Action by the courts to impose strict liability (For elaboration, see Section 35, Quality and Society)

Limitations to Scaling Up.   Despite the forces urging scaling up, progress will be slow. The American economy is huge and, like a huge aircraft carrier, it has a great turning radius. Most companies have a sizable backlog of needed quality improvements; it will take them years to work this off. It will take additional years to improve the quality planning processes so as to minimize creating new chronic wastes.

A preview of the pace of scaling up is seen in the time required for companies to attain the status of role models. No company known to the author became a role model in less than 6 years; more usually it took 8 to 10 years. This length of time was consumed by several common steps:

Conduct a pilot test of selected strategies

Analyze the results

Make the needed mid-course corrections

Scale up

The Upcoming Century of Quality.   The twentieth century can rightly be called the Century of Productivity. During that century, the United States became the most productive country on earth, thanks in part to adoption of the Taylor system. Productivity is still an important element of competition, but meanwhile, quality has moved to center stage. The twenty-first century will probably be known as the Century of Quality.

The lessons learned from the role models have identified the principal sources of quality leadership, such as:

Upper managers take charge of quality by carrying out certain nondelegable roles. (See above, under LESSONS LEARNED—THE CORE STRATEGIES; Upper Managers in Charge.)

Quality improvement is carried out at a revolutionary rate, year after year.

In the view of the author, the United States is now well poised to share world quality leadership during the next century. The failures of the 1980s provided lessons learned about what *not* to do. The role models provided lessons learned about what *to* do. Scaling up is under way, and the pace seems to be accelerating.

Nevertheless, for this scaling up to permeate the massive size of the American economy will take decades (as it did in Japan). Moreover, public perception lags behind events, sometimes for years. It may well take another two or three decades before "Made in USA" is widely accepted as a universal symbol of world-class quality.

DEVELOPMENT OF MODERN QUALITY CONTROL IN JAPAN

Introduction of Quality Control from the United States.   Prior to World War II, Japanese research on and application of modern quality control were limited. Japanese product quality was poor relative to international levels. These poor products were sold only at ridiculously low prices, and it was difficult to secure repeat sales. Among the exceptions were the high-technology products of some Japanese companies, primarily for military use, which were manufactured without successful application of mass production techniques.

The concepts and techniques of modern quality control were introduced from the United States immediately after World War II. The General Headquarters (GHQ) of the Allied Occupation Forces in Japan was experiencing difficulties with the poor state of the country's communication systems and the defective quality and late delivery of communication equipment and components ordered from Japanese manufacturers. GHQ's Civil Communication Section (CCS) was instructed to provide communication equipment manufacturers with business management guidance, including advice on quality control. Many Japanese manufacturing companies received help from the members of the Section such as Frank Polkinghorn, Charles Protzman, W. G. Magil, and Homer Sarasohn.

CCS Course.   To bring all these efforts together, Protzman and Sarasohn ran a seminar in the autumn of 1949 called the CCS Course, mainly for the top executives of communication equipment manufacturers. This course was designed to elevate the quality of management, and quality control was a part of it (Ikezawa et al. 1990, Hopper 1985).

It was thought then that the statistical methods used in the quality control activities were very helpful, indeed, indispensable, for the reconstruction and development of Japanese industries. It should be noted that during the War, Japanese industries were almost completely destroyed. Since Japan lacks abundant natural resources and has virtually the highest population density in the world, it became an overriding national priority to design and manufacture industrial products of superior quality and export them to foreign countries. Modern quality control is the most important and indispensable tool for improving and maintaining the quality of manufactured products.

Establishment of the Japanese Union of Scientists and Engineers.   The Japanese Union of Scientists and Engineers (JUSE) was established in April 1946 and has been at the core of quality control activities in Japan (Kondo 1978). This nonprofit organization is not financially supported by, or controlled by, the government. It was established with the aim of "contributing to the development of culture and industry through the comprehensive promotion of various projects and activities needed for the advancement of science and technology." To achieve this aim, close cooperation between scientists and engineers has been emphasized, as is evident in the name of the organization.

Among JUSE's early activities was the formation of the Quality Control Research Group in 1949, which was composed of people from industry, academic institutions, and government. The same year, the Basic Quality Control Course (the first one lasting 12 months, and subsequent ones lasting 6 months) was inaugurated with the aim of reporting the Quality Control Research Group's findings to industry. The course has since been held 89 times through April 1996 and has been attended by 29,741 engineers, who went on to provide the nucleus of quality control activities in their respective companies.

A famous American, W. Edwards Deming, accepted the invitation of JUSE to visit Japan in 1950. He lectured at JUSE's 8-day quality control courses for engineers and quality control seminars for top management held in several large cities in Japan. His lectures at these seminars helped the Japanese participants to understand the importance of statistical quality control (SQC) in manufacturing industries (Deming 1986).

Deming Prizes.   In recognition of Deming's friendship and contributions to Japan, at JUSE's suggestion the Deming Prize was established in 1951 to encourage the development of quality control in Japan. JUSE serves as secretariat to the Deming Prize Committee. The Deming prizes include the Deming Prize itself and the Deming Application Prize. The former is awarded every year to a person whose contribution is judged outstanding in theoretical research work and in the practical application of statistical methods. Those who promote increased use of statistical methods in the industries are also eligible.

The Deming Application Prize is awarded every year to the companies (including public institutions) or divisions that have achieved the most distinctive improvement of performance through the implementation of company-wide quality control based on SQC. The Deming Application Prize provides a powerful incentive for Japanese companies to promote and achieve their quality control activities.

Since their inception, the prizes have been awarded to 140 companies and 5 divisions. JUSE's managing director is responsible for the procedures of awarding the Deming prizes.

Development of the Quality Control Concept into Company-Wide Quality Control. Statistical methods were found by Japanese engineers to be very effective for assigning causes of variation in manufacturing processes, clarifying the correlation between manufacturing conditions and product quality, and reducing the work force needed for inspection by introducing sampling inspection techniques, among other benefits. However, during the first decade after their introduction from the United States in the late 1940s, the application of these methods was limited only to the fields of manufacturing and inspection.

Although the application to these processes yielded remarkable results, it became clear that it was not a sufficient condition for achieving the main objective of quality control, that is, customer satisfaction. To achieve this objective, it is of course necessary not only to place more emphasis on the processes that take place before manufacturing (e.g., market surveys, research, planning, development, design, and purchasing), but also to apply the quality control approach to those that take place after inspection (e.g., packaging, storage, transportation, distribution, sales, and after-sales service).

For example, it is well known that design flaws often occupy the top position in Pareto diagrams of complaints relating to household electrical appliances. Eliminating such shortcomings, elucidating their causes and taking steps to prevent them from recurring in the design of new products are important actions not only for eliminating customer dissatisfaction, but also for improving the health and character of the company itself. More and more people began to recognize the significance of this in the mid-1950s, as trade liberalization became imminent. The importance of company-wide quality control (CWQC) was emphasized and began to be understood by manufacturers. For Japan, with its scarcity of natural resources and need to pay for them by trading in highly competitive international markets, improving product quality to levels acceptable for export was indispensable.

In 1954, Joseph M. Juran visited Japan at JUSE's invitation to hold quality control courses for top and middle managers. These courses had an immeasurably large impact on Japanese quality control in the sense that they extended the quality control philosophy to almost every area of corporate activity and clearly positioned quality control as a management tool. Taking its lead from these courses, JUSE initiated the Middle-Management Quality Control Course in 1955 and the Special Quality Control Course for Executives in 1957. These courses are improved and still held today (Ishikawa and Kondo 1969, Mizuno and Kume 1978).

Teijin Co. (a synthetic fiber manufacturer) and Sumitomo Electric Industries Co. won the Deming Application Prize in 1961 and 1962, respectively. In these companies, the quality control activities were defined broadly to include marketing, design, manufacturing, inspection, sales, and administration departments and subsidiaries, and the companies achieved outstanding—even epochal—results, for which the prizes were awarded. Their success stimulated other Japanese companies, providing them with a very powerful incentive to broaden their quality control activities.

The internal quality control audit by top management, started in many companies in the latter part of the 1950s, was also found to be very effective for promoting and improving CWQC activities. The type of CWQC practiced in Japan has two principal features. The first is the wide span of coverage of the quality control activities practiced, and the second principal feature of CWQC is total employee participation in quality control activities and ancillary activities. They are explained in more detail later.

PDCA Cycle. A usual definition of control is checking and directing action. This means comparing the actual results of an action with a standard or target, monitoring the disparity between the two, and adopting corrective measures if that disparity becomes abnormally large. This process is the familiar plan-do-check-act (PDCA) cycle shown in Figure 41.1*a*.

Following this PDCA cycle is more effective than adopting the perfectionist approach of concentrating exclusively on developing flawless plans. In addition to the factors which can be controlled accurately, usually there are many other extraneous factors likely to influence the results, and it is almost impossible to establish standards over all such factors. For this reason, even though the plan may be nearly perfect, we still need to keep on checking and taking corrective actions in this way.

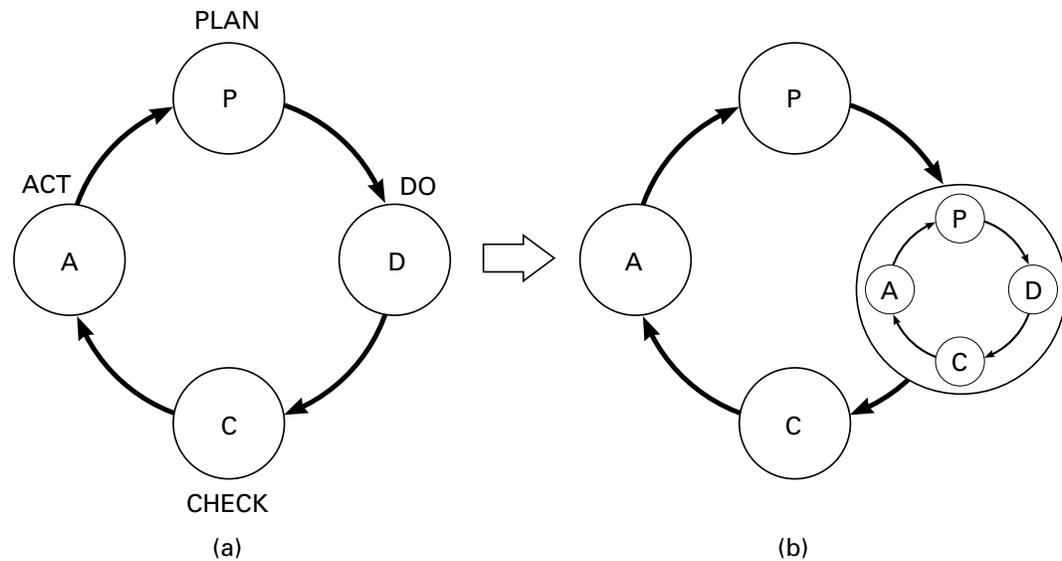
The Crosby-style exhortation to "do things right the first time" is criticized (Tsuda 1990), for if this were all that was necessary to obtain good quality, we would all have an easy time of it. But it seldom is possible to judge immediately whether things have, in fact, been done right. The PDCA


FIGURE 41.1   PDCA cycle. (*Source: Kondo 1977.*)

cycle means continually looking for a better method of doing things. By following this PDCA cycle, it is expected that the results will be obtained, and also that the process itself will be improved in an upward spiral. This leads to improvement and strengthening of the company structure.

In some forms of manufacturing planning, the quality standard and operations manual are established by the engineering staff and management, and the workers are requested only to perform their jobs in accordance with the established manual. Thus the planning and execution are separated.

In such cases, if manufactured products are found to be defective, the supervisor may seek the causes and reproach the worker. The worker may then reply, "I am not responsible for the defect. I honestly followed the operation manual that you gave me. You are responsible for the result." It is clear that when workers are responsible only for following the established manual, their responsibility for quality becomes obscure. Such vague responsibility is detrimental to high quality of conformance, which is achieved only if the workers are conscious of quality and have a keen sense of responsibility.

It is true that the workers are assigned to perform the manufacturing job. However, this job performance is also composed of a plan-do-check-act cycle, as shown in Figure 41.1*b*. The extent to which the PDCA cycle is followed in this portion of the overall job is considered to reflect the self-control of workers. Everyone is in a state of self-control to a greater or lesser extent. Thanks to this ability of self-control, we humans can enjoy our lives, including sports and leisure. Of course, education and training are to a certain extent necessary to cultivate the self-control capacity of the workers.

Regarding checking, we tend to stress identifying the deficiencies in a process. We advocate quantifying deficiencies relating to quality, quantity, and cost, and expressing them in the form of hard data, since this is the first step in improving the process. This is correct and should be strongly emphasized. However, it should be underlined that as long as processes have deficiencies they are also bound to have their opposite, that is, strengths. While it is important to identify deficiencies and prevent them from recurring by eliminating their causes, it is equally important to identify strengths and ensure their recurrence by standardizing their causes.

There are two types of corrective action—temporary and permanent. The former is aimed at results, while the latter is targeted at processes. Because temporary corrective action consists of adjusting or reworking the results of a process, it can be implemented without knowing why the abnormality occurred in the first place. Permanent corrective action, on the other hand, consists of investigating the abnormality, identifying the reasons for its occurrence, and either preventing or institutionalizing its recurrence by eliminating or standardizing its causes. This makes it essential to understand the causes. Permanent corrective action thus focuses on the process rather than on the results. The reason companies introduce and promote quality control is said to be the desire to improve company health. In order for this to happen, it is not good enough for the company simply to produce acceptable outputs; the internal processes giving rise to those outputs must also pass

muster. The permanent corrective actions we undertake every day in our workplaces may be individually insignificant, but together these small improvements can result in major improvements to the health of an entire company. In light of this, permanent corrective action is obviously far more important than temporary corrective action.

Education and Training of the First-Line Workers and the Birth of the Quality Control Circle.

The importance of the role of first-line workers has been recognized along with the progress of company-wide quality control. Without the daily efforts of those workers, the quality of conformance of manufactured products cannot be achieved. To offer training to the workers, a 13-week shortwave radio series, "Quality Control for the First-Line Supervisors," was planned and broadcast from October to December 1956, and it was continued by NHK (the Japan Broadcasting Corp.) until 1962. During the first year about 100,000 transcripts of the radio broadcast text were sold. In 1959 a weekly television series on quality control was initiated. *Quality Control Text for Foremen,* edited by K. Ishikawa, was published by JUSE in 1960, and 200,000 copies were sold before the end of 1967. Thus the education and training of supervisors and first-line workers were carried out very enthusiastically. This provided the most important basis for the birth of the quality control circle movement.

In 1962, JUSE began publishing the monthly magazine *Gemba-to-QC* (*Quality Control for Foremen*) as a sister magazine of *Hinshitsu Kanri* (*Statistical Quality Control*), which began publication in 1950. This new publication aimed at

1. Education and training of supervisors and workers and dissemination of statistical methods among them
2. Formation of quality control circles
3. Application of the workers' knowledge to their own daily jobs, attainment of the set target, and elevation of their own capability

A quality control circle consists of a group of workers and a foreman who voluntarily meet to solve job-oriented quality problems. These activities are intended to be tightly linked with company-wide quality control activities. The quality control circle activities are the quality control activities of the first-line workers on the shop floor, who are responsible for attainment of the design quality of manufactured products. Quality control circle members study activities on the shop floor, using the *Hinshitsu Kanri* magazine as a textbook, and they thus become the core of the activities.

In May 1962, the first quality control circle was registered at the Quality Control Circle Headquarters of JUSE in Tokyo, and thereafter the number of quality control circles and the number of members have been increasing year after year. The number of registered quality control circles at the end of May 1996 was 397,216; registered members numbered 3,038,038.

Recognition of the daily efforts of quality control circle members is important, and JUSE undertook to organize quality control circle conferences for presentation of the members' case studies. The first Foremen's Quality Control Conference was held in Tokyo in November 1962, which was the third nationwide Quality Month; 12 papers were presented and 235 foremen attended. In parallel with this annual conference, the first nationwide Quality Control Circle Conference was held in May 1963, where 19 papers were read and 193 people attended. These conferences and local quality control circle meetings have continued with great success. Mutual visits and discussions among quality control circle members from different companies were also revealed to be very effective in motivating the workers and broadening their viewpoints. These visits were started in March 1963, and JUSE assists in arranging them when its services are requested.

According to the Quality Control Circle *Koryo* (*General Principles of the Quality Control Circles*), published by JUSE in 1980 and revised in 1990 and 1995, the major purposes of the quality control circle movement are

1. To improve the leadership and management abilities of the foremen and first-line supervisors in the workshop and to encourage improvement by self-development
2. To increase employee morale and simultaneously create an environment in which everyone is more conscious of quality problems and the need for improvement
3. To function as a nucleus for company-wide quality control (CWQC) at the workshop level

The basic goals behind these immediate purposes are

1. To display human capabilities fully and eventually to draw out unlimited possibilities
2. To develop respect for humanity and build a happy, bright workshop, which is meaningful to work in
3. To contribute to the improvement and development for the enterprise

As recommended by Juran, JUSE has been sending foremen's quality control teams composed of quality control circle leaders and members abroad since 1968. They visit various plants in foreign countries and present papers on their own case studies in the workshop at various conferences and meetings. The Quality Control Circle Cruising Seminar was also started in 1971; the members spend two weeks on a boat trip and attend seminars and discussion meetings held on the boat. They visit various countries in Southeast Asia during the trip.

Regarding the major effects of quality control circle activities, it can be said in the first place that the willingness, creativity, and viewpoints of first-line workers are enhanced or broadened, which results in the formation of centers of quality control activities in the manufacturing process. The elevation of morale and the improvement of human relations among workers are clear. The reduction of manufacturing defects is always evident, and this brings out the elevated level of quality assurance. Thus the engineers and staff personnel can, without any worry, entrust to the foremen and workers the greatest part of their daily duties as troubleshooters in the manufacturing line, and they can concentrate their efforts on their own proper duties (development of new products and techniques, etc.)

The recent quality control circle activities are further marked by the following features (Kondo 1976):

1. *Division of a quality control circle into subcircles and minicircles:*   As study among workers progresses and their capabilities are enhanced, the quality control circles are often divided into smaller circles. Some workers become the leaders of these smaller circles, to which the foremen, who were the former leaders of the larger quality control circles, serve as advisors and promoters.

2. *Formation of joint quality control circles:*   Joint quality control circles are also often organized by combining quality control circles along manufacturing lines or quality control circles of manufacturing and inspection, etc. These joint quality control circles are effective in finding and solving new quality problems.

3. *Service of workers as quality control circle leaders:*   Formerly, it was the custom for the foremen to be elected as the quality control circle leader. However, as the quality control circle members progressed in their studies, many of them assumed prominent leadership roles in quality control circles. In many Japanese companies it became customary to rotate the leadership among the quality control circle members.

4. *Establishment of autonomous administrative systems in quality control circle activities:*   Conferences and meetings of quality control circles are always conducted by the attending members who were assigned as the session moderators. The company staff members and university professors serve only as the advisors.

5. *Expansion of quality control circle themes:*   The themes being chosen include not only the reduction of defects, elevation of productivity, and reduction of manufacturing and inspection costs, but also improvements in preventive maintenance jobs, the manufacturing schedule, and other aspects of production.

6. *Improvement of techniques employed:*   In quality control circle activities the elementary statistical tools are called the "seven tools." These are: stratification of data, Pareto diagram, checksheet, histogram, cause-and-effect diagram, graphs such as control charts, and scatter diagram. In addition, techniques such as regression analysis, process capability studies, analysis of variance, and value analysis are being used.

7. *Quality control circle activities in supporting operations:*   Quality control circles are being formed, and their activities are becoming broader, not only in manufacturing and inspection workshops but also in supporting services such as warehousing, transportation, purchasing,

administration, reception, and telephone operation. The above-mentioned statistical methods are helpful and effective in quality control circles in these areas.

8. *Quality control circle activities in subsidiary companies:*   Quality control circle activities in subsidiaries that make parts and components or carry out an intermediate manufacturing process are recognized to be very important, in fact indispensable, for ensuring product quality, and parent companies are encouraging the formation of quality control circles in their subsidiaries. Mutual visits and discussion among quality control circle members from the parent company and from its subsidiaries are always effective in identifying and solving quality problems.

Along with the expansion of company-wide quality control activities in the service industries in Japan, quality control circles are becoming active and effective in hospitals and in companies that operate hotels, restaurants, banks, department stores, supermarkets, retail stores, etc.

Quality Revolution in Japanese Industry—Breakthrough.   At the end of World War II, the former Japanese military and political leaders were no longer in power, having been replaced in large part by relatively young industrialists who wanted Japan to advance as an industrialized country and not to fall back into the old agricultural economy of the type prevalent in some parts of developing countries. After this decision was made, however, they faced a difficult road. Poor product quality was a principal obstacle; no one wanted to repeatedly buy such low-quality goods. For a country so lacking in raw materials, the inability to sell finished goods for export also meant an inability to earn foreign currency and hence an inability to buy the materials needed to create an upward spiral of industrial development. Thus a revolution in product quality became essential (Juran 1981). This quality revolution has been taking place in Japan since the early 1950s as the result of efforts to apply the concepts and techniques of statistical quality control on a company-wide scale. Three of the principal reasons often cited as to why this has been relatively easy to accomplish in Japan are as follows.

1. Japan is a uniform society composed of people of the same race who speak the same language.

2. Japan has a comprehensive system of compulsory education, and the general education level is high.

3. Japanese companies practice the custom of lifetime employment and the turnover rate of employees is therefore low.

Of these three, the second is likely to continue in the future and education levels may well improve even further. However, labor shortages are becoming more and more severe and it is impossible to say whether the first will continue to hold, although this will depend on how the labor shortages are dealt with. Even the third may not apply so strongly in the future as more young people become reluctant to take up employment in industry and those who do so tend to change jobs more frequently. It is important to keep a watchful eye on these trends. Various other reasons are given in addition to the above three.

In Japan, apart from a limited number of occupations such as medicine and the law, professionalism is not so strongly entrenched as it is in the Western countries. Each of the unique features of these countries has its own particular advantages and disadvantages, but their existence gives rise to some noteworthy differences.

For example, in the United States, people improve their status by moving from company to company without changing their specialty to any great extent. In contrast, in Japan, although there may be exceptions, people typically get promoted by changing jobs within the same company. This process of promotion makes it necessary for them to learn a series of different jobs, so in one way it may be rather hard on them. However, the richer experience within the company and the deeper understanding they gain of the relationships among different departments are great advantages. The fact that the custom of lifetime employment continues in Japan even today, whether or not it will in the future, may be because this in-company promotion process gives people the opportunity to experience a wide range of different jobs and helps them remain interested in their work over a long period of time.

The quality revolution was indispensable for the survival of Japanese industries. However, the following "trade-off argument" is often commonplace:

Improving quality is a good thing, but it raises costs, so it needs to be done judiciously.

There is an optimum to quality of conformance with regard to the manufacturing cost. As shown by the solid line in Figure 41.2, increased conformance reduces the losses incurred by defects, but the cost of quality improvement needed for greater conformance rises sharply as quality approaches the perfect state. Thus the optimum should always fall short of perfection because the total cost soars as the percent defective approaches zero.

However, the above optimum is doubtful. Both basic manufacturing cost and losses incurred by defects are easily defined, but the cost of quality improvement is usually indefinable. When creative ideas by which we can increase the conformance with less additional cost are introduced, the curve of quality improvement cost is shifted down as shown with broken lines in the figure. Then the total cost can be reduced, and the optimum moves toward zero defect. Thus the optimum is indefinable and movable. We must really search for the ways and means by which we can reduce the defects with minimum cost, instead of trying to find the indefinable optimum. It may be said that this approach is a "breakthrough," which is quite different from the superficial optimization. It is clear that the successful breakthrough is always accompanied by the creative idea and strong will of the people concerned (Kondo 1977).

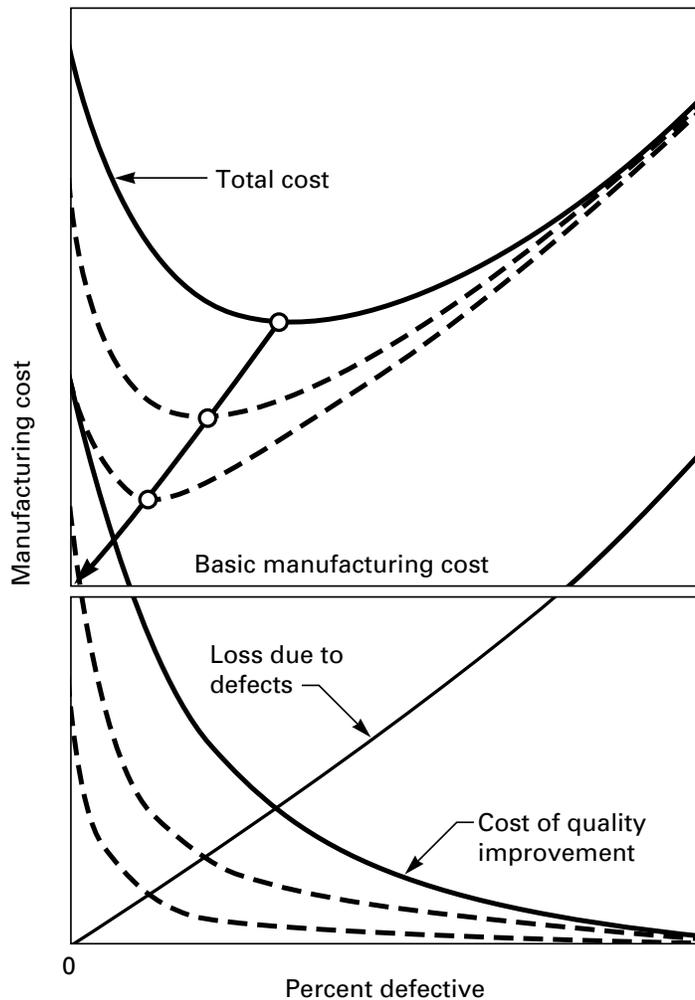
Dividing quality into two categories of must-be quality and attractive quality is an important step to attain customer satisfaction (Kano et al. 1984). As described later, the former quality can be related to the reduction of cost and the latter concerns the enlargement of market size and share and the increase of profit. Thorough investigation of both qualities is indispensable for the quality revolution.


FIGURE 41.2   Plausible optimum of manufacturing cost. (*Source: Kondo 1977.*)

Juran (1981) summarized three features of quality control activities in Japanese industries that created the revolution in quality:

1. A massive quality-related training program
2. Annual programs of quality improvement
3. Upper management leadership of the quality function

Company-Wide Quality Control after the Energy Crises.   Although there were variations among countries and industries, the world economy in general showed significant growth from the latter half of the 1960s to the early 1970s. This rapid growth was checked by the first and second energy crises, in 1973 and 1979, respectively. Japan is particularly vulnerable economically, since it depends on other countries for its supplies of crude oil and other natural resources. During the energy crises, there were even attempts in some quarters to corner the market in goods such as detergents and toilet paper, but the Japanese government and individual companies took various steps to deal with the situation.

The energy-saving measures introduced during that time can be broadly divided into energy saving in manufacturing processes and the like, and the creation of energy-saving products. In addition, companies had to institute a wide range of countermeasures on an organizationwide scale. These measures included providing education and training for the surplus personnel they now had in their production and engineering departments (as a result of the drop in manufacturing volumes) and assigning them to sales departments to provide extra support. Various benefits accrued from giving a higher priority to these kinds of countermeasures. For example, engineering staffs dispatched to sales departments were able to obtain a better understanding of the market, and the education and training programs carried out by companies enabled them to speed up production extremely rapidly when the economic good times returned.

The Japanese economy was subsequently rocked by the rapid appreciation in the value of the yen. However, many Japanese companies were able to emerge stronger each time they came through one of these difficult experiences. In this sense, the energy crises in the 1970s could be regarded as heralding the new dawn of the 1980s and 1990s.

According to Juran (1981), by the mid-1970s the Japanese had caught up with their Western counterparts in terms of creating quality products. The successful efforts made by Japanese industry to cope with the energy crises and to create quality products could probably be considered early indicators of the industrial restructuring that was to take place in Japan beginning in the early 1980s. In addition, these efforts and the restructurings are evidence of the realization by the Japanese that they were in the process of surpassing other countries and becoming a world leader in terms of product quality, and point to Japan's new sense of mission and responsibility.

Since the early 1980s, diversification of business has been a common feature of Japanese companies. However, expansion into a new area of business is accomplished in a distinctly Japanese way. While a company may be extremely enthusiastic about the move into a new line of business, and while this move may mean reducing involvement in an old, mature business, it is only in exceptional circumstances that the company abandons the old business completely. This is because Japanese companies tend to feel that they ought to continue with a business as long as some customers still require them to, even if the business has matured and demand has shrunk. Many companies even continue to actively develop new products in these mature fields with considerable success.

A notable difference between Japan and Western attitudes toward companies is that in Japan, even privately owned firms are regarded more as public institutions than as their owners' possessions. Japanese executives appear to feel more strongly that they are stewarding their companies for the benefit of society.

An interesting feature of new product development in Japanese companies is the active development of applications, particularly nonmilitary ones, for new products. Compared with new products for military use, products for the civilian sector are not subject to as rigorous usage conditions and generally have lower quality and reliability requirements. However, the demand for products in the civilian sector is far greater than that for the military, making it easier for industries to become

established in this sector. There are also more opportunities for producing improved versions of products, and it is easy to obtain quality information under a variety of usage conditions. The development of carbon fibers for use in fishing rods and tennis rackets is a good example.

Because of intense competition in global and domestic markets, a company's ability to develop new products and technology became an important and indispensable factor determining its competitive advantage. It became extremely difficult for a company without this kind of ability to ensure its continued growth through diversification and entry into new business fields. In the hope of making some important gains, more and more Japanese companies are establishing research and development facilities in Japan and overseas.

Japan's direct overseas investment began to increase in the latter half of the 1960s, and the rate of increase has been particularly high since the late 1980s. This overseas activity builds on a long and successful experience of joint ventures between Japanese and foreign corporations going back to the 1970s. It is interesting to see that there are many examples in which the excellent quality management activities of a Japanese subsidiary have had beneficial effects on their overseas parent companies and have contributed greatly to the promotion of quality management in those companies. In fact, the joint ventures of Aisin Warner, Fuji Xerox, Yokogawa-Hewlett-Packard, and the Bipolar Department of Texas Instruments, Japan, have won the Deming Application Prize, and they have accelerated the progress of quality management in their parent companies.

After being invited in 1961 by the government of Thailand to manufacture dry cells there, Matsushita Electric Industries faced up to and overcame many difficulties in making the business a success (Tsutsumi 1988, 1991). The company used this valuable experience to formulate the following basic policy regarding its overseas operations:

1. We will conduct the sort of business operations that will be welcomed by our host country.

2. We will execute our business activities in accordance with the policies of the host nation's government. At the same time, we will make constant daily efforts to ensure that the host country's government fully understands Matsushita's philosophy.

3. We will promote thorough localization of people, materials, finance, and know-how in the local community in the spirit of responsible self-management.

For this purpose, Matsushita intends to foster a positive participative outlook in a desire for improvement on the part of local employees. It ensures that all employees enjoy their daily work and find it worthwhile and engenders a sense of responsibility toward their manufacturing activities. Matsushita encourages them to see that they are contributing to their own country's development through those activities. These basic policies are backed up by specific strategies actively promoted in each of Matsushita's overseas companies.

In this way, more and more Japanese companies are setting up manufacturing operations abroad, and more and more of the components and materials used in Japan are being purchased overseas. How to use the CWQC expertise effectively in this kind of global industry, particularly in Japanese overseas manufacturing operations, is an important subject that will probably require continued investigation.

Deming Application Prize for Overseas Companies.   Originally the Deming Application Prize was for Japanese companies only. However, companies from countries outside Japan expressed a strong interest in it. In response, the Deming Prize Committee drafted new regulations for the operation of the Deming Application Prize in 1984, making it possible for companies from countries outside Japan to apply. This opened the door for overseas companies passing the examination to receive the Deming Application Prize for Overseas Companies. The first company to win this prize was the American electricity utility Florida Power and Light Company, in 1989. The next was Philips Taiwan, in 1991, and the third was AT&T Power Systems in the United States, in 1994. These successes, which indicated Japanese management systems can be applied to any kind of industry anywhere in the world, attracted worldwide interest.

COMPANY-WIDE QUALITY CONTROL IN JAPAN

Two Basic Features of Japanese Company-Wide Quality Control.   Japanese quality control activities have been gradually broadened from the narrow fields of manufacturing and inspection to almost all company branches. As mentioned earlier, it became widely known that achievement of "fitness for use and environment" is important to ensure product quality and to secure customer satisfaction and that it is realized by improving not only the quality of conformance but also the quality of design.

The Deming Prize Committee for example, defined the company-wide quality control as follows:

> It is the activity of economically designing, producing, and supplying products and services of the quality demanded by customers, based on customer-focused principles and with full consideration of the public welfare. It achieves corporate objectives through the efficient repetition of the PDCA cycle of planning, implementation, evaluation, and corrective action, doing so by means of the understanding and application of the statistical approach and statistical methods by all employees to all activities for assuring quality, where such activities include the chain of activities comprising survey, research, development, design, purchasing, production, inspection, and marketing, together with all other related activities both inside and outside the company.

Quality control activities in Japanese industries were expanded in the 1960s (Ishikawa 1965) to:

1. Establishing the top management policy on quality and the long-term quality control plan of the entire company to realize the policy
2. Introducing the quality control concept and techniques into new-product development
3. Establishing the quality assurance system, which covers the whole company
4. Conducting quality control audits
5. Expanding quality control activities to include the sales and marketing activities of the agents, the trading firms, the stores and shops, etc.

A second feature of Japanese quality control is the willingness of employees to participate in the quality control activities of the company. For example, the quality control circle movement, discussed before, came from this idea. In Japanese companies quality control activities are not restricted to quality control staff but include all personnel of the company, from the president to the factory workers and the sales persons. Among them, the leadership of top management is indispensable for launching and continuing the activities. Thus the quality control activities in Japanese companies, which we call "company-wide quality control," is a movement that involves the entire company.

Company-Wide Quality Control Education and Training.   Study of and education in modern quality control were started in Japan in 1949. It was a prevailing thought then among the members of the Quality Control Research Group in JUSE that a Japanese model of quality control should be established because of differences in background and cultural pattern between Japan and Western countries (Ishikawa 1972). For example, company-wide quality control, in which all company employees participate, is a specifically Japanese approach. The concept of professionalism, which is rather widespread in Western countries, had not yet been established in Japan as of 1949.

Introduction and promotion of company-wide quality control led to a revolution in management philosophy, which required lengthy, persevering efforts in education and training. Thus, since the early 1950s education and training in quality control have been continued for everyone from top management to first-line workers in each and every department, including research and development, designing, manufacturing, inspection, purchasing, marketing, sales, and administration. As an example, training courses that have been held by JUSE are summarized in Table 41.1. Currently there are more than 60 quality control training courses of different kinds, which are held regularly by

nonprofit organizations such as JUSE, Japanese Standards Association (JSA), and the Association for Overseas Technical Scholarship (AOTS).

Furthermore, many Japanese companies are enthusiastic about quality control education for the employees of both the parent company and the subsidiaries. Many companies have their own education and training programs. Education and training in company-wide quality control usually start with top management and are then extended to middle management, supervisors, and first-line workers. It is often emphasized that the progress of company-wide quality control exactly reflects the leadership of the company's top management.

On-the-job training is also emphasized. One example is the training that results from internal quality control audits by top management, which are effective in obtaining the facts within the company and lead to appropriate corrective actions. Another example is the on-the-job training of engineers. Concerning the training of engineers who design color television sets, Juran (1978) commented as follows:

> A second aspect of training of designers is "practical experience." One major area for such experience is in the production shop, to give the designers an awareness of some of the realities faced by the production personnel and thereby to give them a better understanding of how to design for "producibility." A second major area for designer experience acquisition is in field service work. Through such experience, the designers learn much about the conditions of use, the problems of diagnosing field failures, the difficulties of making repairs, etc. As a result, they understand better how to design for reliability and maintainability.
>
> With respect to such "training by practical experience," there are wide differences between Japan and the West. It is common, though not invariable, for Japanese companies to require that designers acquire such shop and field experiences before being assigned to key responsibilities in product design. In the West the requirement for such experience is unusual.

For the above-mentioned purposes of broadening the viewpoint of designers and engineers, job rotation of employees is also emphasized in Japanese companies. The lack of established professionalism in Japanese society is thought favorable for this rotation.

Policy Management ("Hoisin Kanri") in Japanese Companies.

Quality control activity in Japanese industries is company-wide, and top management personnel are in the position of leading and promoting the quality control activities of their companies. They are responsible for deciding top policy on quality of manufactured products and service and for establishing the long-term plan of company-wide quality control in order to realize that policy. In addition, they evaluate whether the policy and the plan are being realized on schedule and whether any corrective actions need to be taken by top management. These activities are a form of company-wide PDCA cycle and are called "policy management" ("hoisin kanri") in Japanese industries. This concept of policy management is followed in many but not all Japanese companies. Internal quality control audits by top management, which will be described later, are an effective way to evaluate the results as a basis for appropriate corrective actions.

Recently, many Japanese companies have undertaken to investigate and decide at the start of every fiscal year what their long-term plans and targets will be for the coming 3 to 5 years, the plan and target for the first year being set to coincide with the present fiscal year. In this way, long-term plans are taken into consideration in establishing each annual or semiannual plan and target.

A company's basic business philosophy is of fundamental importance, since it underpins the enterprise's annual and long-term policies and provides its employees with a standard by which to measure their behavior. In the future, it will probably become of even greater importance for every company to work out a philosophy that can be accepted and bought into by all its employees, is regarded as an attractive feature by its customers, and forms the basis of goals shared by its entire work force.

The company's basic philosophy has a close bearing on the quality created by the company. Quality has had a far longer history in the life of humankind than either cost of productivity, and is the only one of the three that is a common concern of both company and customers (Kondo 1988). It is for reasons such as these that quality is regarded as a more human concept than cost or productivity. From now on, while quality may not be everything, it will almost certainly be an essential

attribute that can attract customers and act as the focus of a shared commitment on the part of all employees. As described before, quality improvements effected by creative methods result in lower cost and higher productivity and the development of new products with attractive qualities that meet customers' true needs, expand markets, and increase corporate profitability.

It is extremely important for the upper managers to tell everyone in the company their basic philosophy regarding the quality of the products and services their company offers, and the quality management activities the company is undertaking to ensure that quality. This quality policy forms the guidelines for establishing specific quality targets for new products and quality improvement plans for existing products in the course of policy management.

It is widely understood that planning should be results-oriented rather than procedure-oriented. For example, a plan to extend standardization might at the end of the year have produced 100 new procedure manuals. If all this effort failed to improve operating results, this would be evidence that the plan had been procedure-oriented. At the investigation and discussion stage of the draft annual plan, the persons concerned are encouraged to offer many alternative proposals. It is of great importance at this stage to discuss thoroughly the true aim of the proposals and to clarify the "resultant present problem." The above-mentioned extension of standardization is merely a procedure. The high percentage of defects and rework, low productivity and yield, etc., are the resultant present problems. After the resultant problems become clear, data are collected and analyzed. The "vital few" problems can be further determined with a Pareto diagram. Two-stage Pareto analysis always makes the problems and the corrective actions clearer. Once a procedure-oriented policy such as that described above has been converted to a results-oriented policy, the resultant policy consists of the following three items:

1. *Aims:*   The reasons why the policy should be implemented
2. *Goals:*   The direction to move in, how far to go, and the deadline
3. *Priority procedure:*   The methods to be used

Goals should be inspiring; if not, people do not give them serious attention, and they are not achieved. Two Japanese examples are given here.

At the Car Radio Division of Matsushita Electric Industries Co., engineers and staff personnel up to the division manager were discussing an unattained goal of 10 percent price reduction for a car radio as requested by an automobile company. When former President Konosuke Matsushita visited the division, he was told of the situation. He said, "You should consider 15 percent cost reduction when you are requested by a customer to reduce the price by 10 percent." Because he was the founder of the company and was esteemed as a "godfather" by all employees, they started to investigate cost reduction possibilities more thoroughly and finally achieved a 13 percent reduction. After hearing of this success, Matsushita visited the automobile company and expressed his appreciation by saying, "Thanks to your request for a 10 percent price reduction, we have succeeded in achieving a 13 percent cost reduction. Thank you very much for that."

At the Nankai Plant of Bando Chemical Co. near Osaka, where V-shaped belts are manufactured, it was previously the custom for the plant manager to announce the monthly production target and to urge the work force to achieve this target. However, the target was never achieved even though the employees exerted all possible efforts, especially toward the end of every month. On the advice of an outside consultant, the plant management changed the procedure for determining the monthly target by having the plant manager prepare a draft target and ask the work force in every workshop to thoroughly investigate the possibility and the ways and means of attaining the target. In the early stage of this revised procedure, the sum of the individual targets proposed by the work force was more demanding than the draft target indicated by the manager. The plant manager, however, established the proposals of the work force as the targets of the month because they were the result of their thorough investigations. Interestingly, the work force always achieved their targets. Moreover, a few months later the overall target proposed by the work force started to rise month after month, and in half a year or so it even exceeded the previously unmet target of the manager.

There are two ways of determining the target, from the top down and from the bottom up. The example of Matsushita is top-down, and the case of Bando is bottom-up. Both of these were very

successful. Top management is always concerned about the future of the company, and the top-down target is usually determined from the company's needs. On the other hand, the employees usually investigate the draft target indicated by the top management from the viewpoint of feasibility. If the draft target is not investigated thoroughly by the employees, they easily find their own good excuses when it is not achieved.

Many Japanese companies, during annual or semiannual planning, adopt a combination of top-down and bottom-up approaches. Top management prepares a draft plan, which then is discussed, for example, among the top managers and the division managers. From this discussion the draft plans of each division are made. The draft plan of each division is then further discussed among the divisional and lower managers and finally among the supervisors and quality control circle leaders. After these investigations and discussions, the detailed draft plans are formulated. They are brought to the top management, which decides on the final annual plan of the company. This procedure of deploying the annual or semiannual planning throughout the company is called "playing catch" in Japanese companies. The procedure is believed to be effective in establishing the annual plan, although it is somewhat time-consuming. Through this procedure, what was a norm enforced by top management is revised to become the voluntary target of each employee. This revision is extremely important for motivation.

The establishment of results-oriented plans makes evaluation easier, and the characteristics used in the targets become the basis for review by the respective managers. Corrective actions are cooperative. When it becomes clear that a target will not be achieved, for example, companies often assign additional budget, work force, etc., in order to attain the target within the time limit. Although this may be called a type of corrective action, it is actually a superficial countermeasure, or adjustment. A matter of greater importance is to detect the assignable causes by which failures, defects, rework, delays, etc., are created and to remove them from the process. This is the action of "cause removal," which is essential for improving the basic process.

An example of the breakdown of a broad goal into subgoals is that of Komatsu Ltd., a manufacturer of construction machinery. This company originated the "flag diagram" by skillfully combining the Pareto and Ishikawa diagrams (see Kondo 1977). An example is shown in Figure 41.3.

This diagram shows machining time classified into several major items according to the Pareto principle. Each item is further broken down into the respective secondary items. The target line is drawn in the diagram of each item. The subsequent performance is also plotted in the same diagram and compared with the respective target. Each diagram becomes an item for review by the responsible manager and for appropriate corrective action in the event of significant deviations in performance. Such diagrams make it easier for all employees involved to understand their own situations, the roles of their colleagues, and the interrelationship among them. Such understanding contributes to the common interest. New and worthwhile ideas are easily born from discussions among employees who have common interests and yet can see the problems from different viewpoints.

Internal Quality Control Audit by Top Management.   Internal quality control audit by top management is one of the outstanding features of Japanese company-wide quality control (Kondo 1969). It is carried out in ways similar to the activities of checking and taking corrective actions in the policy management discussed above. The aim of this internal quality control audit differs from that of the external audit—its purpose is not merely for the employees "to pass the examination" but to stimulate mutual discussion between the auditors and the people involved in order to find ways and means to improve the present situation. Corrective actions on both sides are required. Thus the internal audit is educational in character, involving on-the-job training as well as the survey itself. It may be defined as follows: The internal quality control audit is a study of the present situation regarding the system of company-wide quality control and the quality functions of whole processes in order to find and take the necessary corrective actions. This is the reason why many Japanese companies prefer to call the internal quality control audit the "quality control diagnosis" or the "discussion meeting of [those performing] quality control activities with top management."

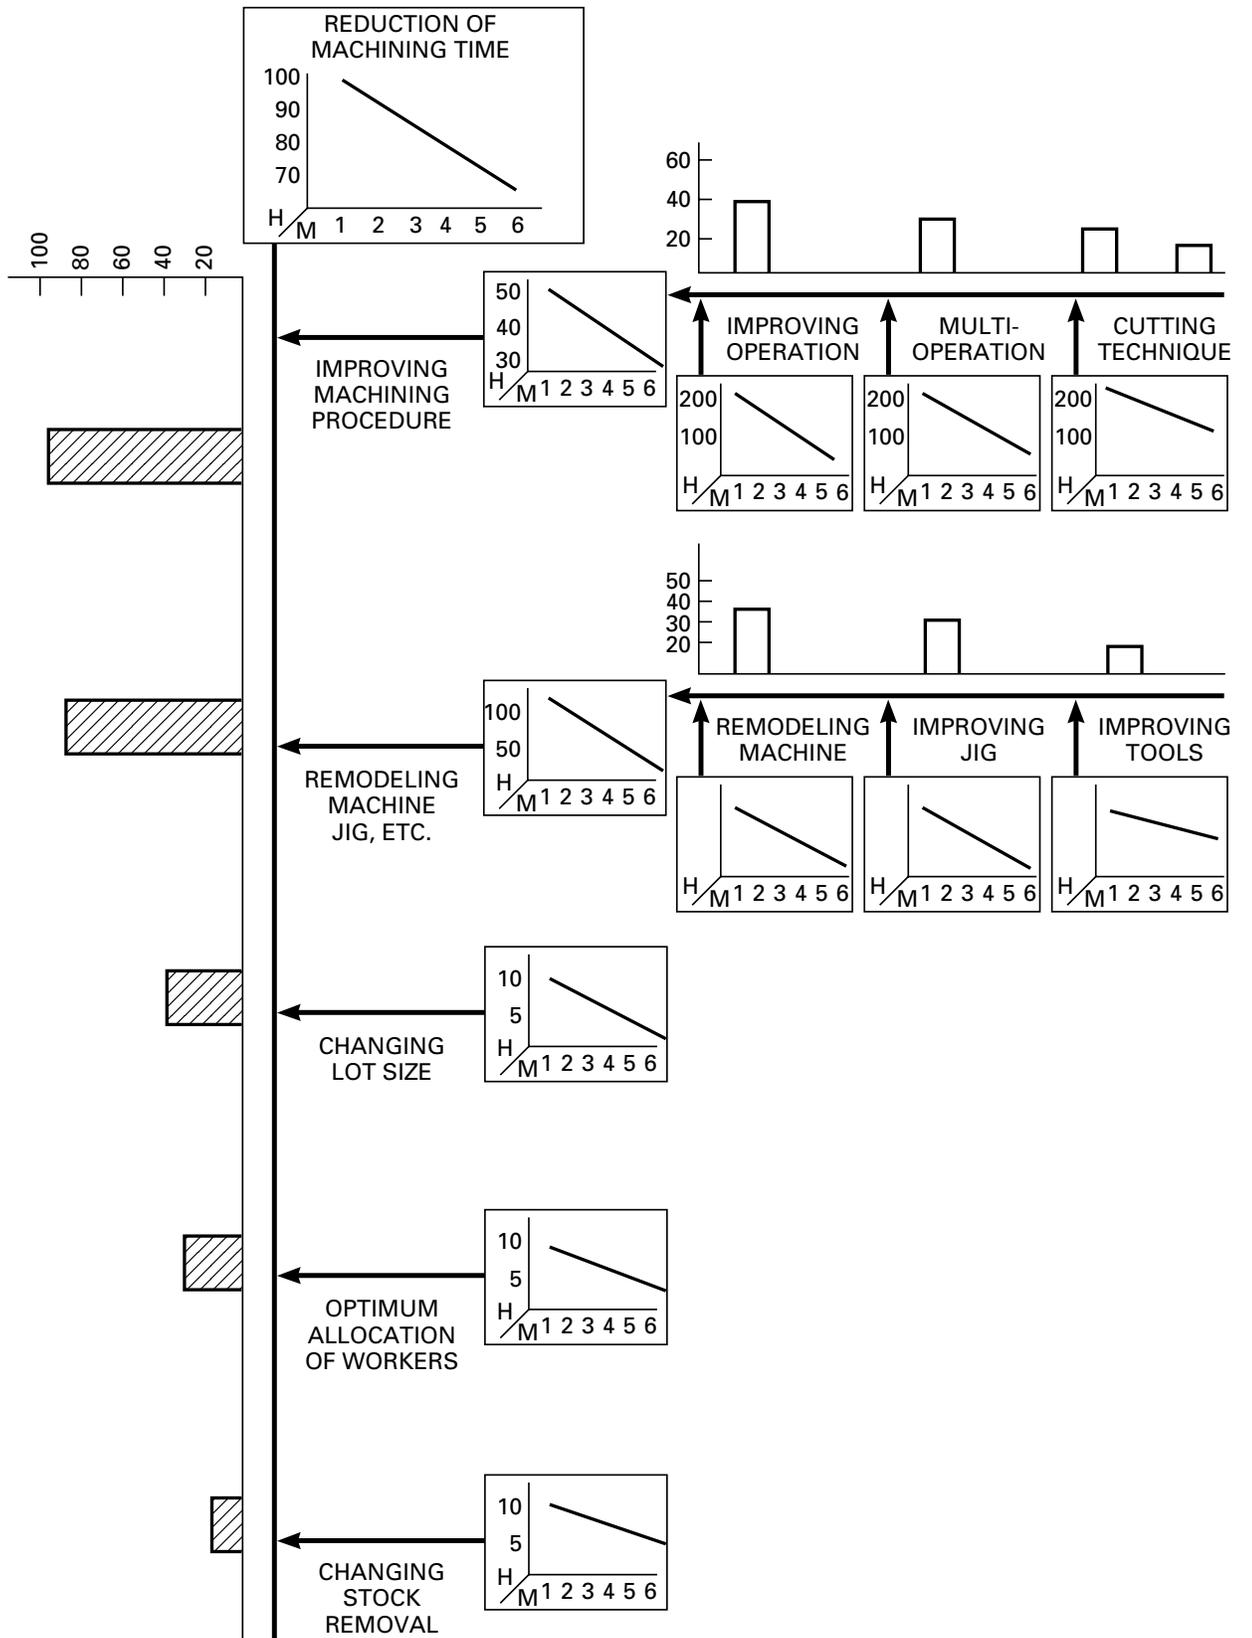
The procedure of carrying out the internal audit is not fixed but is flexible according to the situation of the division, the department, the plant, or the branch office audited. It is also flexible according to the kind of internal audit being undertaken in the company; usually a company has a few kinds of audit at different levels, as will be mentioned below.


FIGURE 41.3   An example of "flag diagram." (*Source: Kondo 1977.*)

The top managers of a Japanese company are in the position of leading and promoting the company's quality control activities. They are responsible for determining the top policy on the quality of products and services and for establishing the long-term quality control plan in order to realize that policy. The aim of the internal audit is to determine whether the policy and the plan are being realized and attained on schedule and whether any corrective actions by top management are needed.

Mizuno (1967) explained the aim of the audit as follows:

> It is essentially desirable in the quality control function that effective daily checks be made and that the important quality problems in the company be pinpointed in order to take corrective actions. However, it is embarrassing for a company to remain unaware of the problems involved. The aim of the internal audit is to investigate and analyze systematically the hidden causes of those quality problems that cannot be detected by daily checking. Because the audit in any form is an energy-consuming job, it is a must for the auditors and the coordinators to pursue resultant benefits that are worthy of the input energy.

The educational character of the audit is considerable. The audit offers the best chance for top management to grasp systematically those facts that may reflect on themselves. The employees audited are also given opportunities to examine and to rearrange their daily work. Moreover, the internal audit contributes to the improvement of mutual understanding and human relations among the employees. Such an opportunity can hardly be obtained through the daily meetings and reports. For these reasons, it is often effective to announce beforehand the audit theme and the checklist being used in the audit.

The audit is usually carried out in either of the following ways: In some companies the audit is done by the president and by the members of the board of directors separately; in other companies it is done by a top management team that includes the president. In the audit by the directors, the emphasis is usually on the general management of the company. In the audit by the management team, there is usually more emphasis on specifics than in the audit by the directors. The two audits are planned to be correlated with each other. Usually, the auditors are accompanied by quality control staff members and sometimes by a university professor as a third party. The audit is done either with or without a predetermined theme. When the theme of the audit is not determined beforehand, it usually covers a wide range of items.

At Toshiba Corp., for example, it was reported (Sugimoto 1968) that the following items were checked by the president during the plant tour:

1. Putting the shop in order—its cleanliness and working environment
2. Layout of the shop and the machines
3. Flow of materials and the line balance
4. Material handling
5. Operation standards
6. Efficient use of jigs and tools, mechanization, and automation
7. Maintenance of machines and measuring instruments
8. Inventories of on-line stocks, materials, and parts
9. Attitude and motivation of workers
10. Administration of storehouse
11. Reducing the number of slips and chits
12. Content and worker-hours of indirect work
13. Production control
14. Quality assurance
15. Supervision of subcontractors
16. Maintenance of buildings, roads, and incidental facilities

When experienced auditors are not available, an audit covering such a wide range of topics tends to become a loose and formalistic one, which cannot be effective. This is why the audit with a pre-determined theme is preferred in many companies; these audits become more intensive. There is also a prevailing tendency for the audit to develop from a departmental one into a functional one, with emphasis being given to the functional interrelationship among departments.

Usually the internal quality control audit is done once or twice a year. This is because it is related to annual planning of the company ("policy management"); the schedule of the audit parallels that of the planning.

The auditors often request a short report explaining the current situation of the department that is to undergo audit. This report enables the reporters ("auditees") to rearrange their ideas in a proper form. Although a checklist is sometimes prepared, the audit items do not always follow it. Since this checklist summarizes the ideas and the points of the audit, it is often effective to announce it before the audit.

Although the way of carrying out the audit is flexible, it usually includes a plant tour and a round-table discussion, which take place after presentation of the report about the current situation of the department. It is essential during the plant tour for the members of the auditing team to be very observant in order not to miss any details. To walk through the entire manufacturing process, from the storehouse to the final inspection, for example, is an effective way to locate and "shoot" the troubles. It is also important for the top managers to talk to the foremen and workers to encourage and motivate them; the audit offers a golden opportunity for conversation between them, which can hardly occur in the course of daily work.

Concerning the short report that is read before the discussion, it is advisable to review the actions taken by the department on comments and recommendations made at the preceding audits. The discussion based on the report and on the facts observed during the plant tour is the most important part of the audit.

After the discussion, comments and recommendations are summarized and announced by the leader of the auditing team. The consultant (often a university professor) also contributes suggestions. In addition to the recommendations for the department to take corrective actions, the statement should include the recommendations made for actions by the auditors. It is also important to include not only the faults but also the merits in the performance of the department under audit. Of course, the recommendations made should be seriously considered by the department audited, and the results should be checked at subsequent audits (Itoh 1974).

QUALITY ASSURANCE AND NEW-PRODUCT DEVELOPMENT

Customer-Oriented Concept.   Quality assurance is the most important company-wide quality control activity in Japanese companies. Several features of the Japanese approach are discussed below.

The first Japanese emphasis is on the requirement that the activities of quality assurance be customer-oriented. While this concept is well known, it is quite common for companies to judge the adequacy of their quality assurance by the amount paid out as a result of customer complaints. In effect, that consists of judging the adequacy of quality assurance by the cost to the company rather than the cost to the customer. The "user's quality cost," as discussed by Gryna (1977), takes account of customer demand and is based on a customer-oriented approach. However, although this user's cost concept is useful, it fails to take account of certain other aspects of customer satisfaction which are not quantifiable in monetary terms but are nevertheless influential in creating customer confidence.

"Must-Be" Quality and "Attractive" Quality.   Ishikawa (1978) prefers to classify product quality as "backward-looking" and "forward-looking" qualities. Later Kano et al. (1984) gave a detailed consideration on this bidirectional way of perceiving quality, calling the former type "must-be" quality and the latter "attractive" quality. Thus they have a dualistic relationship with each other: some products sell well, even though they are the subject of many complaints, because they are highly attractive to customers, while others that receive few complaints do not sell at all because they lack appeal.

Thus, to obtain positive customer satisfaction, we must not only achieve must-be quality by eliminating defects and customer complaints but we must also give our products attractive qualities. Must-be quality is expressed in terms of indicators such as the defect rate, rework rate, and number of customer complaints. It therefore has the property of universality and may be expressed similarly for different types of products. Attractive qualities, on the other hand, are usually highly individual and are consequently different for different products. Thus, while statistical tools such as control charts are effective in controlling the former type of quality, the latter type is best achieved by learning as much as possible from individual examples of failure and success.

Takenaka Komuten, a Japanese building construction company, made extensive process improvements and succeeded in greatly reducing defects and reworks such as cracks in concrete or water leaks. Takenaka designers raised the question: Is this enough to satisfy our customers? To learn the answer, they visited and surveyed employees in the hospitals they had designed and built. During these interviews, they learned for the first time, for example, that nurses encountered daily troubles with the hospital facilities; that patients on the window side complained of the traffic noise and wished to be moved to quieter rooms, and that serious problems with maintenance of air conditioners were found early every summer. (All this had been going on despite the fact that the hospital director and some physicians reported that they were very satisfied with the building and facilities.) The findings were promptly reported to the design department, which took action to revise the design manuals and checklists. This, in turn, resulted in a remarkable increase in the company's share of the hospital construction market.

Quality Costs versus the Manufacturer's Conscience.

Quality costs are frequently discussed in the context of corporate quality assurance activities. Among the many proposals made concerning the classification of quality costs, those made by Feigenbaum (1983) are the most significant. He classified quality costs into the following four categories:

1. Prevention costs
2. Appraisal costs
3. Internal failure costs
4. External failure costs

It is desirable to reduce such quality costs to as low a level as possible and to maintain them at that level. However, as implied by Juran's description of such costs as "costs of poor quality" (Juran and Gryna 1988), they relate mainly to must-be quality, and activities to reduce them have little to do with actively furnishing products with attractive qualities. Such activities are therefore useful for reducing costs but are insufficient in themselves to expand the market size and share and to increase profitability. Both of these activities are important because minimum quality costs do not necessarily mean maximum profit.

There are two main problems with taking quality costs as indicators of quality assurance. The first of these is that, while quality costs address the issue of must-be quality, they take no account of attractive quality. It is therefore impossible for this approach alone to shed light on the conditions needed to produce customer satisfaction.

The second problem is that quality costs represent the amount spent by a manufacturer for maintaining and improving quality; they do not represent the losses or quality maintenance costs borne by customers as a result of poor quality. Although quality is a common concern of both manufacturers and customers, these two parties often view quality from very different perspectives; for example, when complaints are made about quality, the financial losses sustained by customers often far exceed the amount spent by manufacturers for dealing with the complaint. Consequently, while these kinds of quality costs may be useful indicators of a manufacturer's cost-reduction performance, it is doubtful whether they are suitable for measuring the efficacy of its customer quality assurance.

Some attempts have been made to consider quality costs from the user's standpoint as opposed to the costs that must be borne by the manufacturer, mainly in relation to must-be quality. For example, Gryna lists the following seven items as user's quality costs relating to industrial products (Gryna 1977):

1. Cost of repair
2. Cost of effectiveness loss
3. Cost of maintaining extra capacity because of expected failures
4. Cost of damages caused by a failed item
5. Lost income
6. Extra investment cost compared to competing products
7. Extra operating and maintenance costs compared to competing products

These user's quality costs are probably more suitable quality assurance indicators than the manufacturer's quality costs described earlier. Furthermore, because of the recent importance given to environmental issues, it is also necessary to take into account the cost of protecting the environment during manufacturing and use of the product and after the product has reached the end of its useful life (e.g., the cost of scrapping it or recycling it).

Like manufacturer's quality costs, these user's quality costs also focus principally on must-be quality. Since attractive qualities are more product-specific and less immediately obvious than must-be qualities, as described before, it is difficult to assess them in the form of quality costs. However, user's attractive qualities are important product qualities that can create larger markets, bigger market shares, and greater profits for manufacturers, so it is important to take positive steps to develop products that feature them.

More generally, reducing users' quality costs is both an important and necessary aspect of customer quality assurance. However, this alone is insufficient. Ensuring customers' positive satisfaction (including providing them with attractive quality) depends on securing their trust and confidence in the manufacturer, and this is something that cannot be bought with money alone. The first thing that a manufacturer must do to win this confidence is to act conscientiously when it comes to customer quality assurance.

"Fitness for Use and Environment" and "Surplus Quality." In Japan the concept of fitness for use is enlarged to include fitness for the environment. For example, room air conditioners are used extensively in the densely populated Japanese cities. Beyond the need for comfortable temperature and humidity are the requirements of quiet operation and low consumption of electricity. At the initial stage of product introduction, some complaints came from neighbors who were disturbed by the noise of their next-door-neighbor's air conditioner.

In the context of manufacturers' and customers' different perspectives regarding quality, a few points about surplus quality are discussed. Surplus quality is divided into the following two categories:

1. Quality that clearly appears excessive to both the manufacturer and the customer.
2. Quality that tends to appear excessive to the manufacturer but that is strongly demanded by the customer.

As far as the first of these is concerned, it is important for the manufacturer and customer to work together in establishing limit samples and controlling these rigorously.

Acceptable items may be found among those that have failed inspection when there are stringent requirements concerning the quality of parts used in a customer's automated production line in order to maintain the productivity of that line. An extremely low defect rate (1 ppm or less) of electronic components was requested when large numbers of parts were being used for television sets in order to maintain the defect rate of the completed sets at an acceptably low level. Although it is also important in such a case to try to reduce the number of components used (e.g., by combining or modularizing them) and to make attempts to automate the inspection process, the most important thing is to minimize the defect rate of the components and, if possible, reduce it to zero.

Particularly today, when the lifetimes of products are decreasing due to the increasingly rapid appearance of new products on the market, it is becoming more and more important to cope with the competition in quality by achieving zero defects right from the start of new production.

Achieving extremely low or zero defect rates, which may appear at first sight to represent excessive quality, demonstrates the success of manufacturers in developing superior technology and high-quality products. Since they have gone to the trouble of developing these new technologies and products, it surely is extremely important for companies to make effective use of them by actively developing new fields of application for them.

Autonomous Inspection.   Needless to say, the task of manufacturing is to manufacture products whose quality conforms to the quality of design: it is the production of conforming products. This definition of manufacturing includes autonomous inspection, which consists of workers checking their own products to see whether or not they conform. This is the basic premise of autonomous inspection.

Various conditions must be satisfied in order to get autonomous inspection up and running. The most important of these is to decide on the methods by which autonomous inspection is to be carried out (including sampling), clarify the division of responsibility between autonomous inspection and proxy inspection (described below), include the labor-hours used for autonomous inspection in the manufacturing labor-hour figures, provide the measuring equipment needed, and give people the necessary training.

The practice of autonomous inspection does not mean that the people working in the manufacturing process are required to check for every single quality that they are responsible for building into the product. Some qualities will only be checked for the first time when the product is processed or assembled in subsequent processes, and others would require too much time or skill for the people working in the manufacturing process to check them. Some qualities will be inspected by people in subsequent processes or by special inspection personnel rather than by the people who actually make the product. Since such inspections are carried out on behalf of the people who make the product, they are referred to as "proxy inspections." The results of proxy inspections should immediately be fed back to the people manufacturing the product as a motivational tool and to use in the manufacturing process in a way that confirms the controlled state of the process. At the same time, it is hoped that a spirit of cooperation and teamwork will be fostered between the people of the manufacturing process and the people who inspect it on their behalf.

Autonomous inspections, including proxy inspections, have the following additional features: People are instantly aware of the quality of the products they have made. They feel happy if their products are satisfactory, and will wonder what has gone wrong if their products do not conform or an abnormality is discovered in the manufacturing process. Then, because the results are known immediately after a product has been manufactured, autonomous inspections will definitely stimulate people's curiosity and desire for improvement and will motivate them to try to improve the situation.

Process Capability and Control Charts.   Needless to say, the following two conditions must be satisfied in order to make products whose quality conforms to their quality of design, that is, for manufacturing conforming products:

1. Create no defects.

2. Permit no abnormalities.

In order to see whether these two conditions are satisfied, process capability indices and control charts are used.

Recent advances in factory automation, on the other hand, have led to the appearance of many automated and mechanized processes with far better process capability indices than ever before. However, this means that there is a danger of people mistakenly believing that because process capabilities have improved and no more defects are occurring, control charts are no longer needed. It is strongly emphasized once again that defects and abnormalities are different.

Cause and effect relationship should also be clarified to identify the possible relationships between product qualities and the various factors thought most likely to influence them. It is necessary to confirm the principal factors affecting product quality by checking correlation in the case of

variables and by stratifying the data in the case of attributes. Rigorously controlling any factors ascertained by these techniques to have a significant effect on quality enables us to reduce product quality variation and decrease the incidence of abnormalities. The skillful execution of this kind of upstream control is extremely important (Ishikawa 1962).

Creativity and Work Standardization.
Clearly, the desire to work is closely connected to creativity and is in fact inseparable from it. On the other hand, necessity and importance of work standardization is often emphasized from the standpoint of improving work efficiency and assuring quality. Concerning work standardization, however, the following two types of problems are pointed out:

1. Work standardization conflicts with motivation, since it restricts the creativity and ingenuity of the people engaged in the work and reduces their opportunities to exercise those faculties.

2. Even after a lot of time and efforts have been put into standardizing work methods, the standards are actually not often complied with. One survey showed that, although most Japanese companies stipulate in abstract terms that their in-house standards are to be obeyed, more than half of them do not have any definite procedures for ensuring that they are in fact enforced. Preparing standards is known to be a difficult and time-consuming job. Is it so difficult for workers to follow the standards for the work they have been allocated?

To discuss the question of creativity and standardization in more concrete terms, let us examine work standards in a manufacturing process. They usually include the following three items:

1. The aims of the work. In a manufacturing process, this corresponds to the quality standards for the products that the process must produce.

2. Constraints on carrying out the work. The most important restrictions are those designed to ensure employee safety and preserve the quality created in upstream processes.

3. The means and methods to be employed in carrying out the work.

Of these three items, item 1 must always be achieved and item 2 must be scrupulously obeyed by whoever is responsible for doing the work. Clearly, everyone must make conforming products and work safely. But, must item 3 be obeyed in the same way as item 2 regardless of who is responsible for the work? As emphasized previously, establishing and enforcing prescribed means and methods encourages people to avoid responsibility for failure and claim that the failure was not their fault because they followed the stipulated methods. This must be strenuously guarded against.

One of the grounds for asserting that item 3 must be obeyed is that the standardized means and methods are the most productive and efficient, regardless of who uses them. At least the people who drew up the standards think so. However, in view of people's different characteristics and habits, it is highly unlikely that any single standard could be the most efficient for everyone, no matter how carefully it was formulated.

We know that this kind of standardization of action is missing from sports. To excel at a sport, we must first master the basic actions by reading textbooks and taking lessons, but this alone will never allow us to produce a new world record right away. The only way to keep improving our personal best is to build on these basic actions through hard work, that is, by continually practicing and exerting great ingenuity to discover the method that suits us best.

In light of this, item 3 should be regarded as the training manual for beginners, equivalent to the basic actions in sports discussed above, and not as rigid instructions to be obeyed without fail. Item 3 is for helping people understand the basic actions and making the process of learning the job more efficient.

In using these manuals, it is also important to make clear to all trainees at the end of their basic training that the working methods they have learned so far are no more than the standard actions that are useful hints for improvement, and that, having mastered them, they should actively try to further develop methods of working that really suit themselves as individuals. They should be told that this will help them to improve their skills, and that the managers actively support and encourage them to do so. Conversely, forcing novices to perform standard actions exactly as they have been taught is

an absurd way to proceed, since it not only leads to shirking responsibility but also prevents them from improving their skills.

If workers are encouraged to improve their skills, they are requested to use their own initiative to develop standard actions into practical working methods, and discover the secrets of performing the work efficiently. Creativity and standardization are thus not mutually exclusive but mutually complementary. By encouraging and promoting the standardization described here, managers will help the people engaged in the work make full use of their creativity, and discover methods of doing the work even better.

Teamwork Relationship among Departments.   In order to achieve the goal of quality assurance, it is important, even indispensable, first to improve the quality of design to meet the target of fitness for use and environment. Second, the quality of manufactured products should be in conformance with this quality of design.

Although this procedure for assuring product quality is accepted, another general rule emphasized in Japan is teamwork among all departments. In other words, the cycle of plan-do-check-act should be rotated to involve marketing, design, manufacture, inspection, and sales. Quality assurance is one of the most important company-wide functions. It is also important to remember that quality assurance, cost and profit control, and control of factors such as delivery performance, production volume, and productivity are closely interrelated These activities are often regarded as cross-functional management, which consists of the following steps:

1. Making plans for each important corporate function
2. Passing the plans down to the specific line divisions that will implement them
3. Using policy management and daily management within these line divisions to implement the plans, check the results, and take any necessary corrective action
4. Further reviewing the results of implementing the plans from the company-wide standpoint and then taking any necessary corrective actions

The key point of cross-functional management is that the action plans for each of the functions formulated from the company-wide standpoint should not be implemented just by the supervisory head office or operating division department in charge of those functions. They should be passed down to all of the relevant organizational units within the company and be reflected in the duties of each, and they should be implemented, evaluated, and subjected to corrective action through teamwork among the different units. The PDCA cycle is rotated for each function on a company-wide basis by consolidating individual units' implementation results for each function and comparing these with the company-wide cross-functional objectives. Thus the head office or operating division supervising department does not bear the sole responsibility for implementing cross-functional management; it is shared by all of the company's line divisions in accordance with their respective duties.

A company usually sets up supervisory departments such as a quality assurance department within its head office or operating divisions to plan these activities, support their implementation, and evaluate them from the company-wide standpoint. However, these supervising departments usually are not very large.

It is also usual practice to set up a quality assurance committee for each function in order to effectively promote cross-functional management while liaisoning between the different departments. Each of these committees is chaired by the director responsible for the particular function, and the head office or operating division supervisory department responsible for each function acts as the committee's secretariat.

Teamwork Relationship with Relatively Few Suppliers.   The quality and reliability of modern complex products depend heavily on the quality and reliability of components and parts. This product quality cannot be assured solely by 100 percent inspection. Japanese manufacturers have been trying to establish and maintain a cooperative relationship with their suppliers in order to improve and assure component quality. This requirement will probably become more stringent as the number of new products entering the market increases and their life cycles shrink.

Such strict quality requirements cannot be met by means of suppliers' final inspections or manufacturers' incoming inspections based on the usual types of sampling inspection plans. In addition to implementing automated "screening inspections," manufacturers are placing more and more importance on promoting the type of quality control that extends to the quality assurance activities of suppliers themselves.

As a result, increased emphasis is being placed on establishing cooperative relationships and good teamwork between the suppliers making the components and the manufacturers using them. The establishment of teamwork relationships starts with the selection of suppliers. Questionnaires are distributed and visits made, and the suppliers are screened on the basis of financial status, facilities, basic ideas and policies of top management, enthusiasm for quality improvement, level of education and training of employees, etc. Large Japanese companies usually have an established procedure for this selection and a standardized checklist.

Good teamwork relationships with suppliers are based on mutual trust and confidence and cannot usually be established in the short term; it takes at least a few years. Importance is attached to the basic philosophy and the enthusiasm of the top management personnel. Because of the smaller size of the supplier companies, quality control activities and product quality and reliability are rather rapidly improved under the positive leadership of their top management. Independent ideas and attitudes of the suppliers are emphasized, rather than a dependent relationship to the purchasing company. Positive guidance and quality control educational services are made unsparingly available by the company on the understanding that voluntary efforts will be made by the suppliers. The importance of education and training—which become more effective in the relatively long term—is emphasized.

There is a recent trend in Japan for smaller manufacturers of components and parts to have their own test laboratories for these components so as to ensure that their quality and reliability are adequate before permitting the design department of the purchaser to specify them for use in the final manufactured products. Such test laboratory activities by the parts manufacturers are also effective in the development of new products of their own. It is fairly common in Japan for data on the process capability index and manufacturing process control charts in supplier organizations to be sent to the purchasing company and utilized in the manufacturing, inspection, and design departments in addition to the quality control department. Internal quality control audit by top management is voluntarily carried out by the suppliers. In this audit, appropriate representatives of the purchasing company are sometimes invited to attend the audit and express comments as outside authorities.

"Ten Principles for Vendee-Vendor Relations from the Standpoint of Quality Control" were established in 1966 and presented by Ishikawa (1969) at the International Conference on Quality Control 1969, Tokyo, as follows:

Preface: Both vendee and vendor should have mutual confidence, cooperation, and high resolve of "live and let live" based on the responsibilities of enterprises for the public. Following the above spirit, both parties should sincerely practice the following "Ten Principles."

Principle 1: Both vendee and vendor are fully responsible for quality control application with mutual understanding and cooperation on their quality control systems.

Principle 2: Both vendee and vendor should be independent of each other, and esteem the independence of the other party.

Principle 3: Vendee is responsible to bring clear and adequate information and requirements to the vendor, so that the vendor can understand what should be manufactured.

Principle 4: Both vendee and vendor, before entering into business transactions, should conclude a rational contract between them in respect of quality, quantity, price, delivery term, and terms of payment.

Principle 5: Vendor is responsible for the assurance of quality that will give full satisfaction to vendee. Vendor is also responsible for submitting necessary and actual data upon the vendee's request, if necessary.

Principle 6: Both vendee and vendor should decide the evaluation method of various items beforehand, which will be admitted as satisfactory to both parties.

Principle 7:   Both vendee and vendor should establish, in their contract, the systems and procedures through which they can reach amicable settlement of disputes whenever any problems occur.

Principle 8:   Both vendee and vendor, taking into consideration the other party's standing, should exchange information necessary to carry out better quality control.

Principle 9:   Both vendee and vendor should always perform business control activities sufficiently, such as in ordering, production and inventory planning, clerical work, and systems, so that their relationship is maintained upon an amicable and satisfactory basis.

Principle 10:   Both vendee and vendor, when dealing with business transactions, should always take full account of the consumer's interest.

These principles were formulated through enthusiastic cooperation and thorough discussions among purchasers and suppliers. Their meaning is obvious, although they have not always been adhered to. It is hoped that they will further be utilized as much as possible as a basic guideline for improving the manufacturer-supplier relationship.

Quality Information—Quality Complaints versus Systematic and Positive Collection of Quality Information.

In a paper on quality design, Aiba (1966) emphasized the importance of securing external quality information from customers in the marketplace. Such raw information is then converted into measurable quality characteristics.

In this connection, external quality complaints, while demanding prompt and remedial action, are collectively a poor index of quality. They reflect must-be quality—the poor quality of product dissatisfaction. In addition, quality complaints are subject to the following kinds of problems as a measure of quality:

1. Complaints are influenced by the unit price of the product.
2. Any kind of information, not only that on complaints, can very easily become distorted when transmitted orally.
3. Complaints are also affected by the type of customer and the economic climate.
4. Some complaints vanish en route to the manufacturer.

Quality complaints might be expressed as sporadic and passive information on must-be quality. However, they are still a valuable source of information that we should use to improve the quality of our products.

In tandem with this process, the systematic and positive collection and utilization of external quality information on the following are also important:

1. Customer demands, i.e., how the commodities are used by the customers and the conditions of use
2. Quality of similar commodities manufactured by competitors
3. Actual conditions of transportation and storage by distributors' channels and by retailers
4. Present and future market trends

At the Cotton Underwear Division of Gunze Co., Japan, the division director received a letter from an elderly male customer expressing his hearty appreciation for the excellent quality and durability of Gunze cotton underwear, stating he had been wearing the same articles for more than 10 years. This customer also urged the director to develop new products of such high durability. The director requested a consultant's opinion about the development of such new products. The consultant asked, "How long do customers usually wear your underwear?" Since the division had not investigated the life span of the underwear, it conducted a market survey. When the results were summarized in the form of a histogram, the distribution of life span clearly was well approximated by a normal distribution curve, with a mean of about 3 years and a standard deviation of about 0.5 years. It became evident from this histogram that the number of customers who continue to wear the

same underwear for longer than 4.5 years was 1 to 2 per 1000. The data suggested that the market for a new product of much higher durability was very limited.

To avoid possible adverse consequences of reacting to sporadic customer information, it is necessary to collect market quality information on a systematic basis. Such systematic collection is comparatively easy for products of high unit price, as in the case of the Takenaka Komuten construction company, mentioned earlier. With products of low unit price, some ingenious methods are necessary. A questionnaire card is often enclosed with the product, asking customers their reasons for purchasing, the name of the retailer, impressions of product performance, conditions of use, etc. In Japan customers often mail this card immediately after their purchase and before using the product. Hence their comments about quality and reliability are meaningless. Furthermore, only a small proportion of the cards are usually sent back to the manufacturer. A better way is to utilize the returned cards to design follow-up surveys and then to apply sampling techniques based on types of customers and conditions prevailing during use. Interviews with the customers are usually far more fruitful than mailed questionnaires.

Apart from special situations, the external quality information is usually collected by regular company sales or marketing personnel. However, although the collection and feedback of external quality information is an important part of their quality assurance task, it is not their only job, and they usually have to squeeze it into the gaps in their busy and complicated daily sales and service schedules.

Consequently, the enthusiasm of these people for collecting external quality information at the request of design and engineering departments easily tends to evaporate if the purpose for which it is being collected is unclear, if hard won information is left idle and not utilized for new-product development or quality improvement, or, if after having worked so hard to collect the information, they are not informed of the benefits achieved through its utilization.

As users of this external quality information, which has taken so much effort to collect, the engineering and design departments should therefore provide positive feedback to the sales people responsible for collecting it. They should tell them how effective it has been and how they would like it to be improved. If, through poor communication, the sales personnel collecting the external quality information receive no reaction from the departments requesting it no matter how much information they pass on, they will feel that their efforts are not valued. Conversely, if the quality information that they have spent so much time and trouble gathering is used effectively within the company and they are given information on how it can be improved, this will increase their enthusiasm for collecting it. This is very important both for motivation and for the smooth operation of a quality information system.

New-Product Development.

Since Japan has few natural resources of its own, the only way it can survive and grow is by obtaining the necessary foreign currency by profitably developing, manufacturing, and exporting high-value-added products that satisfy customers' actual and potential needs and that they are delighted to use. It is impossible to achieve this in regard to product quality simply by reducing user's quality costs relating to must-be quality. It also requires action to satisfy customers in positive ways, including the development of new products. Through this, we aim not just to minimize quality costs but to maximize corporate profits.

Quality function deployment (QFD) (Kogure and Akao 1983; Akao et al. 1987), a "design approach" based on deductive reasoning, has recently been widely adopted as an effective technique for new-product development, with eye-opening results. At the same time, however, we must not forget that the analytical approach using the quality control story is also highly effective. It is important to make positive use of the valuable lessons that past successes and failures have taught us, and not just discard them because the present project happens to be different from previous ones.

We know that we can increase the likelihood of a project's success if we appoint as team leader someone who has already succeeded with previous projects, even if they were different from the present project. This is because such people not only have confidence in their ability to succeed but also know how to make use of their past experiences in the present project—in other words, they follow the PDCA cycle.

Many companies try to prevent the repetition of new-product development failures by collecting examples of past failures and having those involved in current projects study them. This is also an

attempt to utilize the analytical approach based on the quality control story. However, as long as they are collecting examples of failures, it is equally important to try collecting examples of past successes and make use of these. The reason for the success of a project is not usually the opposite of the cause of its failure; the two are often different. Publishing compendiums of failure case studies certainly reduces the chance of making similar mistakes, but it is doubtful whether it increases the possibility of success.

Companies that are good at new-product development and enjoy a high success rate usually appoint their deputy CEO or a senior director as their new-product development manager. It is often said that the enemies of new-product development are to be found within the company. When the work of developing a new product or technology begins, some people will always come out with negative comments like, "There's no point in doing that," or "We already know it can't be done." A new idea is like a flower bud—it is easily squashed, but we do not know how good it really is until it has been allowed to develop to some extent. The most important duty of the new-product development manager is to foster these ideas he or she believes are important and are likely to prove useful in the future, shield them from criticism within the company, and make something of them.

In many Japanese companies new products are classified into the following groups on the basis of their novelty:

1. New in the world
2. New in Japan
3. New in the company
4. Model change of a current product, etc.

Such a classification is effective for determining the steps and stresses in new-product development. For a new-product of class 1, the quality, including safety, and the reliability should be most strictly assured even though time and money are needed. The new users of these products should also be broadly pursued and developed.

It is frequently stressed that the development of new applications must not be ignored when thinking about new-product development. In view of the many new materials that have been developed recently, it seems that the development of the material precedes the development of uses for it. In short, the development is "seeds-led", with the development of needs lagging behind. An example of this is the recent development of a brassiere employing shape-memory alloys that is selling well, particularly in the American market. This illustrates how important it is, in developing new applications, to be thoroughly familiar with the quality characteristics of newly developed materials or technology, to identify latent customer needs that existing technology has been unable to satisfy, and to pool ideas to come up with ways of resolving the situation.

In contrast, for new products of classes 3 and 4, the emphasis is on promptness, so that product development cycle time can be shortened in order to cope with competition in the market.

During quality design, there is a need for conversion of true quality characteristics requested by customers into measurable substitute characteristics (Aiba 1966). The QFD technique mentioned above is being widely used for this purpose. After converting the true quality characteristics into the measurable substitute characteristics, it becomes easier to determine the quality specifications for each item.

The measurable substitute characteristics thus evolved become the focus of various checkpoints in the manufacturing and inspection processes. During the design and pilot stages of the manufacturing process, a "quality control process chart" is established for assurance of quality in the manufacturing process. Figure 41.4 shows an example of such a process chart, which, as may be seen, uses substitute characteristics. Thus the quality function is implemented throughout the whole company (Kogure and Akao 1983).

The steps in new-product development are roughly as follows:

1. Market research
2. Conceptualization
3. Experiments, market research

NAME OF PART	FLOW CHART — MATERIAL PROCESS / MAIN PROCESS	NAME OF PROCESS	OPERATION MANUAL	ITEM	METHOD	PERSON	SAMPLING	MEASUREMENT
		Preforming	32-2-RC-1	T.W.	X-R Chart	Mr. F	Every lot, random n = 5	Autobalance
				T. dia.	Check sheet	Mr. F	Every lot, random n = 10	Gauge
				Appearance	p-Chart	Mr. F	Every lot, total n = 300	Eyes
				Temperature		Mr. F	Twice a day	Drum
				Speed constancy		Mr. F	Twice a day	
Lead chip		Preheat	22-RCG –005 –006	Temperature	Check sheet	Mr. S	Twice a day	
		Forming	222-RCG	L-dimension	X-R chart	Mr. S	Every lot, random n = 5	Slide calipers
				Temperature	Check sheet	Mr. S	Once a day	
				Pressure	Check sheet	Mr. S	Once a day	
		Aging	222-RCG 6-1	Temperature	Check sheet	Mr. S	Once a day

41.29

  4. Application for patent

  5. Quality design

  6. Pilot-scale manufacturing and qualification testing

  7. Process design

  8. Full-scale production testing and sales

  9. Mass production

 10. Termination of initial warning system

 11. Termination of mass production

These steps and the company departments involved may be summarized by a chart of the quality assurance system, an example of which is shown in Figure 41.5. This chart will vary with the novelty of the products.

Development of new products is usually a time-consuming undertaking, involving many trial-and-error procedures. However, the procedures of evaluation, qualification, review, etc. carried out during the various steps can be standardized, which becomes the first step in introducing quality control to new product development.

Market Research and Hypothesis Testing.   Two stages of market research are shown in the above-listed steps of new product development (steps 1 and 3). The preliminary market research is rather general in character and may lead to an idea for a new product. The later market research is to confirm the effectiveness of this idea.

For example, in the late 1960s (Yoneyama 1969), the half-size camera was becoming popular in Japan. The first manufacturer was company A. At company B, there was discussion among top managers about developing a new half-size camera to compete with that of company A. Mr. Y. was appointed a senior member of the development team. First, he collected statistics on monthly camera sales from the relevant government report and classified them into sales of half-size and full-size cameras. He found that total sales were rising mainly because of the increased sales of half-size cameras. When fitting the increase in demand for half-size cameras to a logistic curve, it became clear that this increase was not likely to slow down. From this study, top management decided to develop a new camera.

The second market research program (step 3) was then launched. It happened that company B was also selling color film, which was ultimately developed at the company's central laboratory. It was found from the analysis of developed film that the pictures taken indoors by half-size cameras were often blurred. It was decided on the basis of this fact that the new camera should be equipped with a better lens.

Mr. Y went out every Sunday with two counters in his pockets. He strolled in downtown Tokyo and then in suburban resorts and counted the number of people who carried a camera; he pushed one counter for each full-size camera and pushed the other counter for each half-size camera. He found that the ratio of half-size to full-size cameras was lower downtown than in the suburbs. It became clear that the customers were buying the carrying convenience and light weight of a half-size camera. It was then further decided that the new camera should be lighter than the camera of company A.

These two features of company B's new half-size camera became very profitable sales points. It should be noted that the ideas conceived in step 2 above need to be examined and confirmed in the market research of step 3. Systematic and positive collection of quality information from the market is also important for determining test conditions in qualification and for improving the items subject to design evaluation and review in the intermediate stages.

Design Reviews—Corrective Action on Physical Objects and Process.   Design review, evaluation, and qualification done at proper stages of development, such as steps 5, 6, and 8, are prevalent in Japanese companies. These evaluations aim at determining whether

WORKING STEP \ DEPARTMENT	DOMESTIC BUSINESS AND EXPORT	APPLICATION ENGINEERING	MANUFACTURE ENGINEERING	QUALITY ASSURANCE	MANU-FACTURING	PRODUCTION CONTROL
PLANNING	Market survey	Examination of specification				
	Decision of development planning

					Customer	

FIGURE 41.5   Chart of quality assurance system. (*Source: Takanashi 1978.*)

1. The quality of design was appropriate

2. The design of the foregoing procedures was adequate

With regard to exported goods, quality information from foreign markets is extremely important because environmental conditions (temperature, humidity, dust, etc.), laws, weights and measures, customs, conditions of use, physical constitution of customers, etc. are quite different compared to the domestic market. Although these data in foreign markets cannot be anticipated in the earlier stages of foreign trade, records of previous failures of various kinds are accumulated and utilized as much as possible to prevent recurrences. Those corrective actions that improve the design, testing, and evaluation procedures are most effective.

Full-Scale Production Testing. The aim of the full-scale test (or trial), which is the final stage of new product development, is not always clear. It is often carried out by skilled workers, with quite satisfactory results. When mass production starts, however, the manufacturing department is always worried about problems in the manufacturing process. The reasons are clear: They reflect the differences in the skill of the workers engaged in the full-scale test run and in mass production. The distribution of the quality of components and parts is also sometimes different. The true aim of the full-scale test should then be clearly defined and achieved. One of its most important purposes is to thoroughly eliminate weaknesses in manufacturing and take corrective actions before the start of mass production.

Taking this approach even further, we arrive at the concept of upstream management discussed previously. Not only should we eliminate all remaining problems before the start of mass production by performing full-scale production testing under mass production conditions, but we should also investigate those problems closely to determine whether or not they could have been discovered only at the full-scale production testing stage or whether they could, in fact, have been discovered in earlier processes and prevented from occurring in the first place. We should also think about how the development process could be improved in order for this to happen. We should put these improvements into effect, check the results, and identify any remaining problems. Thus we will continue to rotate the PDCA cycle.

SECTION 42

QUALITY IN THE PEOPLE'S REPUBLIC OF CHINA

Yuanzhang Liu

THREE THOUSAND YEARS OF QUALITY—AN INTRODUCTION

Historical Background.   China's long recorded history can be traced back to the twenty-first century B.C., more than 4000 years ago. Its political history began taking recognizable shape during the period when the Yangtze River basin was dominated in succession by two great feudal dynasties, first the Shang, whose kings ruled from around 1750 B.C. until 1125 B.C., then the Zhou, who conquered the Shang people around 1125 and ruled until 250 B.C.

The last 2 centuries of Zhou rule were marked by warfare among the city-states of the Middle Kingdom, as the Yangtze region was then called by its inhabitants. The larger city-states began to conquer and absorb the smaller, weaker ones. The Zhou dynasty collapsed late in the third century B.C., bringing a temporary end to political order. In 221 B.C., Shi Huangdi, king of the western city-state of Qin, unified the Middle Kingdom politically for the first time, becoming its first emperor and the founder of the short-lived Qin dynasty (221–206 B.C.). (Though the dynasty ended with the death of its founder, its name lives on, in altered form, as "China.")

Over the next two millennia, China was ruled by a succession of imperial dynasties. When the Qing dynasty (1644–1911 A.D.) came to an end, relinquishing rule in 1911, the 4000-year era of feudal/dynastic rule in China ended with it.

For purposes of tracing the history of quality management, it isn't necessary to trace the history of the rise and fall of all of the dynasties which came to rule China. It is only necessary to point out

the fact of this succession. The emergence of a dynasty generally signaled a period of relative absence of threat, either from internal factions or external invaders, when social and technological development could take place. The eclipse of a dynasty, involving the transfer of great power, was usually accompanied by military action and social disorder which threatened all development.

The Shang and Zhou dynasties are associated with the earliest expressions of high civilization in China, especially their rich religious and ceremonial life. The production of bronze ceremonial artifacts was an important part of that tradition. By the early years of the Shang dynasty, the handicraft industry which produced these objects was already established. Its outstanding achievement is recorded in classical Chinese writings and is evidenced by archaeological relics and by the remaining items of handicraft. This industry was the foundation for the manufacturing tradition that survived the long succession of dynasties that followed.

All of this evidence leaves no doubt that the management of product quality has long been understood and practiced in China. However, the West has had access to few details of quality management as practiced by the ancient Chinese. The work of Jin et al. (1995) offers a rare exception.

It may be appropriate to review briefly what is known of the history of quality management, to better understand quality management as it is practiced in China today.

The Nature.   In ancient times, quality management was applied only to the handicraft industry, which at that time included many trades, such as metallurgy, vehicles, ships, textile and leather, pottery and woodworking, weapons, musical instruments, and architecture. As written in *Zuozhuan, the Thirteenth Year of Cheng Gong* (Annals of the Zhou dynasty), "Sacred ritual and war are major matters of prime importance to the State." Strict quality control began first on those products to be used in offering ritual sacrifice and in making war. The fine quality of bronze vessels, sets of bells, and swords made in the Shang and Zhou dynasties are well-known and provides tangible evidence of attention paid to their quality.

China's ancient handicraft industry was dominated by workshops owned by feudal lords, especially by the emperor. (For simplicity, we will call all such workshops "officially owned workshops.") This does not mean that there were no civilian handicrafts made during the long history of China. But no matter whether in scale, or in sophistication of technology or of management, civilian industry was no match for officially owned industry. The civilian handicraft industry was mainly a collection of small family workshops. To create such an enterprise, a family spent a lot of energy and undertook a great deal of risk. Risk was especially high during the chaos which often accompanied a change of dynasties. Lacking official protection, an individual workshop was often too weak to survive. On the other hand, the officially owned workshops, recognized and valued by rulers in every dynasty, had the power to survive and develop. As an important element of the surviving officially owned workshops, the official quality control and quality management systems survived virtually intact, with only incremental change over time. This helps account for the continuity of the quality management system throughout China's 3000 years of feudal history.

There are three fundamental aspects of this ancient system of quality management which are of interest: its content, its limitations, and its lessons for the future.

Content.   Of the content of the Chinese quality management system, four main points can be made.

Concept.   From the earliest times, it was based on a clear concept of quality. In 403 B.C., in *Kao Gong Ji* (Records in Inspecting the Works), it was written that "Heaven having time, earth having energy, material having beauty, work having skill, add these four and the result is quality." The recognition that quality is the result of many contributing factors was reflected in the practices of later generations of workshops, including the way they applied the concept of division and cooperation of labor as well as management.

Training.   The system paid full attention to training and caring for skilled labor. China's workers as a class were never treated well, nor did they attain high status in the social hierarchy of the feu-

dal system. In fact, during the early dynasties, craftsmen were slaves. Nevertheless, the emperor used to visit their workshops to inspect the quality of their product and to inquire about their techniques and skill. As slavery was gradually abolished, the officially owned workshops began to use conscription to recruit craftsmen. After the Qin dynasty, many generations of succeeding dynasties practiced the same methods of recruitment. As in the times of slave labor, the craftsmen working for the officially owned workshops were forced to live together in the workshop, to make it more convenient for their bosses to manage and train them. The craftsmen thus conscripted were of relatively high technical capability to begin with; living collectively with fellow craftsmen made them more skillful through mutual teaching and learning. In addition, the collective arrangement made it easier to enforce official standards and rules for production and quality, assuring the product's conformity and superiority.

Standards.   From the time the first emperor of Qin unified the metrological system in China, succeeding dynasties all promulgated laws and decrees to enforce the adoption of a unified standard of measures and weights, which helped greatly in the uniform practice of quality control in all industries throughout the country. For instance, according to *Tang Lu Shu Yi, Za Lu Men* (Introduction to the Laws of the Tang Dynasty, Miscellaneous Categories), compiled in 635–640 A.D., a law stipulated that measuring tools were to be checked every August, and were to be used only after the seals were affixed. Moreover, the concept of standardization went beyond its application to measuring tools. Application extended to the industrial products themselves, as well as to production practice, with the introduction of interchangeability of parts. The famous terra cotta army buried in the tomb of the first emperor of Qin was actually assembled from parts.

Table 42.1 presents a sample of surviving writings which bear on the subject of managing quality over the period from 403 B.C. (during the Zhou dynasty) until late in the Qing (last) dynasty. All of these books contain compilations of industrial standards and specifications. *Tian Gong Kai Wu,* the last reference in Table 42.1, is an especially important example of writings on Chinese technology, and was praised by Joseph Needham, the world's pre-eminent authority on the history of Chinese science and technology.

TABLE 42.1   A Sample of Ancient Chinese Writings on Quality Management

Kao Gong Ji (Records in Inspecting the Works)	403 B.C.	A recognition of quality as the combined result of "the time of heaven, the energy of earth, the beauty of material, and the skill of the workman"
Tang Lu Shu Yi, Za Lu Men (Introduction to the Laws of the Tang Dynasty, Miscellaneous Categories)	Compiled in 635–640 A.D.	A law stipulated that measuring tools were to be checked every August, and were to be used only after the seals were affixed.

Cong Cheng Zuo Fa Gui Ze (Regulations in Engineering Projects)	Qing dynasty (1644–1911 A.D.)	Subject: construction
Tian Gong Kai Wu (Technology and Manufacture)	1637 A.D. by Sung Yingxing	Subject: manufacturing

Responsibility.   The system provided for strict responsibility. From the time of the Zhou dynasty onward, the centralized autocratic state had a centralized system of quality control over the whole process of handicraft production. Special officials were appointed to manage specific organizations in charge of various production matters, from the administrative ministries down to the local workshops. Those officials, together with the craftsmen, were to be responsible for the quality of the product. For this purpose, a unique measure, entitled "Articles to be inscribed with the names of the craftsmen and the officials in charge," was enacted as early as the Zhou dynasty, and was continued in force by the governments of later dynasties. If someone made product of inferior quality, he could be traced and was to be punished properly. For the sake of justice and fairness, a system of product examination was devised, including in-process mutual, patrol, and final inspection. A method of sampling inspection was invented and used as part of the system. China's ancient quality management, though rather primitive in its early days, became quite systematic and efficient in its later development.

Limitations.
This system had limitations. In the 3000-year period from the Zhou dynasty to the Qing dynasty, the basic political system changed little; so also did the basic organizational structure for control of industry, which, by and large, was a collection of officially owned and bureaucratically managed business. Despite the fact that these businesses faced no competition, and despite the fact that they were protected by state authority, their quality control and management were carried out with strict discipline. However, because all the products were demanded either for the luxury of the royal court or for the needs of the state, production cost was totally ignored. Furthermore, a state policy of "stressing agriculture and suppressing commerce" was adopted at the time of the Zhou dynasty, and maintained for the 2 millennia which followed. There may have been a valid argument for such an emphasis on agriculture at the expense of commerce 2000 years ago, but it goes without saying that clinging to this policy posed a severe hindrance to the development of a national manufacturing industry in China's feudal era.

As a consequence of these factors, the development of quality management stagnated—no further innovation was believed to be necessary. Another more serious consequence was that the science and technology of China also began to stagnate and to fall behind. Whereas until the sixteenth century China was among the most advanced nations of the world, it began a period of decline, the victim, perhaps, of its feudalism and its self-sufficient small-scale peasant economy.

Lessons for the Future.
Without the felt need to innovate, and without the help of advancing science and technology, quality management could not evolve further. When we look at the China of today, we can find in its state-owned industries, in their administration by various ministries, and quality management by governmental regulations, a considerable resemblance to the ancient system. Yet this ought not to be surprising, as China is, after all, a country of tradition.

While tradition can sometimes stifle progress, it can stimulate it, too. The history of China's ancient quality management system reveals brilliant achievements associated with its application to the production of handicrafts. Today, China faces a new environment—political, economic, and scientific. One challenge of the new environment is to create a new quality management system. Should not the study of this history also provide useful guidance for the men and women of China who face this challenge?

QUALITY IN POSTREVOLUTION CHINA

Quality in the Early Years of the People's Republic (1949–1952).
When the People's Republic was first established in 1949, the predominant task was to fully utilize the meager industry that was left following the Civil War to produce as much as possible to meet the needs of the country and people. All privately owned factories were turned over to the state and rebuilt into state-run businesses. How to run such reborn factories became a problem. There was no experience to follow, no lessons to learn from, and no knowledge base to refer to. What could be relied upon

were only the factory workers who had been just liberated and were full of enthusiasm for production. A new form of organization had to be worked out. Some new concepts for quality and productivity had to be put forward.

Worker Terms. First of all, a democratic management campaign was carried out in the whole country to abolish the feudal gangmaster system which had so cruelly exploited the workers. For example, the Ministry of Fuel Industry issued such an order in 1950 to all mines over the country. Then a new form of organization, the "Administrative Committee," was set up in every factory which was composed of workers of the factory and cadres dispatched by the government to discuss and decide important matters. Needless to say, the quantity and quality of products were the first items to be placed on the agenda. Consequently, laborers enjoyed a new status; they were workers of course, but also, in a sense, managers. A very harmonious relation between management staff and line workers was thus formed.

In such a background and environment workers started to create their own teams. They began to be aware of their responsibility and improved their labor discipline and skill through team activities. A rationalization suggestion campaign spread spontaneously across the country. In August 1950 the Government Administration Council of the People's Republic passed a resolution to give awards for invention, technical innovation, and rationalization, putting the campaign on a more effective path. The consciousness of the labor did raise the industrial productivity and on the whole product quality reached a suitable level for civilian goods but was not satisfactory for more stringent requirements, particularly in military weapons. There had been a report saying that the point of fall of rocket shells produced in 1950 scattered very inaccurately due to the unevenness of charges used in different factories. The official view revealed the fact that inspections and quality control had not been taken seriously and properly. According to a statistical report of September 1950, which covered 29 weapons factories, only 21 had a quality inspection department. Of these, only 5 reported to the factory director. The remaining 8 factories had no inspection system of any sort at all. The sole dependence on the worker's individual consciousness of quality and productivity proved to be insufficient without a coordinated system of quality management.

Corrective Measures. In April 1951 the Central Government began to establish an independent inspection department within every factory. Meanwhile, the central industrial ministries and their local agencies were also asked to have a quality supervision department. In the years 1951 and 1952, a quality management and supervision system was completed, comprising three levels—central government, local authorities, and factory management. The first task was to unify the test and inspection procedures and standards for most of the products which had lacked interchangeability and maintainability. Efforts for this purpose could be seen from the decision promulgated by the central government in October 1951, which made clear the duties and rights of inspection and demanded test equipment to be consolidated, in-process-inspection to be implemented, and inspection specifications to be documented in detail.

Inspection and standardization on one hand, operations improvement on the other—these were the two hands on which China was relying to exercise her quality management in the period of the Korean War. Workers concentrated on the improvement of their operations, because they knew that the only thing they could do to guarantee their product quality and quantity, with machinery equipment being so old and raw material so inferior, was to operate more efficiently and more effectively. They understood that this was the only way to meet the needs both in the front and rear. In cotton mills, coal mines, iron and steel works, machine-building factories and in railroad transportation, there appeared heroic workers who not only created advanced operations methods but also inspired the morale of their group by their devoted labor. As a matter of course, a call from the laboring masses and then a campaign organized by the State to learn from those model workers followed. This kind of learning campaign has since become a tradition which formed an important part of quality management.

Quality Management Introduced from the Soviet Union (1953–1960). China started her first 5-year plan in 1953 with the ending of the Korean War. The basic task was to build

up an initial foundation of industrialization centering around the 156 major projects helped by the Soviet Union. All technology and management necessary were brought to China by the thousands of Soviet experts who came as advisers at every industrial construction site. By the end of 1957, industries that China had never before had, such as automobile, airplane, machine tool, electricity-generation equipment, and high-alloy steel, were successfully established. It was in this period that the rough outlines of quality management as a systematic and scientific activity was first proposed. Since then, quality management has come to have tremendous influence on the later stages in China's economic development.

Organization for Quality Management

Centralized Leadership. A sound quality management system is an institutional guarantee of product quality for which commitment of the leadership is most vital. Following the Soviet experience, the chief of each level in the industrial management hierarchy, governmental and factory, was supposed to bear the entire responsibility and absolute leadership in what was called the "one-boss system." The factory director was in such a position for the factory management, including quality, and the director of the inspection department was in the same position as far as the department was concerned. A circular promulgated in this connection by the Central Committee of the Communist Party of China demanded party organizations in every factory to help strengthen the system. Everyone in the factory had to obey any order from the chief of the group, section, department, and factory office to which he or she belonged. Though the "one-boss system" gave full attention to the accomplishment of every production task, it was criticized as neglecting democratic management and hence inhibiting the workers' initiative. The Soviet-style centralized leadership was abandoned finally in 1961; it was replaced by leadership on the basis of consensus.

The Organizational Hierarchy of Quality Management. During the early years of the People's Republic, China was divided into six large administrative areas. Each area had had its own relatively independent area government. In the years 1952 to 1954, the central government gradually eliminated the large administrative area and tightened up its integrated industrial management in order to push the 5-year plan more vigorously. Industrial Ministries were rearranged and charged with full power and responsibility of administration respectively. State-owned factories were put under the direct and strict administrative management of those ministries, each of which had a department of quality or technical supervision. At the level of provincial and municipal government, there were also established local industrial bureaus and corresponding departments to execute the administrative supervision delegated by the central ministries. Aside from the central and local authorities, the State Economic Commission was created to establish quality management principles and policies and to coordinate the quality management of different ministries and localities. In factories, quality management was carried out at different levels: factory, workshop, and group. The inspection department director had a private staff and posted inspectors in the workshops and on the line, and in worker groups. This is how quality management was deployed, through local agencies, from the central government down to the factory floor. So it remained for the whole period of China's planned economy.

Various Functions of Quality Management. Production units in China's factories were unique and simple, in that such important matters as purchasing and sales were not their business. Each factory was categorized by product and size and reported to a central ministry and local bureau appropriate to that category. Those administrative authorities planned and assigned production quotas to factories. Other commercial ministries provided materials to and acquired products from factories at prices set by the government. There were neither a market nor a commodity exchange, but only products delivered through official circulation channels. Factories could not be regarded as enterprises. Instead, in fact, they were only workshops, since there was no risk to take on the part of the factory, profit, if any, being turned over to the State, and loss, no matter how much, being made up by the State. Regarding quality management, quality standards (and sometimes even product specifications and drawings) were given to the factory by the department in charge of each ministry. The factory was concerned mainly with process specification and control, equipment control and maintenance, operation and work instructions, inspections (incoming, in-process, and outgoing), and disposition of nonconforming products.

In every factory the chief engineer was responsible for all the technical aspects of quality management, while the director of the inspection department was in charge only of the inspections. The independent position given to the inspection department assured the authority of inspection with the side effect that it lost contact with the engineering department and line workers. Consequently, the responsibility of product quality was always an issue of dispute. The inspection department, particularly its director, was supposed to take the final responsibility, but had no authority or responsibility regarding product design or process control. Quality should be the comprehensive result of the efforts of all departments. However, the quality management system of that time was a hindrance to the realization of that ideal.

Shifting the Emphasis from the Product to the Process

Manufacturing Process Design. In 1953, the Ministry of Machinery Industry issued the "Regulations for the Work of Inspection Department" and "Regulations for the Trial Production of New Product," which together laid the foundation of quality management on both the industrial ministry and factory levels. Though these regulations put inspection first in quality management, they also incorporated Soviet-style technical supervision. This supervision began with the specification and design of product and then proceeded to the specification and design of the process. A trial production committee was set up and the inspection department was asked to participate to study the methods and results of test and analysis. The inspection department assisted in drafting technical standards and making modifications to correct deficiencies identified during the qualification test programs. So it could be said that in this way the inspection department was engaged in preventive actions. But it must be added that factories also received concrete help and guidance in their quality management from the ministries, where well-educated and talented technical personnel were concentrated. Therefore, in those days Chinese quality management was not carried out solely by factories, but was done in cooperation between factories and the ministries to which they reported.

Manufacturing Specification. It was gradually recognized through the implementation of trial production that product quality could not be guaranteed by inspection procedures and standards alone and was determined by good workmanship and proper process control, and that both of them should be stipulated by written standards, instructions, and other illustrations. Industries started to systematically work out process specifications and operation instructions. In every factory the inspection department organized its members to learn the process specifications and workmanship criteria and supervise their implementation in collaboration with process technicians and work-group leaders. A task was thus added to the inspection department: to check the integrity and applicability of the process specifications drawn up by other engineering departments. It was intended that the inspection department would reduce its degree of separation from other departments and its isolation in the factory. But things went in a contrary direction. So long as the problem of product quality responsibility had not been solved to the understanding of all parties concerned, disputes between manufacturing and inspection, which had always existed, now intensified. A complete solution had to wait for many years.

Establishing the Metrological System. Invasion by big powers brought different metrological systems to old China. One of the problems that the early industrialization of new China faced was the confusing state of metrological work. With industries and factories being built one after another, the administrative authorities felt it important to unify the system. Beginning in 1954, they set up special departments for metrology and standardization in factories. Measuring and test equipment was installed, qualified personnel were trained, and by 1957 a metrology system began to take shape in state-owned factories. The State Council established the State Bureau of Metrology in 1955 to unify and administer the metrological work nationwide, and issued a decree in 1959 which formally stipulated the adoption of the metric system.

The Disastrous "Great Leap Forward." Everything in quality management seemed to be developing fairly well. Management by the Soviet model, in spite of its shortcomings, had finally put the quality management of the newly built factories on a regular basis. At the same time, modern quality management developed in the United States was introduced to China. In 1957, an operations

research group was founded within the Chinese Academy of Sciences. They began their work with research in statistical quality control, offering courses, training staff, and conducting application experiments in factories. In August 1968, dizzied by the success of industrialization (though the success was in fact very preliminary), the politburo of the Communist Party ordered that a "Great Leap Forward" movement be launched. The backyard steel furnace and the people's commune were the two "indigenous" inventions that were promoted in this movement. They were meant to speed up the development of China's economy and to help China catch up with advanced countries. But they disregarded objective conditions and scientific reason. As a result, the national economy was badly hurt. Industrial management was discarded as a nuisance. In factories, inspection departments were all dismantled, and quality management was forced to disappear. The farce continued for 2 years. And who could have known at the time that when it was over an even madder one would take its place.

Quality in Self-Reliant China (1961–1965)

The Break with the Soviet Union and Its Management.   In 1960, relations between China and the Soviet Union were suddenly ended. All Soviet experts were ordered to leave China, almost overnight, taking with them drawings and technical documents of unfinished industrial construction projects. This aroused in the Chinese people a spirit of self-reliance. From the beginning, the Soviet "one-boss system," the core of Soviet-style management, had been unpopular among Chinese workers. By 1959, some factories had begun quietly changing to a management style based on consensus. So, in March 1960, as an endorsement of this movement, the Control Committee of the Communist Party circulated an instruction generally known as the "Charter of the Anshan Iron and Steel Company," which stressed harmonious leadership through close collaboration of labor and management. It was so named because there had previously been passed to China the "Charter of the Magnetogorsk Iron and Steel Company" representing the stiff and rigid Soviet management. The Chinese edition of the "Charter" was apparently the antithesis of the Soviet one. It was intended to emancipate people's minds from blind worship of untested teachings and proved to be correct for conditions as they existed in China. It encouraged a mass movement of technological innovation and managerial reform.

The Emerging Chinese Model.   In September 1961 the Central Committee of the Communist Party promulgated the "Seventy Regulations in Industry." Drawn from both the positive and negative experiences of economic development and administrative practices of the previous years, the regulations outlined the principles of industrial management to be carried out. It was actually the first comprehensive summary of the exploration of socialist economic management and it had far-reaching influence in later years.

Factory Director's Responsibility.   The regulations clearly stipulated that the factory director took the management responsibility under the leadership of the Party committee in the factory. The decision left a question unanswered from beginning to end. It was expected that the Party committee could motivate the workers and establish good morale, and that the director could manage deputies and department heads in professional discipline. In fact, if the secretary of the Party committee and the factory director consulted and cooperated with each other, then the system would have worked well. If, on the contrary, they did not cooperate for any reason, the system would have led to an unstable or even a harmful situation.

In any case, the responsibility system was built on delegation by the director and regular division of management, and it cleared away the confusion and obstacles from various sources. As to quality management, inspection still played the leading role, but within a better framework than before. Beside the usual first-piece, patrol, and final inspection, there was implemented a combination of self-inspection, mutual inspection, and specialized inspections. A strong quality consciousness was to be consolidated through the new system of inspection.

Democratic Management.   The gist of the "Charter of Anshan Iron and Steel Company" was the so-called two participation, one reform and three-in-one combination, i.e., management staff participate in line work, workers participate in management; reform through mass movement; management, technicians, and workers collaborate in combination to solve technological and managerial

problems. The "Regulations in Industry" also promulgated a democratic management system which embodied the principle that the factory director was responsible for duties under the guidance of the Party committee on the one hand and under the supervision of the Worker Congress on the other. Meanwhile, a campaign of "Learning from Daqing" took place all over the country. Daqing was the first big oil field, discovered in 1960. Within 3 years a huge oil refinery had been constructed there. Needless to say, Daqing contributed enormously to China's economy, but above all was its democratic management, of which the main point was its managerial training of all employees "to be honest, to be strict and to be same." That is, to be an honest person, speaking and acting honestly; to be strict in organization, requirement, attitude, and discipline; and to behave in the same way, no matter whether day or night, in good or bad weather, inspected or not inspected, whether the leader is on site or not on site.

Essentially, the Daqing experience was the revolutionary and scientific spirit which kept the workers' production enthusiasm alive and the enterprise management efficient and effective. With this spirit in daily work, quality management began to put prevention first. For instance, because line inspectors were chosen from quality-conscious and experienced line workers, they were asked to fill a triple role: first, to be a propagandist to explain to the line worker why quality comes first; second, to be an instructor, to tell the line workers how they should operate to protect their product from nonconformity; and last, to be the inspector—to decide whether the products meet the standards. This was a useful measure to prevent nonconforming products, but also proved to be a wise method to avoid the disputes between production and inspection which had often occurred in the past.

A National Campaign. From the beginning of the People's Republic, democratic management in factories was sought. In the best circumstances, democratic management is easier said than done; widespread distrust of the then-dominant autocratic Soviet management model made it even more difficult to achieve. By early in 1957, statistical quality control (SQC) had already been introduced to China by scholars returned from study in the United States. Courses had been offered, technical staff had been trained, and experiments had been done in some factories. However, while SQC remained a useful tool in the hands of the technicians and engineers in charge of inspection, it would be rejected by the management and labor as well. This lesson had already been learned at that time. When the call to "integrate theory with practice" sounded over the country, SQC people, research scientists and college professors, went down to the grass-roots units and realized that SQC had to connect itself with the democratic management movement then in progress if it was to become a useful element of quality management. Data collection, for example, would come to nothing without the wholehearted cooperation of the line workers. For another example, when the concept of the process capability study was introduced to factory people by lectures and experiments, the workers spontaneously grasped the meaning and intuitively recognized that this was the common language by which engineering, production, and inspection could communicate in order to guarantee product quality and was the practical way to implement the "three-in-one combination" and the "two participation" democratic management.

Advancing from product inspection to process control, management, technical staff, and workers got together to discuss quality problems and related matters, such as product specifications, equipment maintenance, work standards, and production costs. Here staff were able to get first-hand data and material in the workshop, and workers were able to work in concert with management. Appreciation of the new quality control thus grew gradually. In 1964, the Ministry of Machine Building decided to promote process control through process capability study in all its factories.

The Cultural Revolution (1966–1976). The so-called Cultural Revolution started, developed, and ended beyond rational imagination. It was a farce, a tragedy. It was a nightmare, a disaster. Daily life— political, economic, and social—fell totally into turmoil. Economic management systems—from the central government to local authorities—were gravely damaged. Order in work and production was disrupted completely. Every principle of the "Seventy Regulations in Industry," such as the proper relationship between the State's centralized administration and the enterprise's independent management, and the management responsibility system, were criticized as evil institutions which "bother, block, and suppress" the working class. Instead the "three-nil factory" was

recommended, which had no administration from above, no management of itself, no rules and regulations at all. Under these circumstances, quality management, which had been implemented and improved so much, became a taboo. In 1972, industrial product quality had deteriorated so dangerously that a proposal was raised by the National Planning Conference to re-emphasize "quality first"; it was overruled. The "Cultural Revolution" brought disorder, irresponsibility, and low morale to factories and put China's economy to the verge of collapse. What is more, intellectuals, engineers, and technicians were vilified as "stinking rascals," their endeavor to absorb knowledge from advanced countries abroad and to apply it to the economic construction of their own country was taken as "blind worship and faith in things foreign." Be it SQC or TQC, it was forbidden in those sad years.

Reform and Open Door (1977 to Present)

Cultural Revolution.   The "Cultural Revolution" was ended in October 1976. Various efforts were undertaken to bring order out of the chaos created in those 10 years. Government organizations were gradually restored and replenished. Factories resumed regular production order and proper leadership, step by step. In April 1977, the State Council convened a national industrial conference which, among other things, decided to promote a nationwide campaign: "Trust me with quality." The campaign aimed to arouse the quality consciousness and sense of responsibility of workers, asking them to inscribe their names on their own products, a measure very like the old one carried out in the dynasties. Though the request was liable to make workers overintense on the processing production line, and could not continue for long, it did educate the workers that quality was a serious matter. Since then the campaign has evolved to an ordinary team-management of factories, where a group or team of good workmanship and quality product would be given the title "Team can be trusted." In April 1978 a new "Thirty Regulations in Industry" was issued, the main points of which were to rectify the management leadership of factories and to put product quality at the first place for factories in fulfilling the state-planned production assignment. A responsibility system was once more put forward and it was stipulated this time that a deputy director of the factory was to be responsible for product quality and related matters. A number of factories with difficult and long-standing problems thus recovered within a short time after the release of the Regulations.

Qinghe Woolen Mill.   As a matter of fact, Total Quality Control began independently at Qinghe Woolen Mill in 1976 and at the Beijing Internal Combustion Engine Factory in 1977 with help from China's own experts, and the success achieved had drawn the attention of the country. But the dispatch of QC experts from Komatsu, a world-famous manufacturing company of Japan, working in the Beijing Internal Combustion Engine Factory under the guidance of Dr. Kaoru Ishikawa in the summer of 1978, gave a tremendous boost to TQC in China. All of a sudden, factory people were astonished to hear about a system of quality control in which all factory members had to participate, and rushed to the Beijing Internal Combustion Engine Factory from all over the country to learn what it was. Next year a group of technicians and engineers of the Factory was kindly invited by the President of Komatsu, Mr. Ryoichi Kawai, to come to its Koyama Engine Factory to practice TQC in the TQC atmosphere of Komatsu. The book written by members of the group, recording their experience in Koyama and published after their return, was circulated so widely that TQC in the early days in China was always connected with the names of Komatsu and Beijing Internal Combustion Engine Factory.

Reform and Opening.   In December 1978 China adopted a policy of "reform and opening to the outside world." It proposed emancipating the mind and at the same time seeking truth from facts. It demanded that issues in management methods and management institutions as well as economic policies be studied and solved carefully. A common acknowledgment was reached that management and technology were the two wheels of the vehicle of production in which China's technology lagged behind the times and management was even further behind. The new policy greatly encouraged Chinese people to strive for a better understanding of the outside world and a better way to rebuild

their country. High official delegations were sent to Japan, the United States, and Western European countries, one after another, to learn business management. They brought back new knowledge and fresh excitement. The China Enterprise Management Association and the China Quality Control Association (CQCA) were set up separately in 1978 and 1979 at the suggestion of one of these delegations. The mission of CQCA with its local and trade branches was to promote TQC among enterprises and to provide consultation and advisory services to governments of different levels. When the State Economic Commission began to take the responsibility of promoting TQC in state-owned factories within the conditions of the planned economic system, CQCA actually became the acting body of the Commission in this respect.

In 1978, the State Council approved the proposal from the quality professionals to make September "Quality Month," during which prestigious awards were given to the enterprises with outstanding quality product and quality management. Propaganda on TQC was conducted on a national scale. Mass media were mobilized. In 1980, a TV program on TQC was broadcast for the first time and repeated in different versions in succeeding years. The TQC TV program was specially featured as an educational course.

Students were recruited through industrial ministries and were qualified if they passed the examination directed by CQCA and other authorities. It was reported that more than 10 million people of different occupations have watched the TQC TV program in the past 15 years. By the time the "Provisional Regulations for the Implementation of TQC" was issued by the State Economic Commission in 1980, TQC had been disseminated broadly throughout the country. Beginning in 1978, QC circles were organized in state-owned factories, and they have held their local and national conventions every year since. In 1983 the "Provisional Regulations for QC Circles" was issued by the State Economic Commission which put the QC circle activities on a healthy footing and in a more influential position. In 1980, the number of QC circles was estimated to be 40,000; by 1995, the officially registered QC circles had increased in number to 1,360,000, with an economic benefit to the enterprises of more than 20 billion yuan ($US 1=8.31 yuan). By the end of 1985, 38,000 state-owned factories in a variety of industries had implemented TQC with special departments in charge of the effort. On the basis of the Seventh Five-Year Plan (1986–1990), which stressed repeatedly the importance and necessity of quality management, the State Economic Commission made a corresponding resolution to examine and reinforce the TQC of 8200 medium- and large-scale factories within the 5-year plan period. Though small in number, these factories account for 60 percent of the entire annual industrial output of China. The heavy promotional task fell on CQCA. A new set of criteria was designed for this purpose which focused on the establishment of a quality assurance system.

New Era. Thus a new era of quality management arrived, a result of the Reform and Open Door policy. The foremost breakthrough was the exchange of ideas and experiences with foreign quality professionals and organizations. As mentioned above, Dr. Ishikawa came first in 1978 and came almost every year thereafter until his death in 1988. Dr. Lennart Sandholm, Dr. Genichi Taguchi, and Dr. Yoshio Kondo were among the earliest experts to visit China. In 1982 in Beijing, Dr. J. M. Juran delivered a week-long series of lectures. Despite Dr. Juran's advanced age, the lectures were moving. Dr. H. James Harrington's enthusiastic help was welcomed. Dr. Hitoshi Kume was also a frequent visitor. Their personal lectures and advices had been most valuable to the development of TQC in China. Doctor A. V. Feigenbaum, though he did not come in person, consented warmly to be an honorary advisor to CQCA. There were so many foreign experts who came to help that it would be impossible to give all their names here. In addition, quality organizations such as the Japanese Union of Scientists and Engineers (JUSE) and the American Society for Quality Control (ASQC) were not reluctant to render their aid and hospitality to China. Numerous delegations and study groups from China also visited many foreign countries, and it must be noted that the first official QC delegation to the United States was invited by the American Association for the Advancement of Science in 1983, and had the honor of meeting prominent American scientists and entrepreneurs on the occasion arranged by the American National Academy of Sciences and the American National Academy of Engineering. Yet the big event would be the First Congress of the Asia-Pacific Quality Organization convened at Beijing in 1985, where Chinese quality professionals were able to become acquainted with so many colleagues from abroad at home. The exchanges of

knowledge and experiences not only enriched the QC expertise on the China side but also enhanced mutual understandings among experts of different countries, the latter being by far the most beneficial and valuable outcome.

Readjustment. In the years since the Reform of 1977, China's economy has undergone several periods of readjustment, restructuring, consolidation, and improvement. In each period it has been emphasized that enterprises should strengthen themselves by improving quality rather than expanding in quantity. This message undoubtedly supported the promotion of TQC. Nevertheless, it has not always been clear for TQC. For instance, in 1988 the "Law on the Industrial Enterprises Owned by All the People" was promulgated, which made a clear separation between ownership and management, assigning more power and responsibility to the enterprise manager.

In the process of enforcing the law, the administrative functions of the government department shifted from exerting tight control on the management of enterprises to creating a better environment for the development of enterprises. This shift should be very helpful to the implementation of TQC in enterprises, but enterprise managers widely misjudged the intent of the Law and took advantage of their enlarged power to pursue quick profit by expanding quantity at the expense of quality. Under these circumstances, quality management was weakened and the inspection department was even abolished in some cases. From this bitter experience several conclusions were drawn. First, Total Quality Control must be "Top's Quality Control" meaning that the top management must learn first and be committed in person if there is to be a really effective and sustainable TQC. Second, product quality must have a veto over other production performance. In the computation of workers' wages and bonuses, their work quality must have priority over quantity and other matters. Third, in the final analysis quality is in the hands of workers. Therefore, their quality consciousness must be first motivated before the training of skill. Equally important was the legislation for product quality and quality management. "The Law of Standardization," effective on April 1, 1989, encourages adoption of international standards. In December 1993, the State Economic and Trade Commission, State Planning Commission, State Science and Technology Commission, and State Technical Supervision Bureau jointly issued the "Regulations of Adoption of International Standards and Foreign Advanced Standards," which supplies preferential merits to enterprises which do so.

As early as December 1988 China adopted the ISO 9000 series of 1987 for national standards in quality management, adding a few technical complements and changing the coding system. The converted standards posed some problems in communication and cooperation with foreign experts because of their nonconformity with the original. In December 1989, a National Technical Committee, as the counterpart of ISO TC 176, was formed to be the technical authority over the standardization of Quality Management and Quality Assurance in China. The "Provisions of Quality Product Certification," issued by the State Council in May 1991, made existence of a quality system a necessary condition for an enterprise to apply for the certificate. As of the end of May 1996, 721 certificates of accreditation had been issued by state-recognized authorities to enterprises in China. Overseas organizations, such as Underwriters Laboratories Inc. in the United States, Canadian Standards Association, British Standards Institute, and others are also involved in quality certification in China. The whole certification system is helping China's enterprises to produce commodities of better quality and safety, in conformity with international standards. In August 1992, the State Council issued the "Decision on Further Strengthening Quality Management". The document summarized the achievements and shortcomings of quality management since the beginning of the Reform and Open Door Policy, and stressed the crucial meaning of quality and quality management. It required governments and enterprises at all levels to have a sense of urgency and crisis regarding quality.

The spirit of the 10 articles of the State Council's decision was to emphasize three elements: the full utilization of the market mechanism to force enterprises to improve their product quality, provision of a framework of laws to guide and regulate enterprises' quality management, and the education of the people to exercise their legal rights regarding product quality. Accordingly, in September 1993, the National People's Congress (NPC) passed the "Laws of Product Quality" stipulating the rights and duties of the producer, and introducing for the first time in China the idea of product liability. A month later, in October 1993, NPC passed the "Laws of Consumer Rights Protection," which made clear the consumer's right to complain and to be compensated for inferior quality.

Though not perfect, these two laws have already begun to put pressure on producers to pay due attention to their product quality, and encourage consumers to seek compensation instead of accepting inferior quality goods in silence.

Quality Long March, a TV Program which began in 1992, is a lively example of educational work in consumers' rights. TV reporters travel around the country to collect and broadcast consumers' opinions on product quality and at the same time secure responses to their complaints from the producers concerned. The TV program did a good job in making known to the consumers their legal right to protect themselves from inferior-quality products and in warning producers of their duties to produce quality goods. Quality Long March has now become a regular national program every year during Quality Month, and has invited quality experts to tour-lecture on quality since 1995. Another event of Quality Month, the China High Level Forum on Quality, also began in 1992. High officials of the State, business representatives, quality experts, and scholars meet at the Forum to discuss quality issues and make pertinent proposals to the parties concerned. Vice premier Zhu Rongji told the Forum in 1992 that quality should be the life of China's economy. In 1993, another vice premier, Li Langing, proposed to the Forum that China could prosper only through superior quality. Their words greatly encouraged China's quality professionals to strive for better quality of products, services, and life.

QUALITY AND THE TRANSITION TO THE MARKET ECONOMY

China's quality and quality management cannot be separated from the economic system of China. A brief introduction to the changes of the economic system is necessary for a clear discussion of quality and quality management. From the first 5-year plan period (1953–1957) to that of the fifth (1976–1980) China had practiced the centralized planned economic system. The Reform and Open Door Policy was proclaimed in December 1978, halfway through the fifth 5-year plan period.

In 1980, the first test of a different economic system was implemented at Shenzhen, a small area near Hong Kong. A system of "mainly planned economy supplemented by adjustment of market" was proposed favorably in the Twelfth National Congress of the Communist Party of 1982. This was equal to admitting the law and function of the market. In the Thirteenth National Congress of 1987 the wording changed to the "planned commodity economy."

How much difference there is between these two phrases is a question which has puzzled many people. In any case, one thing was felt for sure: The economic system of China was going to change. The Fourteenth National Congress of 1992 made the proposal of the "Socialist Market Economy," and the resolution passed by the National People's Congress in 1993 determined officially the new economic system. During the whole process of change of economic system, administration of enterprises by the government and enterprise management itself changed too. So did the management of quality.

The Challenge for China in the World Market.   The transition from the centralized planned economy to the socialist market economy is a challenge as well as an opportunity. The challenge comes from the market. If China meets the challenge with success, then China will prosper. In this way the market offers the opportunity as well. To meet the challenge China must deepen the Reform and widen the Opening.

Nature and Status of State-Owned Enterprises.   The first important and urgent task is to restructure and rejuvenate the state-owned enterprises, which lost their vitality during the almost 30 years of planned economy. The separation of ownership and management power stipulated by the State Industrial Enterprises Law of 1988 has to be accomplished by restructuring the state-owned enterprises to corporate organizations which make their own managerial decisions, take full responsibility for their own profit and loss, develop themselves by their own efforts and resources, and restrain themselves by observing laws and regulations. In 1992, the government issued laws and regulations for State enterprises to change their management mechanism and defined the modern corporation system as the goal of enterprise reform. In 1994, from the tens of thousands of State-owned enterprises, 100

large- and medium-sized ones were chosen to take part in the experimental introduction of the modern corporation structure. The crucial and difficult task in this experiment was transforming the existing administrative relationship between the government and the enterprise into an economic one; that is, the government is the owner of the enterprises' property, which is operated by the enterprise manager. The results were satisfactory and the reform began to spread nationwide in 1996. Though there are many problems, such as property rights, huge debts, and inactive employees, the reform of State-owned enterprises will be achieved with the successful macro economic control.

Unification of Democratic Management and the Legal System.   According to the State Industrial Enterprises Law of 1988, the state is supposed to ensure that staff and workers enjoy the status of the masters of their enterprises, and the enterprise should, through the staff and workers' congress, practice democratic management. The trade union in the enterprise should represent and safeguard the interests of the staff and workers, and should organize them for participation in democratic management and democratic supervision. It is the first time in history that democratic management has been thus stipulated by law. The establishment of a modern corporation system is combined with democratic management. The "Law on Corporations," effective on July 1, 1994, further stipulates the relationship among owner, manager, staff, and workers and the right of the staff and workers' congress and trade union to send representatives to the meeting of the Board of Directors in case there is discussion of matters concerning the interests of the staff and workers. The "Labor Law," effective on January 1, 1995, stipulates the rights and obligations of labor. Under this law, democratic management not only assures the right of employees to participate but also imposes a duty to obey the rules and regulations of the enterprise.

International Business Environment.   Foreign trade has increased rapidly since the Reform and Opening, particularly after the change to the market economy. China has become a country relying heavily on foreign trade; in 1995, the combined total value of exports and imports was more than 40 percent of Gross Domestic Product (GDP). In the same year, foreign investment in China amounted to 150 billion U.S. dollars. Competition in both the domestic and foreign marketplace is becoming more and more intensified. In recent years, the sharp cut in China's import tariffs has especially accelerated the import of foreign-made commodities, which in turn, has put pressure on State-owned enterprises. Competition is good, but Chinese producers of commodities lack competitiveness. This is precisely one of the reasons that the State has speeded up the reform of State-owned enterprises in order to improve product quality and cost. The ISO 9000 family of quality-management and quality-assurance standards is currently popular for the same reason.

An Assessment of Quality in China Today.   Much has been said about quality management at different stages of China's economic development. Let us turn to the question of the status of quality today and the impact on quality of the changes described in the economic system and in quality management.

Quality in Manufacturing Industries.   In the early period of the planned economy, product quality as a whole was guaranteed, though the quality standards were low and the variety of products was limited. But, in parallel with the progress of economic reform, collective and private enterprises mushroomed, suddenly enlarging the workforce without prior and proper training and without resources for management and supervision of product quality. State-owned enterprises expanded their production in pursuit of quick profit by emphasizing quantity at the expense of quality. Even shoddies and counterfeits appeared in the market. A sampling survey of product quality, conducted quarterly by the State Technical Supervision Bureau, shows the percentage of the product tested which met the applicable standards. The summary results for some representative years from 1985 through 1995 are

1985	65.4
1987	77.0

1991	80.0
1992	70.1
1993	70.9
1994	69.8
1995	75.4

The kinds of products and producers inspected vary in each survey; hence, strictly speaking, the figures are not comparable. Particularly, the survey is intended to inspect enterprises whose products caused consumer's complaints. Therefore, the results are not fully indicative of the general situation but rather reflect the product quality of those enterprises whose quality management was poorer and often ignored the national standards. The State-owned large-scale enterprises are usually much better. For instance, the survey results for the first half of 1996 reveal that an average of only 80 percent of products inspected met quality standards, 10 percent higher than the worst years. The large-sized state-owned enterprises in that survey achieved 91 percent.

Quality in Service Industries.   It is perhaps a remnant of the "Cultural Revolution" that the service provided by State-owned enterprises is notoriously poor. A TV program on TQC jointly sponsored by the Ministries of Commerce, Post and Telecommunications, Railways, and others was broadcast for the service industry of China over and over again from 1987 to 1992. It introduced the activities of outstanding QC circles in the service industry and some very simple QC techniques presumably helpful in improving service quality. The response from society was unexpectedly favorable. The Beijing municipal government asked the TV network to broadcast it for the citizens of Beijing on the eve of the Beijing Asian Olympic Games. In 1995 another TV program introduced ISO 9004-2. In it, the Director of the State Technical Supervision Bureau, Li Chuanqing, presented the opening address.

Quality in Government Service.   The 40 years of economic construction of China can be divided into three stages: In the first stage (1949–1952) government took over the economy; in the second stage (1953–1978) government ran the economy, in the third stage (1979–present) government has undertaken to reform the economy. Now economic reform has come to a crossroad which demands reform of government itself. As mentioned above, the key to the establishment of a modern corporation system lies in the separation of government from enterprises. A 3-year plan which began in 1993 has been implemented to reform the administrative management system and the functions of government departments. It set out first to reduce administrative personnel in the departments affiliated with the State Council by 20 percent and local government departments by 25 percent. (The first target was achieved by the middle of 1995, and the outlook for the second is good, according to the report sent to the central government by local institutions.)

It then began to readjust government department functions and the relationships between different government departments to avoid duplicating their functions and to improve their efficiency. Readjustment on the central level has basically been completed. Internal branches and personnel have been established. Government departments thus strengthened their supervision and macro guidance of economic development through prices, taxation and other financial means without touching concrete matters of the management of enterprises. Government services probably is the only area where TQC has not entered yet, though most of the ministries have a quality control association under their administration as a peripheral organization through which the ministry provides guidance of quality management to enterprises and engages in international exchanges of information and experience in quality management.

EPILOGUE

Quality versus Speed.   In retrospect China's product quality has not met expectations, and the reasons are many. However, the dominant one lies in the "go-for-speed" policy explicitly or implicitly

cherished by government officials and followed by enterprise managers. In years past, when officials in charge of a department or a locality were evaluated on their administrative performance, economic growth was almost the sole factor on which they were judged. It was not unusual that stock or products unsold or even useless were calculated as output value. The result was a large output value but small economic benefit.

The "Outline to the Ninth Five-Year Plan (1996–2000) for National Economic and Social Development and the Long-Term Target for the Year 2010," passed by the National People's Congress in April 1996, pointed out that "high speed" is contingent on efficiency and quality, and put forward two fundamental changes necessary for maintaining the sustained, rapid, and healthy development of the national economy: first is the shift from the traditional planned economy to the socialist market economy; the second is the shift of the economic growth mode from extensive to intensive. For this end, it is necessary to bring the role of market mechanism into full play and to reform China's State-owned enterprises from extensive management to intensive management so that they can compete in the market to their advantage. Total Quality Management as an effective means of quality improvement and as a philosophy of management can definitely serve well the demand of an intensive-growth mode.

"Outline of Rejuvenation of Quality."   On September 3, 1996, the fiftieth meeting of the State Council discussed and passed a national program, "Outline of Rejuvenation of Quality." The document was drafted by quality professionals of many fields under the leadership of the State Technical Supervision Bureau in July 1993. The draft had been sent to all ministries to solicit opinions, and the final version was once again discussed and revised by members of the State Economic and Trade Commission in August 1995. The long duration of drafting, discussing, revising, and approving illustrates the complex nature of quality. Everybody knows it, everybody can say something of it, and in the end nobody knows truly what it is.

The outline points out that quality is a matter of strategy in the development of the national economy; the economy will pay heavily if quality is neglected. It set goals for product quality and quality management to be achieved by the year 2010. To promote TQM continuously and to seriously implement the ISO 9000 family of standards, "Quality Management and Quality assurance," are the two important items among others in the national program. Introduction of foreign advanced technology and management is also stressed.

Since this day, September 3, 1996, China finally has had a national program of quality rejuvenation.

SECTION 43
QUALITY IN LATIN AMERICA

Marcos E. J. Bertin

FROM ECONOMY TO QUALITY

The industrialization process began to accelerate in Latin America in the late 1950s. At that time, business leaders responsible for results (company presidents, general managers, owners) became involved in management processes as never before. They were very interested and eager to learn about the elements of business management—marketing, finances, costs, and personnel. They had only a minor interest in quality control. Most of their time was devoted to lobbying the government on matters of trade and to negotiating on labor issues with very strong unions. The degree of their interest in any subject varied according to the then-current level of inflation, economic activity, price and salary controls, import duties, taxes on exports, foreign exchange controls, interest rates, and the probability of devaluation of the local currencies. The leaders also had to deal with the huge government-owned monopolies (all financed with big government deficits) on which their businesses relied for various vital products and services. The most important of these were oil (extraction, production, and distribution), utilities (electricity and water supply), communications, transportation, and steel. With so many monopolies under its control, government, also a major buyer, had many suppliers, thus exerting another form of influence on the economies of the region. Therefore, it is not surprising that business leaders were totally occupied with the effects of government regulations and controls.

At any given moment, a reliable indicator of which business factors were the critical ones was to be found in the categories of experience sought in the help-wanted advertisements in the newspapers. One day the advertisements might stress commercial experience; the next day, financial; the day after, government relations.

Latin America has a long history of able entrepreneurs who knew how to ensure the growth, profitability, and, even in difficult times, survival of their companies. Many of them did it with success, despite an uncertain and even hostile business environment.

Quality and excellence were not critical factors in the business environment of the period from 1950 to 1980. In that economic environment, industrial growth happened largely because of government protection; soft loans were available at terms that amounted to a subsidy to promote investments in local production during periods of high inflation and high import duties. With some exceptions, quality, both in products and services, was below international standards.

Quality control was a subject of interest only within the factory. The people who became the quality pioneers in Latin America were engineers and other technical professionals working in local factories. They became very interested in the manufacturing improvements being reported, mainly in the United States of America, and were eager to learn about the new techniques being credited for those improvements.

As early as 1959, the American Society for Quality Control (ASQC) and, later, the European Organization for Quality (EOQ) and the Japanese Union of Scientists and Engineers (JUSE) helped to develop new professional societies in Argentina, Brazil, Chile, Colombia, and Mexico. During the 1960s and 1970s, experts from the United States, Europe, and Japan belonging to these organizations and to the International Academy of Quality (IAQ) gave courses and participated in conferences that were supported by leading companies. But presidents and general managers did not attend. They did not regard quality as a critical business factor; indeed, it was difficult to dispute this opinion in a time of financial crisis.

In the years 1989 to 1992, when annual inflation reached 2500 percent in Brazil and 1700 percent in Argentina (where it peaked at around 96 percent per month in March 1992), the entire attention and energy of chief executives had to be focused on financial measures to preserve their enterprises. The price of inattention was bankruptcy. The legacy of the prevailing economic system was enormous deficits in government budgets, deficits in the balance of trade, and ongoing crippling inflation.

In the 1980s, Latin America went through dramatic changes. On the political side, military governments were replaced by democratic governments. On the economic side, governments were forced by the severe monetary crisis and the requirements of a highly competitive global economy to carry out economic reforms based on free-market principles.

The most important changes were

- Privatization of government monopolies
- Improvement of the national infrastructure, both in quality and productivity, in response to the needs of business
- Reduction of regulations
- Reduction of government budget deficits (to zero in some countries)
- Control of inflation at low levels
- Reduction of customs duties for finished products, raw materials, and equipment
- Opportunity for businesses to increase participation in international trade, due to trade agreements such as NAFTA (North American Free Trade Agreement, the trade agreement of 1993, which reduced trade restrictions among Canada, Mexico, and the United States) and MERCOSUR (the common market between Argentina, Brazil, Paraguay, and Uruguay), and to lower customs import duties on equipment and raw materials
- A significant increase in private-sector capital investments
- Introduction of government policies conducive to competitiveness.

Throughout the region, the fact that free elections brought democratic candidates to office was widely interpreted as a social consensus of support for these many changes.

The economic environment changed dramatically, and with it changed many rules of the game for business. Many companies and institutions did not survive the crisis; either their cultures changed dramatically or they were succeeded by altogether new companies. As the environment changed, the interest of most CEOs shifted from survival issues to strategies for improving business competitiveness. Quality, productivity, and cost became the key strategic issues. For the first time, presidents and general managers in many companies became directly involved in quality programs—within the company and at the national level. However, there are still many owners and CEOs to convince, especially in the millions of small- and medium-size companies (SMCs) that account for about 40 percent of the gross industrial product of Latin America and which employ around 60 percent of its work force.

According to a 1995 study: "In a nutshell…Chile and Argentina led the revival of Latin America" (*The World Competitiveness Report* 1995). Brazil, Colombia, Peru, and Mexico also showed significant economic improvements over the period 1990 to 1995. (Mexico suffered political and economic setbacks in 1994 and 1995, and is working its way back to health in these areas.)

THE EVOLUTION OF QUALITY: A COUNTRY-BY-COUNTRY REVIEW

The recent history of quality in Latin America is a history of four critical factors:

1. Business competitiveness
2. The economic climate
3. CEO involvement
4. Participation of quality professionals

ARGENTINA

The Business Foundation for Quality and Excellence (FUNDECE). In the early 1980s, some CEOs foresaw the changes that were approaching in the economy. In 1987, after meeting informally for a few years, they founded the Business Foundation for Quality and Excellence. Its mission is

1. To promote the improvement of the competitiveness of business through the implementation of formal quality efforts. FUNDECE emphasizes the importance of the commitment and involvement of CEOs.
2. To improve the quality of life through education, health care, and government services.

Membership in FUNDECE is open only to CEOs. Experience suggests that CEOs listen to and share ideas easily with other CEOs. Only CEOs can attend FUNDECE meetings. When nonmember organizations participate by special invitation, it is only the CEO who is invited. Sometimes high government officials are also invited.

Participants in the meetings value this policy of including only CEOs, as it reinforces the need to maintain the focus of discussion at the highest policy level. There have been a few occasions when second-level managers asked for permission to participate. The requests were always diplomatically but firmly refused. Some of those who were refused admission as lower managers later became presidents and, therefore, members of FUNDECE. One of them was elected to the Board of Directors. Those who had endured refusal as lower managers acknowledged that even at the time of refusal they felt the policy to be sound. In the author's opinion, anyone wishing to create an organization with a mission similar to that of FUNDECE should consider the implications of this restriction on membership.

As of 1995, the membership of FUNDECE comprised the presidents and general managers of 130 enterprises. Of the enterprises represented, about two-thirds are large (companies having 200 employees or more and sales of at least $US40 million for industrial companies, or sales of at least $US24 million for service companies) and one-third are SMCs (companies that do not meet the definition for "large"). The breakdown by company type is roughly 60 percent industrial, 40 percent service. Among large companies, there are two industrial companies for each service company; among the SMCs, the service companies are slightly more numerous than industrial companies. The industrial companies include Argentine affiliates of multinational companies such as IBM, General Motors, Hewlett-Packard, and Reckitt & Colman. There are also Argentine companies not necessarily well known outside the country. Service companies include such categories as private

universities, banks, insurance companies, office equipment providers, health care providers, advertising agencies, and accounting firms.

The Strategic Committee of FUNDECE—a group of presidents and general managers of major companies in Argentina—created the FUNDECE Strategic Model (Figure 43.1). This model serves as a basis for the yearly FUNDECE action plan.

The most important activities of FUNDECE are

- Monthly breakfast meetings for the sharing of experiences and ideas. During visits sponsored by FUNDECE, foreign experts [from IAQ (International Academy for Quality), ASQ (American Society for Quality), EOQ (European Organization for Quality), and JUSE (Japanese Union of Scientists and Engineers)] frequently participate in these meetings. The breakfasts are the dominant and most effective activity of FUNDECE.

- Special projects. Two projects currently under development are the creation of a consultant data bank and the establishment of a library to include a collection of reference cases. Part of FUNDECE's sponsorship of such projects is to assign and fund a project leader. Special projects is the second most effective activity of FUNDECE.

- Seminars for professionals, middle managers, and academia.

- Teleconferences, including the satellite broadcast of the National Quality Forum—the industry quality event cosponsored each year by ASQC and *Fortune* magazine.

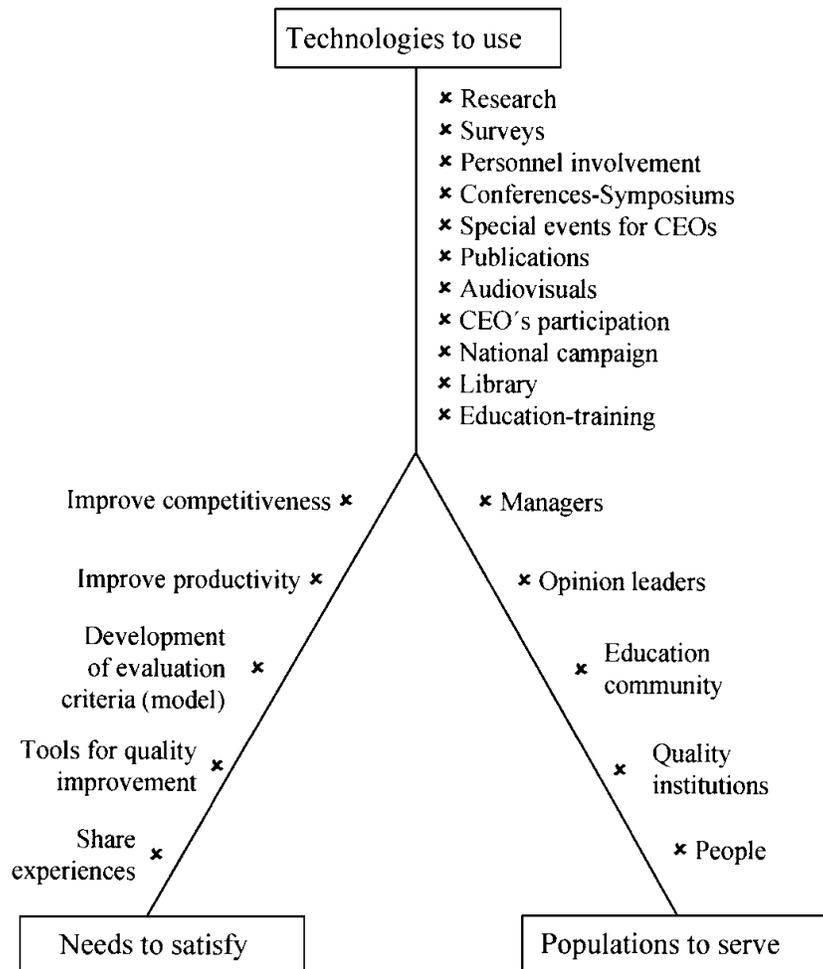
- Management in Argentina of the ASQC certification system.


FIGURE 43.1 FUNDECE strategic model. (*FUNDECE, 1995.*)

- Publication of a newsfax with quality information, both local and international.

- Publishing of videos. These are videos developed by committees chaired by CEOs that include members from an advertising agency and other organizations. The videos feature such topics as quality implementation and problem diagnosis, and are for general business use, both for member and nonmember organizations. Also, in cooperation with the Argentine Advertising Council (an association of advertising agencies and other companies engaged in advertising) and the Argentine government, FUNDECE helped create two TV spot commercials on the subject of quality, for showing on all the country's TV channels.

- Close relations are maintained with international quality organizations—ASQC, IAQ, EOQ, EFQM (European Foundation for Quality Management), JUSE, and with national quality organizations, both in Latin America and the rest of the world.

Three FUNDECE Projects

The National Quality Award.   In 1992, the government called upon FUNDECE to take a leading role in the promotion of quality in industry, services, education, and health care. The objective was to develop an efficient national infrastructure to carry out this promotion. Working with a commission in the legislative house of representatives, the first step was to create a national quality award. The award criteria would give business and other organizations the quality model. A FUNDECE project leader guided the efforts of a team that included members of the House of Representatives commission; Wayne Cassatt, then associate director of the Malcolm Baldrige National Quality Award in the United States' National Institute of Science and Technology (NIST); and members of FUNDECE affiliated with North American companies that had won the award in the United States (e.g., Xerox, IBM). That project leader became the managing director of the National Quality Award Foundation (FUNDAPRE), a private institution created by national law to manage the award for the private sector.

A separate award was established for the government sector, administered by the Secretariat of Public Function. The award criteria provide the quality model preferred by FUNDECE members and the government. Used in self-assessment, the criteria are effective tools, particularly if the scoring system allows for giving more weight to those items that are critical to the particular business assessing itself.

The Argentina National Quality Award began in 1994 with strong support from the government, FUNDECE, and the Malcolm Baldrige National Quality Award administration.

The major difference between the Baldrige and the Argentina Award was that FUNDECE insisted that the scoring of the Argentina Award stress business results. CEOs played a major role in establishing the criteria and weighting points. For some criteria, the points are closer to those of the Baldrige (for example, for customers and planning), and in others they are closer to Europe's (for example, for leadership, personnel satisfaction, social responsibility). All the comparisons are to 1992 data. Since then, weightings in all the national awards have been changed in response to suggestions and experiences of businesses involved in the awards. As of this writing, there is not yet much sharing of experience and ideas among the different national awards administrations. In 1996, at a meeting organized in Lima by Wayne Cassatt, the managers of the Award from Argentina, Brazil, Colombia, Chile, and Peru decided to hold an annual International Quest for Excellence meeting with the managers of awards and companies that won the award. The purpose of the meeting is to share experiences and results, as well as discuss new awards for education and health care. The first took place in Brazil in September 1997.

The Professional Institute for Quality.   The CEOs identified the need for an organization in which their quality managers, their second-level managers of key areas (marketing, finance, etc.), and university professors could be trained, kept up to date, interchange ideas, do research, interact with similar organizations in other countries, and provide support to the National Quality Award and other future projects. To address this need, FUNDECE established a project to organize the technical arm of FUNDECE—a professional society to provide the "how to" of quality. The Argentina Professional

Institute for Quality and Excellence (IPACE) was founded for this purpose. The leader of the IPACE project is today its Managing Director.

The National Quality Movement.   The 1995 FUNDECE project related to the need to focus the national effort for quality and excellence in key areas. Many institutions, both government and private, are working on this. In the sense that more people are becoming aware of the importance of quality, this is good. Still, there are areas where coordination is needed to help people and institutions move in the same direction.

Business leaders should assume the responsibility of leading the process of change for two reasons: (1) it is necessary to convince many more CEOs (CEOs will listen better to other CEOs) and (2) the CEOs' training and know-how is precisely to lead organizations and projects effectively. In the past, national quality programs failed because they lacked such leadership; professionals and government specialists led these programs in an economic environment where quality was not a critical factor for business.

In December 1994, FUNDECE initiated the creation of an integrated National Quality Movement (see Figure 43.2). It is composed of six key organizations: (1) FUNDECE; (2) FUNDAPRE; (3) IPACE; (4) The National Institute for Industrial Technology (INTI)—a government institution dedicated to giving assistance to industries, in technology and in metrology; (5) The Argentinean Institute for Materials Rationalization—the standards institution that also works on ISO 9000 certification; and (6) the General Secretariat of the President—dedicated to distributing information on quality, motivating the involvement and cooperation of major institutions interested in quality, and optimizing the effect of government actions.

The mission of the National Quality Movement is to coordinate major quality activities, to improve the effectiveness of the major programs of various government and private institutions, and to ensure that all organizations and businesses view quality as a national cultural value. To accomplish this mission requires a common vision and culture. It requires a suitable structure, sufficient resources, and coordinated strategies.

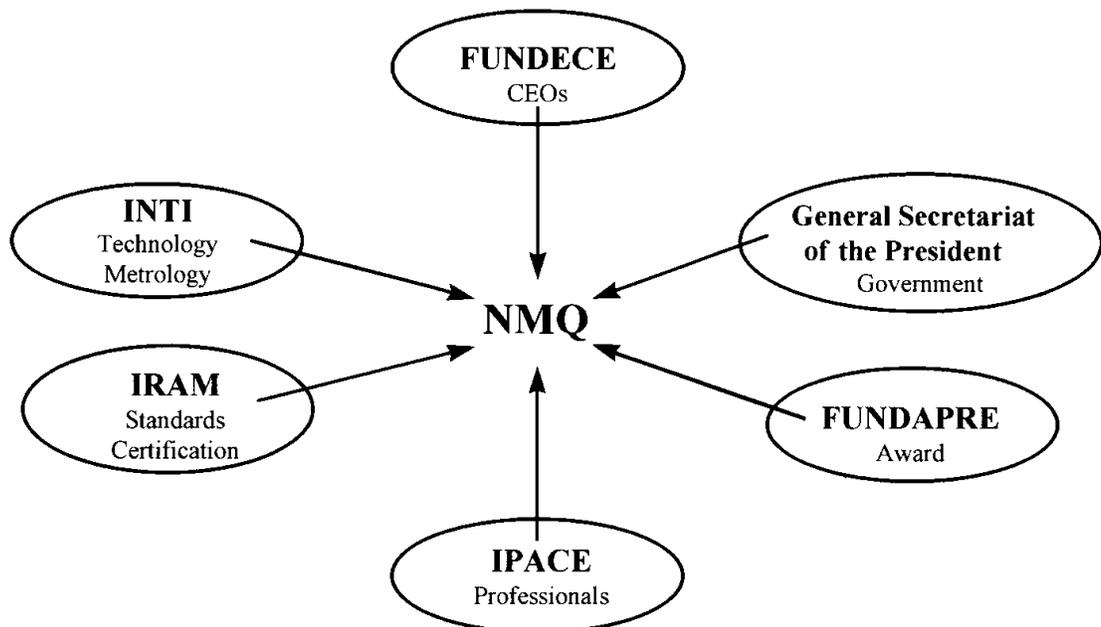
In Argentina, as in many other countries of the world, debate continues on the question of the correct national quality model. Some argue for adoption of the criteria of the national quality award; others support the ISO 9000 series of quality standards as a more suitable model for promotion. FUNDECE's view is that although ISO 9000 certification is sometimes necessary for commercial reasons and a good introduction to quality for newcomers, receiving ISO registration does not


FIGURE 43.2   National movement for quality. (*FUNDECE, 1995.*)

necessarily result in acceptable quality levels in today's highly competitive world. Argentina has very few ISO 9000 certifications. However, in the period from March to November 1995 the number of certifications rose from 37 to 69, indicating that these certifications are on the rise, particularly for SMCs.

In the field of education, universities have shown interest in the subject and application of quality. Three university presidents are already members of FUNDECE. The Buenos Aires Institute of Technology offers a master's degree in quality; several other universities offer postgraduate courses in quality management. The Minister of Education is studying with FUNDECE and FUNDAPRE the recent developments in quality awards for educational institutions in the United States, such as those conferred by the NIST and the City of New York.

BRAZIL

There has been a significant increase in the participation of CEOs in quality programs since 1990, the year the government launched the Brazilian Program for Quality and Productivity (PBQP) as part of its program to modernize the Brazilian economy along the same lines as the other major countries in the region.

The PBQP is led by the government, with the participation of the following sectors and institutions:

- *Business:*   The National Confederations of Industry and Commerce (CNI) and press, advertising, and radio and TV associations.

- *Professional societies:*   The Brazilian Association for Quality Control and other societies representing consultants and specialists in fields that include human resources, research, standards, and industrial engineering.

- *Government institutions:*   The National Institute for Metrology Standards and Industrial Quality, the Brazilian Service for Support of Micro- and Small Companies, the National Service for Industrial Training, and several others in the areas of deregulation, science and technology, and health.

- *Government companies:*   Telebras, Electrobras, Usiminas, and Petrobras—huge monopolies in communications, electricity, mining, and oil.

- *Government offices:*   The ministries of Economics, Education, Labor, Agriculture, and Health, and other groups dedicated to science and technology, education, and quality. The coordination structure of the PBQP, Figure 43.3, is a matrix of general subprograms and sector subprograms.

The general subprograms are

- Awareness and motivation—to promote quality in all sectors of society

- Development and promotion of modern management methods—to stimulate the adoption, by private and government business and by government services, of modern methods for managing quality and productivity

- Training of personnel concerning quality and productivity

- Technological services for quality—to improve the infrastructure of services such as standards, quality certification, metrology, tests, and technical information.

- Institutional coordination—to promote the coordination of activities for quality and productivity among government, industry, commerce, services, academia, and science and technology organizations

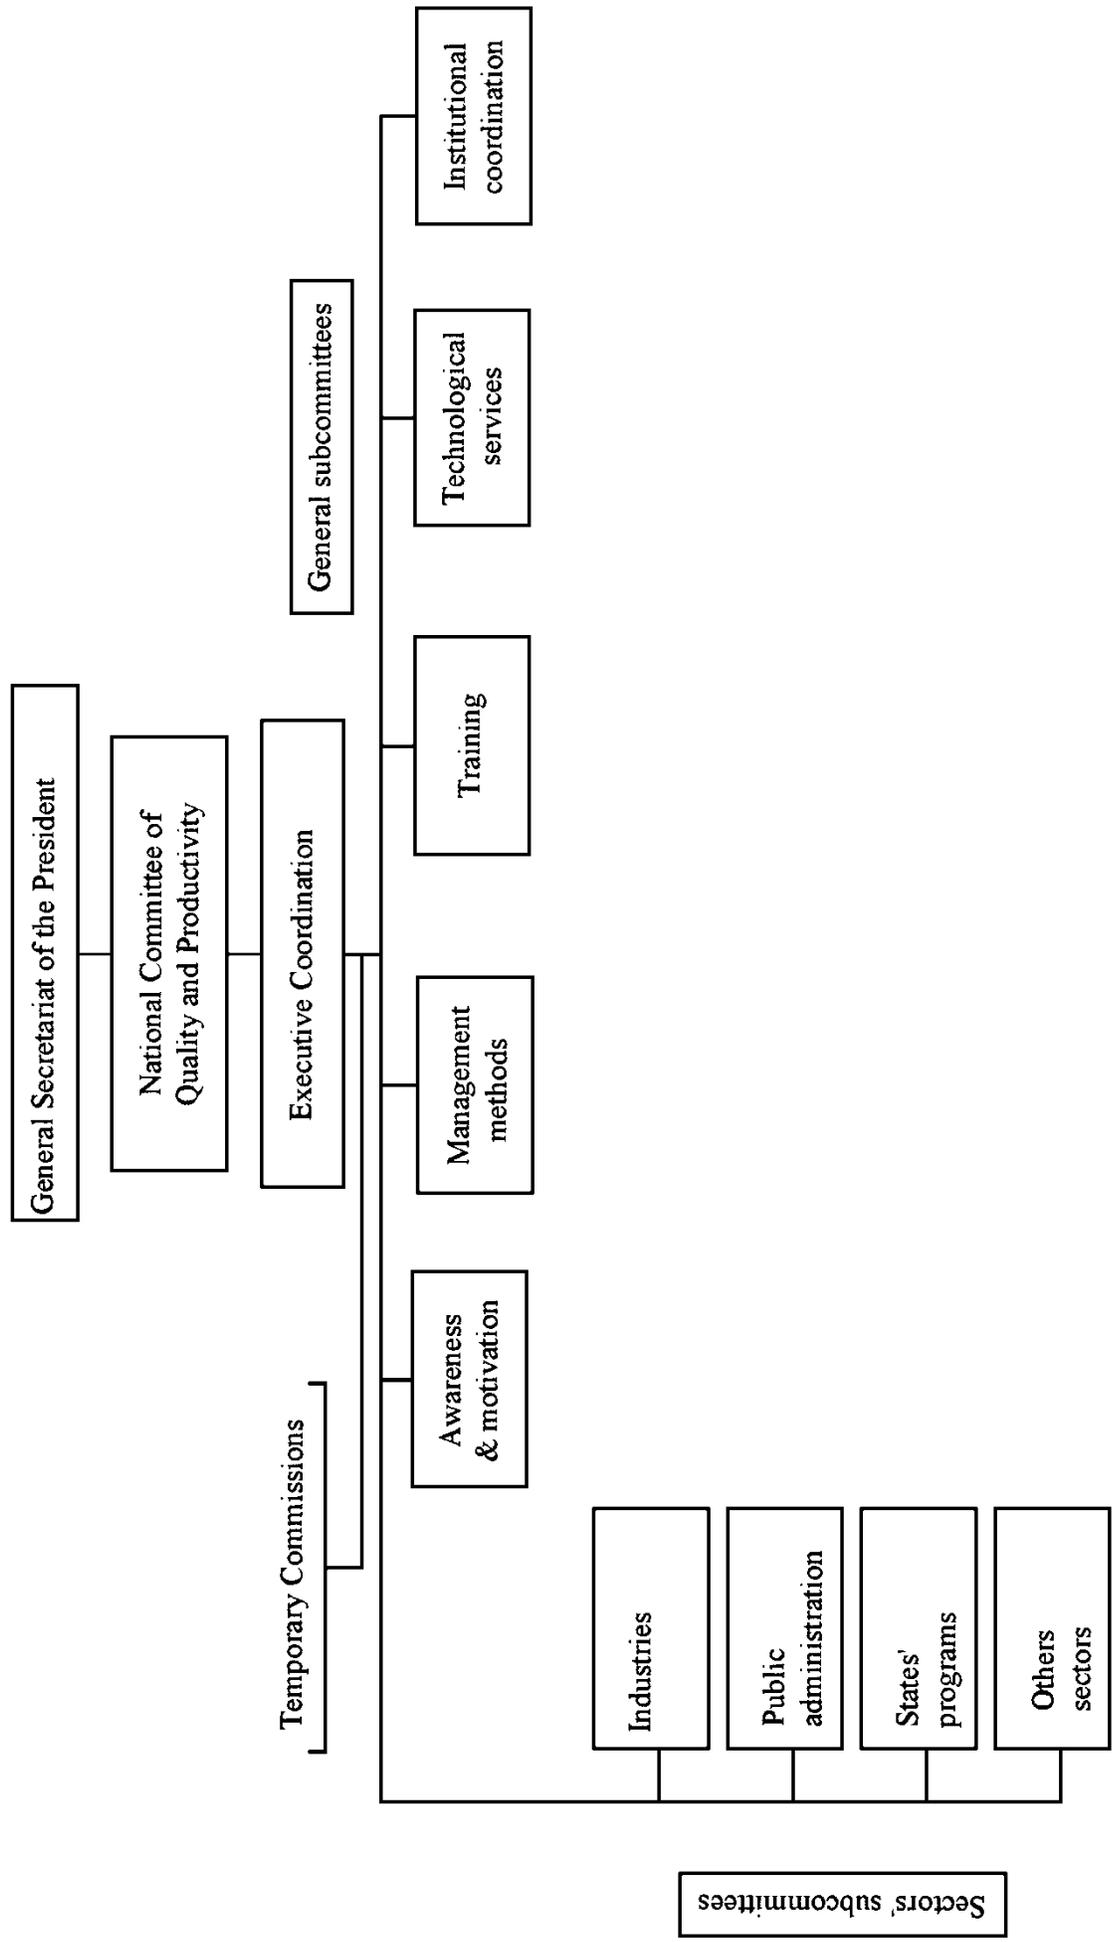
The sector subprograms are individual programs designed for specific sectors, such as industry, public administration, state government agencies, and so on. Each sector prepares a reference plan that includes:


FIGURE 43.3 Brazilian program of quality and productivity structure. (*Industrial Policy Secretary, Ministry of Industry, Commerce and Tourism of Brazil, 1990.*)

43.8

- Quality and productivity diagnosis
- National and international trends in quality and productivity
- Objectives
- Strategies and action plans
- Proposed projects
- A management plan

The PBQP, through the National Quality and Productivity Committee (comprising four government officials and three representatives of private business designated by the government) provides a review of each sector subprogram as well as guidance in the creation of the sector support structure and in carrying out the subprogram. The PBQP was revised in 1995, Figure 43.4, adding the voices of consumers and workers to the coordination body. Development and publication of indicators was also included as a separate function. Supplier development and financial support were added to the general subprograms and tourism, agriculture and livestock, and services and commerce were added to the sector subprograms.

The most effective parts of the PBQP, as reported by the CNI and several CEOs, are the actions taken by the private sector, led by industries through their chambers, where each industry (e.g., chemicals, steel, leather) is represented by its own chamber. Each industry chamber has quality and productivity committees working for industry improvement and collaborating with the PBQP. Today 240 business and technical institutions are working on these programs under the industry sector sub-committees. CEOs are becoming increasingly involved in these activities.

The PBQP has made another contribution whose significance may be difficult for readers from outside the region to understand. Historically, national development programs throughout Latin America have focused on population centers—Buenos Aires, Rio, Mexico, etc. It has been a natural consequence of taking programs where there is a base of industry to build on. A frequent effect has been neglect of other geographic areas, especially rural ones. The PBQP program, however, has been effective throughout the country, with the involvement of the different states.

The major contributions of the PBQP to quality and productivity in Brazil are

- It increased collaboration between government and private institutions.
- It motivated the adoption of quality and productivity programs in many private companies.
- It provided a timely and reliable source of information to help business adapt to the new, highly competitive environment.
- It revealed a new role for business chambers, accustomed as they were to focusing on lobbying.
- It reinforced the importance of standards, metrology, and certification.
- It reinforced the importance of customer service.
- It promoted closer relations between customers and suppliers.
- It increased training efforts, and contributed to a change in management mentality.

Some weaknesses remain:

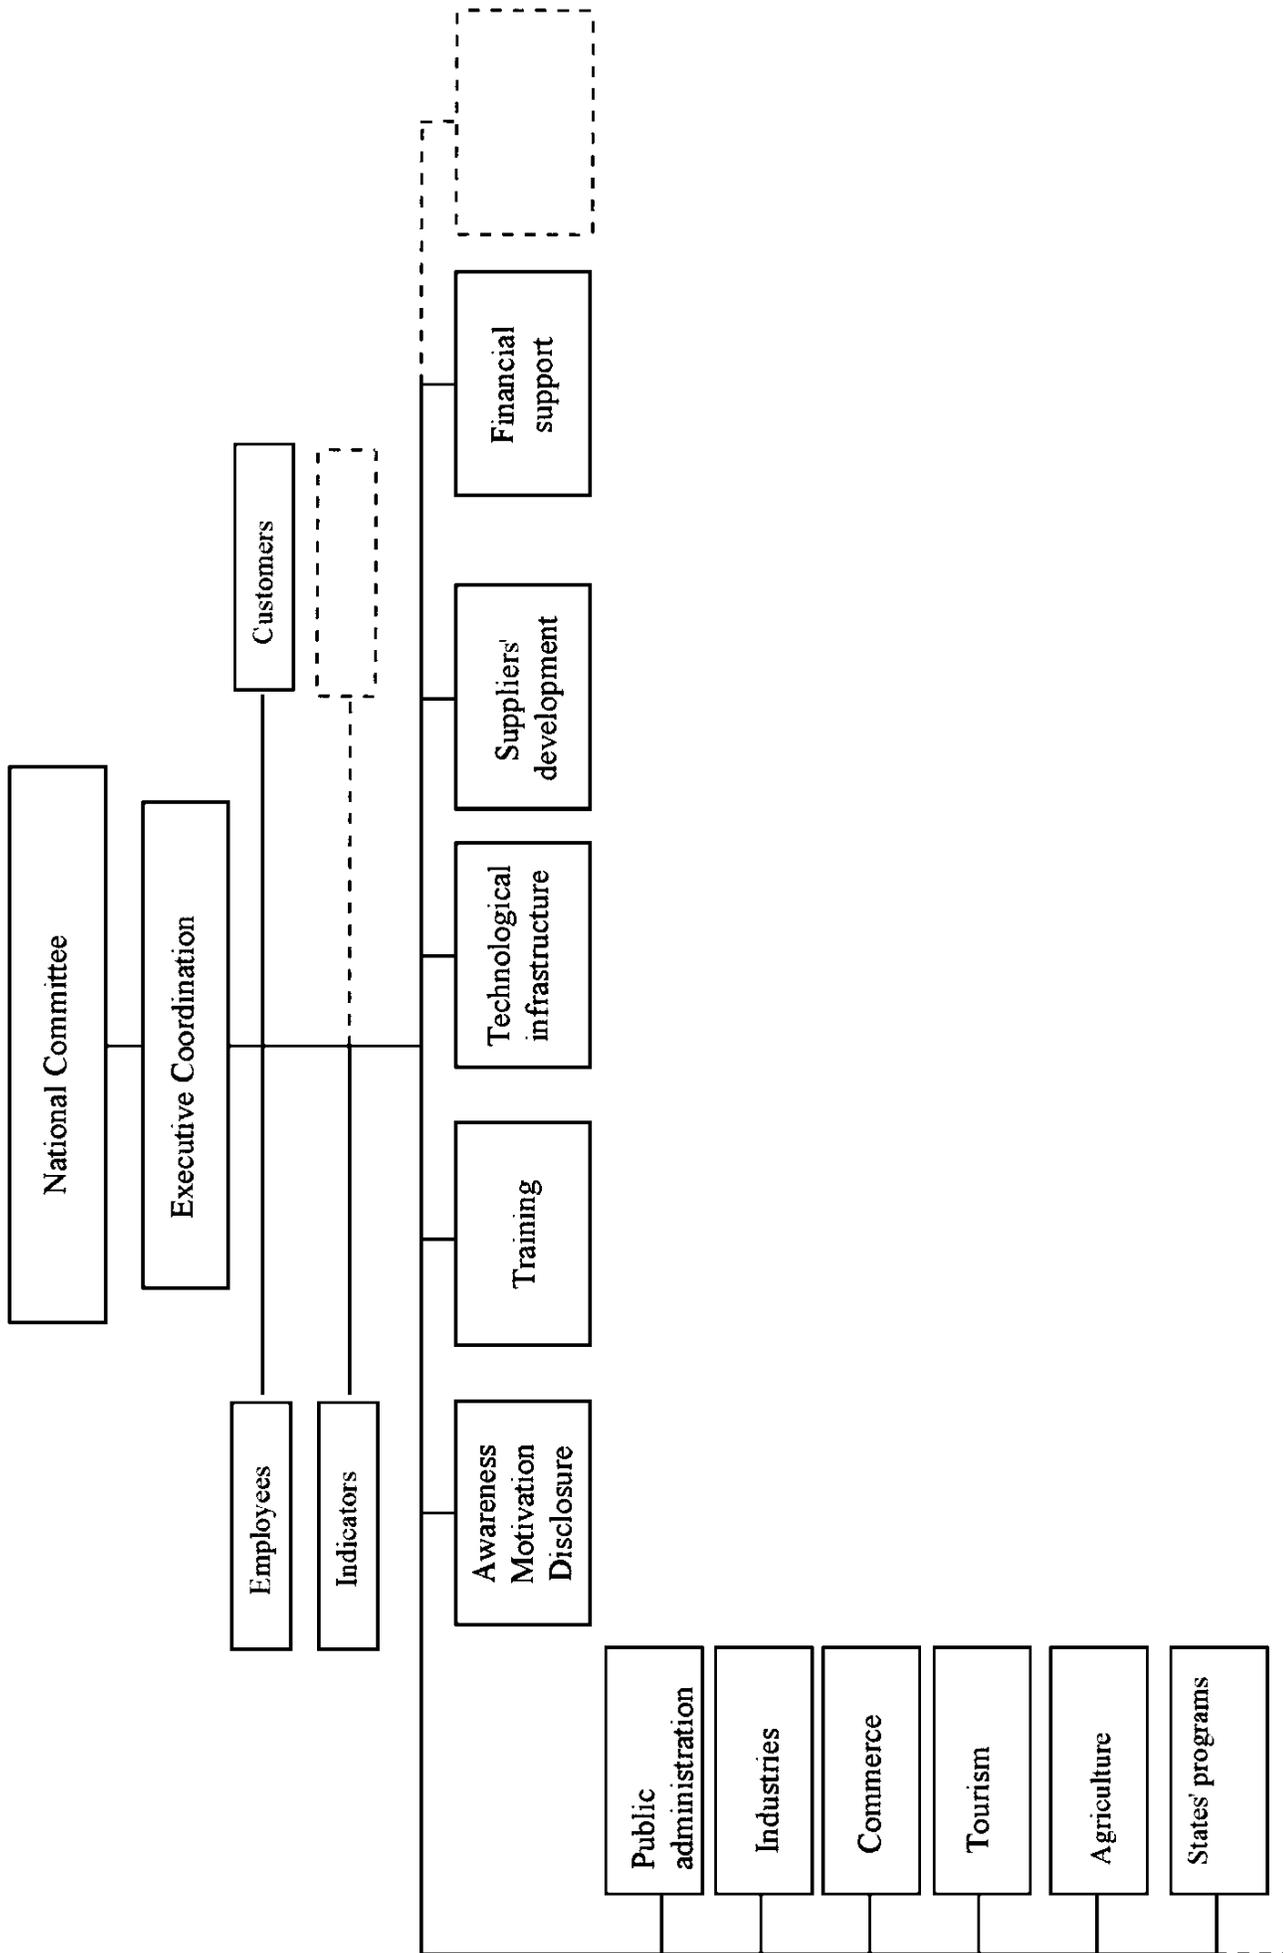
- Government leadership—the actions in place have little support in the various government departments
- A low rate of workers' union participation
- Poor coordination of program activities
- Insufficient infrastructure—privatization of government enterprises is necessary to improve the efficiency of the economic system in transportation, energy, and communications and to revise the role of government.
- A low rate of participation by universities and technology centers—These organizations have great potential, not yet realized, to support the efforts to improve quality and productivity.


FIGURE 43.4 Brazilian program of quality and productivity structure PBQP 2000. (*Industrial Policy Secretary, Ministry of Industry, Commerce and Tourism of Brazil, 1995.*)

- Absence of design and innovation as topics in the programs
- Numbers of unconvinced executives, particularly within the SMCs
- The reduced resources available from the government

These efforts are reflected in increasing acceptance of Brazilian goods in international trade. Furthermore, in the period 1992 to 1994, industrial goods exported from Brazil accounted for a rising proportion of total value of goods exported—from 73.4 percent of total exports to 76.6 percent. (See Figure 43.5.)

This increase was especially impressive, considering that in the same period the world prices of the traditional commodities exported rose significantly. In the same period, Argentina showed a comparable increase—from 62.6 percent to 65.8 percent. The MERCOSUR agreement also had an influence on these results. With the elimination of tariff barriers between the member countries (Brazil, Argentina, Uruguay, and Paraguay), trading among these countries more than doubled, and many new investments have come into the area, induced by the incentive of a larger market potential.

Of all the countries in Latin America, Brazil has the most ISO 9000 certifications—over 1000 and increasing as of 1995 (63 percent of the total for the region). Brazilian companies see certification as an effective first step toward a quality program, or toward fulfilling a commercial need to export or to sell, in the local market, to certain major local companies.

As in the rest of the world, the emphasis is switching from satisfying the requirements of ISO 9000 to performance according to the criteria of the National Quality Award.

The Brazilian National Quality Award was initiated in 1992. As in other countries in the region, the award criteria derived, with minor adaptations, from the Baldrige Award model. The NIST supplied all the needed information regarding such matters as the award criteria, selection and training of examiners, selection of judges, code of ethics, evaluation process, etc. The Brazilian Quality Award Foundation, which administers the award, is supported mainly by private business. To date, the Foundation has trained about 1000 examiners and contributed improvements to the award process, such as a computerized system to simplify the evaluation of examiners. The Award is now presented by the president of Brazil.

CHILE

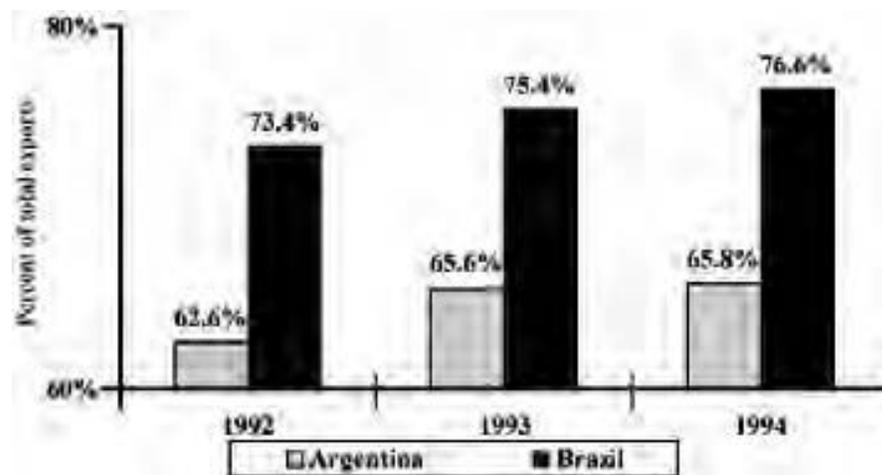
Chile was the first country in the region to carry out economic reforms, beginning in the early 1970s. These growing reforms have provided a very favorable economic environment for business, reflected in


FIGURE 43.5   Industrial exports share of the total. (*Brazil: Secretary of Industrial Policy, Ministry of Industry, Commerce and Tourism, 1995; Argentina: National Institute of Statistics and Census, 1995.*)

renewed growth and prosperity. CEOs were able, for the first time in years, to concentrate their energies on managing their companies and increasing sales, particularly of exports to the United States, Europe, Asia, and elsewhere in Latin America. Some larger companies began investing in new factories in Argentina, Peru, and Brazil. Customer demands forced companies engaged in international trade—export of goods and investment in foreign plants—to incorporate quality management into their operations. As in the other countries of the region, many heads of smaller companies remain unconvinced of the relevance of quality to their operations. Even in those smaller companies which are growing rapidly toward international prominence, the CEOs have been reluctant to put energy into developing a national infrastructure to support quality; they judge it to be more important to spend the energy growing their own businesses. As of 1994, just a few pieces of quality infrastructure were in place:

- The Chilean Association for Quality, the organization for quality professionals, is very active in conferences, courses, and publications. There is very little participation by CEOs.
- Several universities offer postgraduate studies in quality management (Chile and Santiago). The Catholic University has a very active center for productivity and quality.
- The government provides both an excellent economic environment for SMCs and, through an industrial promotion institution, financial help for quality improvement programs. The Industrial Productivity Center, a private organization representing 3000 SMCs, administers funds for this promotional activity.

In 1995, a collaboration of government and some interested CEOs led to the founding of the National Center for Quality and Productivity. The Center is chaired by the Minister of Economics and comprises the heads of business organizations (CEOs in industry, commerce, and services), universities, several government departments, and representatives of workers' unions. Some leaders had seen a dangerous trend in the complacency and boastfulness with which some businesses reacted to small early successes. The reaction, they felt, revealed industry's failure to grasp the need for continuous improvement in the face of rapidly changing and highly competitive global markets. The Center was a response to what they thought was the need to develop further the infrastructure for quality, to create a model such as the Baldrige Award criteria, and to conduct research to identify the most successful quality tools for Chile.

The Center's first action (in 1996) was to present its first National Quality Award. The NIST collaborated in the development of the Award.

The organization, strategies, and plans of the National Center for Quality and Productivity are not available. The Center will probably be led by business and dedicated initially to improving the national infrastructure for education and training on quality, helping the introduction and implementation of ISO 9000 certification, and generating quality awareness, especially in SMCs.

COLOMBIA

National Quality Week began in Colombia in 1975; a national quality award has been presented annually since then. The leading private organization for quality is the Colombian Institute for Technical Standards (ICONTEC). The 15-member Board of ICONTEC contains 10 members from business organizations and 5 from government. Besides providing consulting and publication services and conducting training courses, ICONTEC serves as a registrar for ISO 9000. It is the interface between the government and private business for quality programs. Historically, business participation has largely been among second-level managers, but CEOs are becoming increasingly involved.

Other institutions focused on quality are the Colombian Association for Quality, the organization for quality professionals; the Colombian Association for Quality Circles; and several business and government organizations, including two in health care—Hospital Management (GEHOS) and Companies for Promotion of Health (EPS).

Future needs for quality promotion include involving SMCs and increasing opportunities for education and training.

MEXICO

In 1988, a group of major industrial and service companies came together to create the Mexican Foundation for Total Quality (FUNDAMECA) just a year after the need had been identified. Today, FUNDAMECA has a membership of more than 500 individuals and organizations. Membership is not limited to CEOs.

In 1989, in close cooperation with the Secretary of Commerce and Industrial Promotion, FUNDAMECA announced the creation of the National Quality Award. The first award was presented by the president of Mexico in 1990. FUNDAMECA has administered the award since its inception. In the same year, FUNDAMECA created the Mexican Association for Total Quality Managers, an organization for quality professionals.

In Mexico, CEOs mobilized for quality for the same reasons that had moved their southern neighbors to action: their companies needed to become competitive in the free market economy and within newly emerging common markets, especially NAFTA. Because of its proximity and participation in NAFTA, the United States participated in this mobilization through institutions such as the NIST, the Quality and Productivity Management Association, and the Interamerican Network of Quality and Productivity Centers.

The member companies of FUNDAMECA made significant progress during the early years, with many successes. There remains much to do to gain the involvement of the many companies not yet a part of FUNDAMECA.

Several Mexican universities, such as the Tecnológico de Monterrey, have postgraduate studies in total quality management. Years of intensive training of professionals both in Mexico and in the United States have resulted in the development of many capable professionals in the field of quality.

The economic crisis of 1994 and 1995 was a strong incentive for change, and Mexico has in place the necessary institutions for this process.

PERU

The National Society for Industry (SNI), founded in 1896, claims a membership today of 2000 Peruvian companies. The society began working on quality programs as early as 1980, but with no success, due to the economic environment at that time. When the economic changes affecting the region began to happen in Peru in 1991, SNI organized quality workshops and created a quality award. In 1992, the government made the award official. In that same year, the government and SNI founded the Center for Industrial Development, a private institution with strong ties to the government, to administer the award. In 1995, a joint team of government and SNI members worked with the NIST to incorporate lessons from the Malcolm Baldrige Award into Peru's award. CEOs of member companies of SNI provide the driving force of leadership in these organizations.

URUGUAY

Facing the new challenges of Uruguayan membership in MERCOSUR, Uruguayan CEOs founded the Uruguayan Association of Companies for Total Quality (AUECE) in 1993. By 1995, more than 50 CEOs were members of AUECE. FUNDECE (of Argentina) worked very closely with AUECE and helped stimulate its organization.

The National Committee for Quality, chaired by the Secretariat of the President of Uruguay, developed and manages the National Quality Award. The first award was presented in 1993 by the president of Uruguay.

AUECE, like FUNDECE in Argentina, is leading the Uruguayan quality programs.

CONCLUSIONS—FOUR CRITICAL FACTORS

Four critical factors underlie the emergence of quality in the countries of Latin America: business competitiveness; a favorable economic climate; the leadership and involvement of business leaders, especially the CEOs of business organizations; and the availability of capable quality professionals.

The first critical factor, competitiveness of business, is measured in comparative terms. In today's global economy, every company in the world with similar capabilities must be considered a potential competitor. Competitiveness is a measure of a company's ability to make and sell product against all their potential competitors in the global marketplace. Quality is an important determinant of that ability. The opportunities and challenges offered by common markets, such as NAFTA and MERCOSUR, combined with the importance of quality, are powerful motivators for individual businesses to improve quality performance. In turn, improved quality performance in these businesses exerts a positive effect on the country's aggregate quality performance.

The second critical factor for quality success is a favorable economic environment. Most of the countries in Latin America have been carrying out similar economic reforms since 1990. The economic environment is changing very rapidly toward open, free, and unregulated markets. Governments are aware that their policies must encourage competitiveness. Creating those policies means a new role for government, one that requires government to work with business rather than dominate it.

The third critical factor is the participation of CEOs, both in leading the quality improvement efforts within their own companies and in organizing and leading the larger effort within the country.

The fourth critical factor is to have the participation of capable professionals to support the implementation of the quality efforts.

To date, the major accomplishments in Latin America are the establishment of the national awards, a growing trend toward ISO 9000 certifications, and the collaboration of CEOs in establishing quality institutions at the national level. What remains to be done?

- Advance further in economic reform
- Convince the leaders of smaller companies to implement quality programs
- Improve the quality of education at all levels
- Include the quality sciences in the curriculum of universities
- Intensify training in quality at all levels and in all sectors
- Introduce the application of quality concepts and methodologies into sectors not yet affected

In Argentina, FUNDECE remains at the center of the quality movement, and serves as a model for other countries in Latin America. FUNDECE's major activities are designed to provide information to its members, to professionals (through IPACE), and to other sectors of society (through the National Quality Movement) about what is being done in quality in Argentina and in other parts of the world. FUNDECE maintains a sustaining membership in the ASQC as a means of helping its members participate in ASQC activities and of keeping them up to date in quality subjects.

An example of the impact of FUNDECE is the case of health care in Argentina, a sector that has not changed its traditional approach to quality in many years. There are today several health care organizations that participate actively in FUNDECE. These groups are gathering information and support to launch a quality initiative.

In other countries, organizations such as FUNDECE continue to provide the means to bring the latest developments in quality to various sector leaders, offering hope that the list of work yet to be done is more than a "wish list."

SECTION 44
BASIC STATISTICAL METHODS

Edward J. Dudewicz
Department of Mathematics,
Syracuse University, Syracuse, New York

THE STATISTICAL TOOL KIT

Most decision making in quality control, as in most other areas of modern human endeavor (e.g., evaluation of new medical treatments and scanning machines, planning of scientific polling, and marketing and investment strategies, to name a few), rests on a base of *statistics*—defined narrowly as the collection, analysis, and interpretation of data or, more broadly, as "the science of decision making under uncertainty." For the practitioner, *statistics* can be thought of as a kit of tools that helps to solve problems. The statistical tool kit shown in Table 44.1 lists problems to be solved, applicable statistical tools, and where in this handbook the tool is to be found.

Examples of actual practice will be used as extensively as the space allocated to it allows to provide the reader with both a model for solution and a data set with correct analysis that can be used to verify the accuracy of local computer software. Annotated computer program output from such packages as SAS and BMDP will be used in many of these examples.

In addition to the basic statistical methods discussed in this section, four other sections cover specific areas—Section 45, Statistical Process Control; Section 46, Acceptance Sampling; Section 47, Design and Analysis of Experiments; and Section 48, Reliability Data Analysis. Many other sections include additional applications. Also, Appendix III, Selected Quality Standards, Specifications, and Related Documents, includes documents on statistical techniques and procedures.

SOURCES AND SUMMARIZATION OF DATA

The source of a set of data that we desire to analyze to solve a problem is a very important consideration. The two sources we will address and that are the most common are historical data and data from planned experimentation. Investigators using historical data are like blind people probing an elephant, for reasons discussed below under Historical Data, Their Uses, and Caveats, and under Data from Planned Experimentation. Note that all data need careful review, as discussed under Data Screening, below.

Planning for Collection and Analysis of Data. The tools cited in Table 44.1 must be used in an effective manner to yield a return appropriate for the cost of using them. To achieve this return, it is not sufficient to plug numbers into formulas. The full process must include careful planning of data collection, analysis of the data to draw statistical conclusions, and making the transition to answer the original technical problem. A checklist of some of the key steps in achieving this is as follows:

1. Collect sufficient background information to translate the engineering problem statement into a specific statement that can be evaluated by statistical methods.
2. Plan the collection of data.
   a. Determine the type of data needed. Variables data (readings on a scale of measurement) may be more expensive than attributes data (go or no-go data), but the information is much more useful.
   b. Determine if any past data are available that are applicable to the present problem; however, bear in mind the hazards of historical data sets.
   c. If the problem requires an evaluation of several alternative decisions, obtain information on the economic consequences of a wrong decision.
   d. If the problem requires the estimation of a parameter, define the precision needed for the estimate.
   e. Determine if the error of measurement is large enough to influence the sample size or the method of data analysis; laboratory error often can dwarf experimental variability.
   f. Define the assumptions needed to calculate the required sample size.
   g. Calculate the required sample size considering the desired precision of the result, statistical risk, variability of the data, measurement error, and other factors.

TABLE 44.1   The Statistical Tool Kit

Problem	Statistical tool	Reference pages or sections
Planning a statistical investigation	Planning and analyzing data for solving specific problems	44.2–44.4
Summarizing data	Frequency distributions, histograms, and indices	44.7–44.17
Predicting future results from a sample	Probability distributions	44.23–44.41
Determining a probability involving several events	Basic theorems of probability	44.17–44.23
Determining the significance of difference between two sets of data or between a set of data and a standard value	Tests of hypotheses	44.58–44.81
Determining the sample size required for testing a hypothesis	Sample size determination for hypothesis testing	44.78–44.79
Determining the ability of a sample result to estimate a true value	Confidence limits	44.41–44.46
Determining the sample size required to estimate a true value	Sample size determination for estimation	44.45–44.46
Determining tolerance limits on single characteristics	Statistical tolerance limits	44.47–44.51
Determining tolerance limits for interacting dimensions	Tolerance limits for interacting dimensions	44.50–44.54

    h. Define any requirements for preserving the order of measurements when time is a key parameter.

    i. Determine any requirements for collecting data in groups defined so as to reflect the different conditions that are to be evaluated.

    j. Define the method of data analysis and any assumptions required.

    k. Define requirements for any computer programs that will be needed.

3. Collect the data.

    a. Use methods to ensure that the sample is selected in a random manner.

    b. Record the data and also all conditions present at the time of each observation.

    c. Examine the sample data to ensure that the process shows sufficient stability to make predictions valid for the future.

4. Analyze the data.

    a. Screen the data.

    b. Evaluate the assumptions previously stated for determining the sample size and for analyzing the data. Take corrective steps (including additional observations) if required.

    c. Apply statistical techniques to evaluate the original problem.

    d. Determine if further data and analysis are needed.

    e. Conduct sensitivity analyses by varying key sample estimates and other factors in the analysis and noting the effect on final conclusions.

5. Review the conclusions of the data analysis to determine if the original technical problem has been evaluated or if it has been changed to fit the statistical methods.

6. Present the results.

    a. Write a report, including an executive summary.

    b. State the conclusions in meaningful form by emphasizing results in terms of the original problem rather than the statistical indices used in the analysis.

    c. Present the results in graphic form where appropriate. Use simple statistical methods in the body of the report, and place complicated analyses in an appendix.

7. Determine if the conclusions of the specific problem apply to other problems or if the data and calculations could be a useful input to other problems.

Historical Data, Their Uses, and Caveats. *Historical data* are data that we already have and which may seem to be relevant to a question or problem that has arisen. Such data are sometimes also called *existing data sets.* Often data are saved during the production process, for example. If a satisfactory process goes out of control after some years of operation, it is often suggested that it would save both time and expense to statistically analyze the historical data rather than perform a planned experiment to obtain data that could lead to process correction. Thus we have available data that may consist of measurements Y (such as a process yield, e.g., the strength of a material produced) and associated process variables $x_1, x_2, \ldots, x_k$ (such as $x_1 = $ pressure and $x_2 = $ acid concentration, with $k = 2$).

    This situation is extremely different from that where experiments have been run at each of a number of settings of $x_1, \ldots, x_k$ that were selected in advance by statistical design criteria, and often little can be learned from such data even with the most thorough statistical analysis. Some of the reasons for this are

    The x's may be highly correlated with each other; hence it may not be possible to separate an effect as due to (for example) x_1 or x_2.

    The x's may have been manipulated to try to control the output Y of the process (some of them perhaps even in directions that move the output in directions that are not desired), hence giving spurious indications of directions of effects when analyzed.

    The x's may cover a very small part of the possible operating range, so small that any indications of changes in Y attributable to changes in the x's may be overwhelmed by the size of the variability of the process (measured by "standard deviation," discussed below).

    Other variables that affect the output of the process (e.g., time of day, atmospheric conditions, operator running the process, etc.) may not have been held constant and may in fact be the real

causes of changes observed in the process (while an analysis conducted based only on the x's may erroneously yield a model that has no basis in reality).

For these and other reasons, much more information generally can be obtained from a carefully designed experiment than from extensive analysis of historical data sets collected in uncontrolled circumstances. The best one usually can hope for from such historical data set analysis is an indication of the most important variables to include in the designed experiment.

As an example of one of the failings described above, suppose that a historical data set consists of a yield Y at each of the five (x_1, x_2) pairs given in Table 44.2. We see that there is what appears to be a good spread on the x_1 (acid concentration) values, from 80 to 110, and also a good spread on the x_2 (pressure) values, from 105 to 144. However, a plot of the data points (x_1, x_2), as shown in Figure 44.1, shows that in fact all five of the data points lie on a straight line. Thus there is no hope of any analysis of these data telling us whether any effect we see is due to x_1 or to x_2. The points do not "cover" the space of x_1 between 80 and 110 and x_2 between 105 and 144 well at all. Also, to solve the production problem, it may be desirable to explore outside this space of historical operation, and this is not allowed for in the historical data set.

A problem such as that shown in Figure 44.1 is called *multicollinearity* of the data points, i.e., of the sets of $(x_1 \ldots, x_k)$ that we have available for analysis. With $k = 2$, such a problem is easy to detect by a graph such as that in Figure 44.1, and such a graph should always be made. With $k = 3$ it may be possible to detect such a situation graphically using computer graphics packages. Often, however, k is much larger than 2 or 3, and then statistical analysis is needed to detect multicollinearity. Near multicollinearity (i.e., when the points almost fall on a line when $k = 2$, on a plane when $k = 3$, or on what is called a $k - 1$ dimensional hyperplane when k is larger than 3) is just as much of a problem and is much harder to detect. For an extensive bibliography and comments on computer routines for this problem, see Hoerl and Kennard (1981). For some more recent results, see Huh and Olkin (1995), where numerical illustrations using the classic data of Longley (1967) are included.

Data from Planned Experimentation.   *Data from planned experimentation* are data gathered in an attempt to study a problem that has arisen or is contemplated. Such data are gathered at various settings of the variables felt to be of importance $(x_1, \ldots, x_k)$, while holding constant (if possible, and recording the values of in any case) all other variables that could conceivably have an effect on the output $(x_{k+1}, \ldots, x_m)$—for example, atmospheric pressure may not be able to be controlled in most circumstances but should be monitored and recorded in every experiment if it is felt beforehand that it might have an effect on the output. (If it is irrelevant, it can be disregarded later; if it is relevant but not recorded, we will not be able to detect that relevance.) Details of designs to use, i.e., how to choose the values of $(x_1, \ldots, x_k)$ for the experiments once the variables to be varied have been chosen, are considered in Section 47, Design and Analysis of Experiments, and in Dudewicz and Karian (1985).

Data Screening.   Once the data specified in the preceding checklist for collection and analysis of data, step 2, has been collected (step 3), the first step in its analysis (step 4*a*) is to screen the data.

TABLE 44.2   Historical Data Set

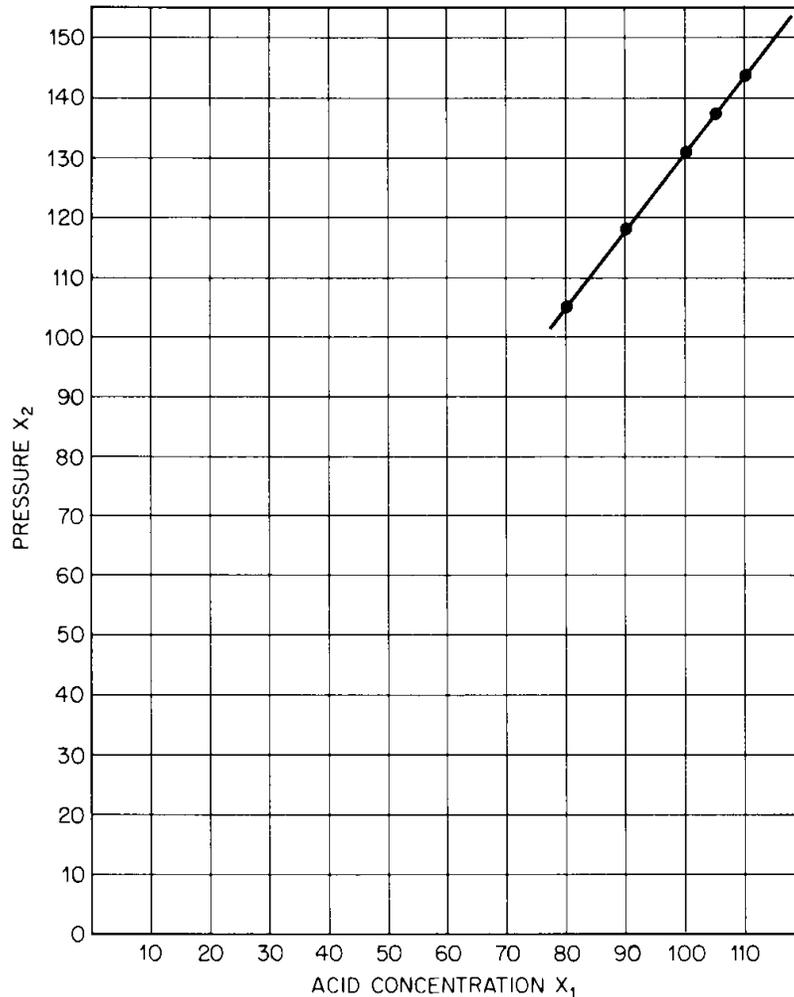
Data point	x_1 (Acid concentration)	x_2 (Pressure)
1	100	131.0
2	90	118.0
3	105	137.5
4	110	144.0
5	80	105.0


FIGURE 44.1   Plot of (x_1, x_2) in a historical data set. Five data points have been plotted, and a straight line has been drawn through them.

We will now discuss the need for this critical (and often omitted) step, some common methods of screening, and a very commonly used method that has some great dangers.

The Need for Data Screening.   A data set that contains no instances of incorrectly transcribed values, contains no values that are technically correct but where the experiment went awry for some reason (such as equipment malfunction), and where the basic model does not change its form over the region of experimentation is called a *clean* data set. Such data sets are commonly expected to be obtained by experimenters who exercise care in their experimental conduct and recording. However, contrary to this expectation of the experimenters, few statisticians have ever seen a clean data set (despite many years of studying many data sets arising in many areas). It follows, then, that all data sets need, as a first stage of analysis, to be examined for values that may cause invalid inferences to be made if those values are left in the data set. Procedures for performing this examination are called *data screening methods*. Among the most powerful such methods are those which are used on the results of a regression analysis (studied later in this section).

There are also a number of methods that can and should be used at the outset, before any regression analyses are performed, with the goal of detecting *outliers,* that is, observations (or groups of observations) that deviate markedly from the other available data. Numerous tests are available for detecting outliers [see Sheesley (1977) for some of these]. One simple rule calls an observation an outlier if it lies 2.5, 3, or 4 standard deviations or further from the mean (Draper and Smith 1981). This is discussed further below.

Methods of Data Screening.   One of the most common methods of data screening is to classify observations as outliers if they are outside an interval of *L* multiples of the standard deviation about the mean. (Standard deviation is discussed below under Sample Characteristics.) The number *L* is commonly taken to be 2.5, 3, or 4. The larger *L* is, the less likely it is that outliers will be detected, while the smaller *L* is, the more good observations one will wrongly detect as potential outliers. For example, from Table B in Appendix II, we see that if $L = 3$, then $(100)(.0027) = 0.27$ percent of the observations will be further than 3 standard deviations from the mean even if there are no outliers in the data set; this assumes a normal distribution for the observations. Thus, if one uses $L = 3$, one expects to find about 3 possible outliers in a data set of 1000 data points (since 0.27 percent of 1000 is 2.7, i.e., roughly 3). As the data set being considered becomes larger, the more possible outliers one will identify even if there are no problems with the data (which is quite unlikely). For this reason,

Outliers should be deleted from the analysis only if they can be traced to specific causes (such as recording errors, experimental errors, and the like).

Typically, one takes *L* to depend on the size of the data set to be screened; with $n = 1000$ points, $L = 3$ is reasonable; with $n = 100$, $L = 2.5$ can be used and only $(100)(0.0124) = 1.24$ outliers will be expected to be found if the data have no problems.

After bad data are deleted or replaced (this is desirable if the experiment can be rerun under comparable conditions to those specified in the experimental plan), the data should be screened again: With the "worst" points removed/corrected, less extreme cases may come to be identified as possible outliers. Another commonly used method, that of crossplots, is discussed below.

Crossplots and Their Hazards.   In *crossplots* (also called *scatter plots*), one simply plots each pair of variables in the data set on a set of axes. For example, in the example of Table 44.2, one would plot Y versus x_1, Y versus x_2, and x_1 versus x_2. The last of these plots was given in Figure 44.1 (and showed some problems with the data that have already been discussed). Note that when using this technique, one uses all variables that were measured (and not just the variables that are thought to be of primary interest; see Nelson 1979, Section 4).

Such plots must be used with great caution. While points that seem odd (e.g., away from the majority of the data points) should be subjected to examination to see if there are problems with them, one should not use such plots to conclude relationships of the yield with x_1 and/or x_2. For example, suppose one has the data set of Table 44.3. Then from crossplots of Y versus x_1 and Y versus x_2 (see Figure 44.2), one would be tempted to conclude that Y is a decreasing function of x_1 and an increasing function of x_2 (and so, in attempting to maximize yield, might set x_1 as low as possible and x_2 as high as possible). However, as can easily be verified, the data in Table 44.3 came exactly from the relationship (model) $Y = 10 + x_1 + 2x_2$. Thus, in fact, Y is an increasing function of x_1 (not a decreasing function as the crossplot had suggested). Daniel (1977) has suggested that the data set of Table 44.4 may give additional insight here. Crossplots for that data set are given in Figure 44.3. Thus one sees that even with a strong true relationship (here $Y = 10 + x_1 + 2x_2$ is used again), the crossplots may yield no insight at all. Even worse, clearly by choosing the points (x_1, x_2) one may give the Y versus x_1 relationship any slope (negative, as with Table 44.3 and Figure 44.2; zero; or positive), or the relationship can be smoothly curved in any direction or degree of complexity. (Note that the regression methods given later in this section would not be fooled by the relationships in the data of Table 44.4. They would give the true relationships.) Thus crossplots are useful for detection of possible outliers; however, they are not a substitute for regression and can easily be misused.

Descriptive Statistics for Summarizing Data.   Many of the most practical methods of summarizing data are quite simple in concept. Depending on the goals of the data summarization, sometimes one method will provide a useful and complete summarization. More often, two or more methods will be used to attain the clarity of description that is desired. Several key methods are plots versus time order of data, frequency distributions and histograms, sample characteristics (mean, median, mode, variance, standard deviation, and percentiles), measures of central tendency/location, and measures of dispersion.

TABLE 44.3 Data Set *A* for Crossplots Example

Plots versus Time Order of Data.   After a data set has been obtained, it is very instructive in many situations to plot the output Y against the time order in which the experiments were run (which is essentially a crossplot of Y versus time t). Among the possible phenomena that may come to our attention from such a plot are these:

A few observations, often at the start of the experimentation, are far from the others; this often represents a learning curve of the experimenters with the experimental situation, and those experiments should be repeated if possible.

There are trends within each day (or within each week, etc.); this may represent such phenomena as warming of a machine or process, operator fatigue, or similar time-related trends.

Variability decreases (or increases) with time; this may be due to a learning curve or raw material characteristics (as when one lot of material is used up and the next lot has less or greater heterogeneity).

While the preceding trends may be apparent even in a plot of the original observations Y versus time, they are often more easily spotted in plots of the residuals of the observations (difference between the observed and predicted value) after a regression analysis. See later in this section under Regression Analysis.

Frequency Histograms.   The *frequency histogram* (or distribution) is a statistical tool for presenting numerous data in a form that makes clearer the central tendency and the dispersion along the scale of measurement, as well as the relative frequency of occurrence of the various values.

Table 44.5 shows "raw data" representing measurements of electrical resistance of 100 coils. A practitioner scanning these 100 numbers has difficulty in grasping their meaning.

Table 44.6 shows the same data after tabulation. Note how the analyst's tallies in the column "Tabulation" make more evident where the central tendency is and what the dispersion is. The column "Frequency" is merely a recorded count of these same tallies. The column "Cumulative frequency" shows the number of coils with resistance equal to or greater than the associated resistance value.

Table 44.6 exhibits a range of values from 3.44 to 3.27, or 17 intervals of 0.01 Ω each. When it is desired to reduce the number of such intervals, the data are grouped into "cells." Table 44.7 shows the same data grouped into a frequency distribution of only six cells, each 0.03 Ω wide. Grouping the data into cells simplifies presentation and study of the distribution but loses some of the detail. (However, one can always go back to the original data if necessary.)

The following are the steps taken to construct a frequency distribution:

1. Decide on the number of cells. Table 44.8 provides guidelines that are adequate for most cases encountered. These guidelines are not rigid and should be adjusted when necessary; their aim is not only to provide a clear data summary but also to reveal any underlying pattern in the data.

TABLE 44.5   Resistance (Ohms) of 100 Coils

3.37	3.34	3.38	3.32	3.33	3.28	3.34	3.31	3.33	3.34

		100	

2. Calculate the approximate cell interval i. The cell interval equals the largest observation minus the smallest observation divided by the number of cells. Round this result to some convenient number.
3. Construct the cells by listing cell boundaries. As an aid to later calculation:
   a. The cell boundaries should be to one more decimal place than the actual data and should end in a 5.
   b. The cell interval should be constant throughout the entire frequency distribution.
4. Tally each observation into the appropriate cell and then list the total frequency f for each cell.

There are several ways of showing a frequency distribution in graphic form. The most popular is the frequency histogram. Figure 44.4 shows the electrical resistance data of Table 44.7 depicted in histogram form. The diagram is so easy to construct and interpret that it is widely used in elementary analysis of data.

One example of wide, effective use of frequency histograms is comparison of process capabilities with tolerance limits. The histogram of Figure 44.5 shows a process that is inherently capable of holding the tolerances drawn on the same figure. The high degree of defectives being produced is the result of running this process at a setting that does not locate its central tendency near the midpoint of the tolerance range. (See Section 22, under Operations Analysis, for other examples.)

Analyses of histograms to draw conclusions beyond the sample data customarily should be based on at least 50 measurements.

Sample Characteristics: Mean, Median, Mode, Variance, Standard Deviation, Percentiles. Faced with a large data set, *descriptive statistics* furnish a simple method of extracting information from what often seems at first glance to be a mass of numbers without rhyme or reason to it. These characteristics of the data may relate to a "typical (or central) value" (mean, median, mode), a measure of how much variability is present (variance, standard deviation), or a measure of frequency (percentiles). The first two types of characteristics (typical value and variability) will be discussed below, but first we will present the concept of percentiles.

TABLE 44.8 Number of Cells in Frequency Distribution

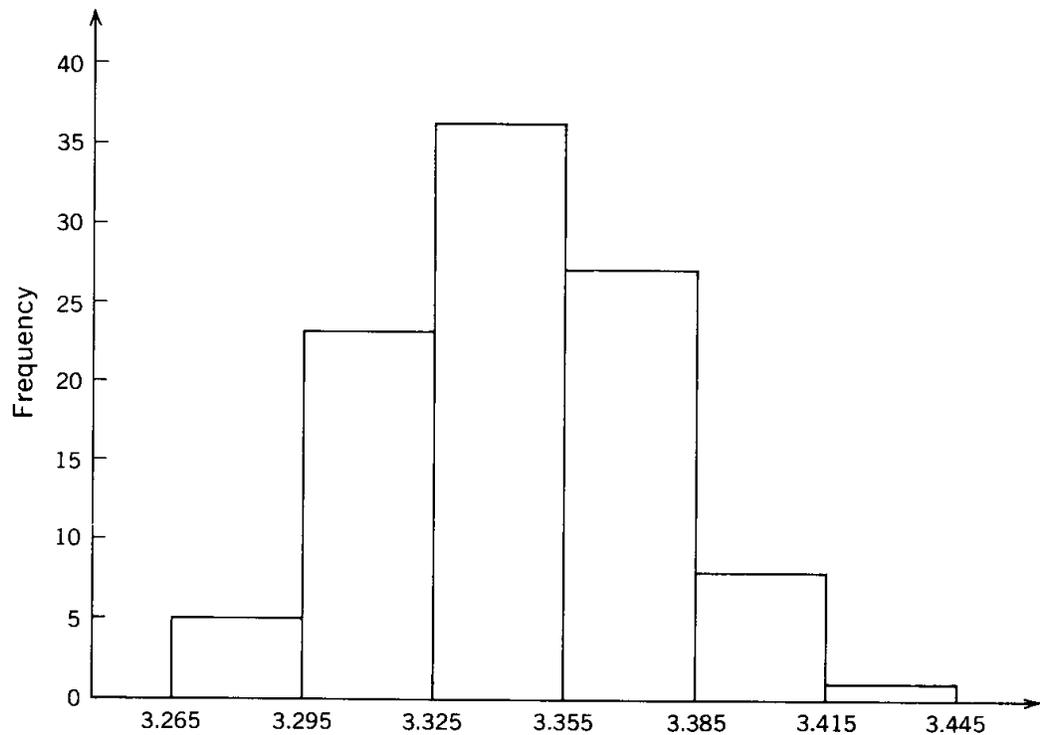
Number of observations	Recommended number of cells
20–50	6
51–100	7
101–200	8
201–500	9
501–1000	10
Over 1000	11–20


FIGURE 44.4 Histogram of resistance.
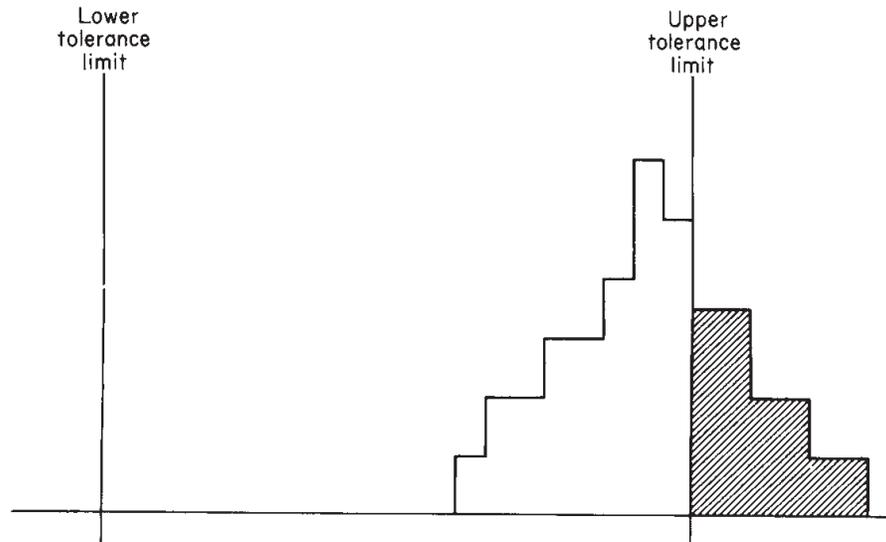

FIGURE 44.5   Histogram of a process.

A *percentile curve* is a plot of the percentile rank of the data against the data values. For example, for the data of resistance of 100 coils given in Table 44.6, 1 percent are at or below resistance 3.27, 2 percent are at or below 3.28, 5 percent are at or below 3.29, and so on, as given in Table 44.9. The percentile rank plot (or percentile curve) for these data is given in Figure 44.6. Note that while the data will result in a "rough" curve (since the percentile curve of the data will jump at each data point and remain constant between actual data points), a smooth curve drawn through the data will be a better representation of reality; this is the dashed curve drawn in Figure 44.6. (Thus while values 3.42 and 3.43 did not occur in our sample, we expect they would in a larger sample; hence the smooth curve is the one we would utilize to assess their chances of occurring.) Note that no data are discarded (or grouped) in making the percentile curve of a data set; in this sense, this is a more precise process than construction of a histogram of the data (since no information is "lost" in the process). Most statistical work uses the percentile curve, under the name *distribution function* of the data. (In early papers this was called the *cumulative* distribution function.) Since the distribution gives the proportion of the data falling at or below each value, the graph and curve are the same; only the scale on the vertical axis is changed to read from 0 to 1 (since 0 to 100, divided by 100, runs from 0 to 1).

Measures of Central Tendency/Location.   Most frequency distributions exhibit a *central tendency,* i.e., a shape such that the bulk of the observations pile up in the area between the two extremes. Central tendency is one of the two most fundamental concepts in all statistical analysis.

There are three principal measures of central tendency: arithmetic mean, median, and mode. The *arithmetic mean* (the ordinary "average") is used for symmetric or near symmetric distributions or for distributions that lack a clearly dominant single peak. The arithmetic mean $\overline{X}$ is the most generally used measure in quality work. It is employed so often to report average size, average yield, average percent defective, etc. that control charts have been devised to analyze and keep track of it. Such control charts can give early warning of significant changes in the central value (see Section 45, Statistical Process Control).

The *mean* is calculated by adding the observations and dividing by the number of observations. A short method for calculating the mean is given in a subsequent example under Measures of Dispersion.

The *median* (the middle value when the figures are arranged according to size) is used for reducing the effects of extreme values or for data that can be ranked but are not economically measurable (shades of color, visual appearance, odors) or for special testing situations. If, for example, the average of five parts tested is used to decide whether a life-test requirement has been met, then the life-

time of the third part to fail can sometimes serve to predict the average of all five, and thereby the decision of the test can be made much sooner. As shown on Figure 44.6, the median is simply the horizontal scale value where the percentile curve reaches the height 50 percent.

The *mode* (the value that occurs most often in data) is used for severely skewed distributions, describing an irregular situation where two peaks are found, or for eliminating the effects of extreme values. The statistical "efficiency" of these measures varies. See Dixon and Massey (1969, chap. 9) or Dudewicz (1976, pp. 221–222) for elaboration.

Measures of Dispersion.   Data are always scattered around the zone of central tendency, and the extent of this scatter is called *dispersion* or *variation.* A measure of dispersion is the second of the two most fundamental measures in all statistical analysis.

TABLE 44.9   Percentile Rank of Resistance Values in Table 44.6

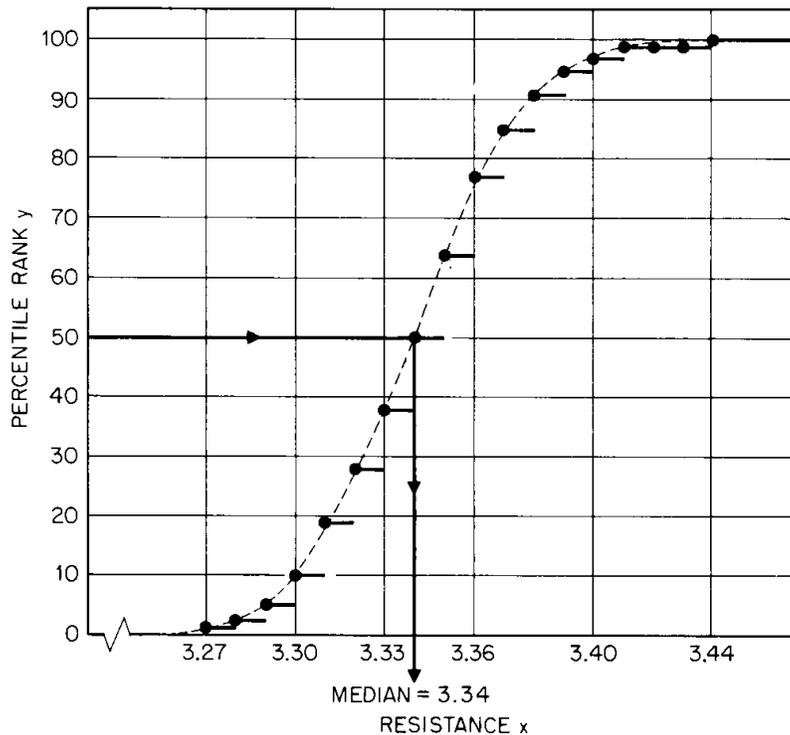
Resistance (x)	3.27	3.28	3.29	3.30	3.31	3.32	3.33	3.34
Percentile rank (y)	1	2	5	10	19	28	38	50
	3.35	3.36	3.37	3.38	3.39	3.40	3.41	3.42
	64	77	85	91	95	97	99	99
	3.43	3.44						
	99	100						


FIGURE 44.6   Percentile curve of a data set.

There are several measures of dispersion. The simplest is the *range,* which is the difference between the maximum and minimum values in the data. Since the range is based on only two values, it is most useful when the number of observations is small (about 10 or fewer).

The most important measure of variation is the *standard deviation.* The definition of the sample standard deviation is

$$s = \sqrt{\frac{\Sigma(X - \overline{X})^2}{n - 1}}$$

where s = sample standard deviation
Σ = "sum of"
X = observed values
$\overline{X}$ = arithmetic mean
n = number of observations

For calculation purposes, an equivalent formula is

$$s = \sqrt{\frac{n\Sigma(X^2) - (\Sigma X)^2}{n(n - 1)}}$$

The square of the standard deviation is called the *variance.* There is also a measure called *covariance,* which gives information on the relationship between pairs of observations on characteristics X and Y. This is defined as

$$s_{XY} = \frac{\Sigma[(X - \overline{X})(Y - \overline{Y})]}{n - 1}$$

Further discussion of the relationship between two or more variables is given later in this section under Regression and Correlation Analysis.

With data in frequency distribution form, shortcut calculations can simplify finding the average and the standard deviation. This is illustrated in Table 44.10. To start, an arbitrary origin A is assumed as 3.37. A zero is arbitrarily placed on this line in the d' column. The other figures in this column indicate how many cells the entry is above or below the arbitrary zero. Minus signs are attached when the entry is smaller than the assumed value, 3.37. The fd' values in column (4) are found by multiplying together the entries in columns (2) and (3). Similarly $f(d')^2$ is found by multiplying the figures in columns (3) and (4). Note that the totals in the last two columns are identified in the formulas as $\Sigma fd'$ and $\Sigma f(d')^2$, respectively, and i is the cell interval. Since the multiplications are small enough to be carried out mentally, the complete table can be made quickly.

$$\overline{X} = A + \left(\frac{\Sigma fd'}{n}\right) i = 3.37 + \left(\frac{-87}{100}\right) 0.03 = 3.344$$

$$s = i \sqrt{\frac{n\Sigma f(d')^2 - (\Sigma fd')^2}{n(n - 1)}}$$

$$s = 0.03 \sqrt{\frac{100(185) - (-87)^2}{100(99)}} = 0.031$$

For sample sizes of about 10 or fewer observations, the standard deviation can be approximated from the range by calculating R/d_2, where d_2 is a factor in Appendix II, Table A. For example, suppose the first column of values in Table 44.5 represents a sample of 10. The range is $3.40 - 3.29$, or 0.11. From Table A in Appendix II, $d_2 = 3.078$. The estimate of the standard deviation is therefore $0.11/3.078 = 0.036$. This is much simpler than calculating the standard deviation directly. Subsequent

TABLE 44.10 Calculation of Average and Standard Deviation

Midpoint (1)	Frequency f (2)	d' (3)	fd' (4)	$f(d')^2$ (5)
3.43	1	$+2$	2	4
3.40	8	$+1$	8	8
3.37	27	0	0	0
3.34	36	-1	-36	36
3.31	23	-2	-46	92
3.28	5	-3	-15	45
	$\Sigma = 100$		$\Sigma = -87$	$\Sigma = 185$

topics in this section further illustrate this feature of the range. Dixon and Massey (1969, pp. 136–140) furnish procedures and tables for a variety of applications of the range.

A final measure of variation is the *coefficient of variation.* This is defined as the standard deviation divided by the mean and is thus a relative measure of variation. It can be helpful in comparing several sets of similar data that differ in mean value but may have some commonality in *relative* variation.

The methods of summarizing data covered in the previous paragraphs can be performed on a computer, as discussed below. (Also see Section 10 in general for additional information on computer programs for quality control.)

Stem-and-Leaf Plots, Boxplots, and Statistical Graphics. Looking at data to find patterns and other characteristics is very important. In fact, it is often said that "the first rule of statistics is: Look at the data." This does not mean to pass the data on to be fed into some computer program without a careful examination of them. It does mean to visually scan the data, to calculate classic measures of important characteristics, to check to see if known measures of validity are satisfied, and to make graphic representations of some data characteristics. There are many methods and approaches to this initial stage of data analysis, some favored by one or another school of statisticians, all of some use, and the total group being of significant size and utility. Some widely valued methods (in addition to those covered in detail earlier) include stem-and-leaf plots and boxplots, for which one can refer to many introductory statistics texts. The area as a whole is part of what is called *statistical graphics,* and computer programs to perform such calculations are widely available. However, to achieve their full potential (and rise above mediocrity or inferiority), these methods need to be used carefully and intelligently (as we saw earlier with crossplots, for example). An excellent reference in this regard (one that is filled with examples, and when the examples are of bad graphics shows how to use a good graphic on the same data) is Schmid (1983).

Accurate Calculation of Descriptive Statistics.
Accurate calculation of even simple descriptive statistics is not as easy a task as it might seem at first, as the example in the paragraph on coding of data below shows. In particular,

Calculation by hand is an error-prone process, especially if there are 10 or more data points.

Construction of computer programs to perform the calculations is a task that requires knowledge of both statistics and numerical analysis as well as computer programming; hence it is inadvisable to "roll your own" in most cases.

Many of the computer software routines that come with computers (especially microcomputers) are not of high quality.

In light of the preceding, it is recommended that a high-quality package of computer routines for statistics be obtained and used for all such analyses. In particular, I suggest packages called SAS,

BMDP, STATPRO, and LABONE. These are of high quality and among them cover a wide variety of computers on which they will run (including IBM and Data General mainframe computers, APPLE and IBM PC microcomputers, and a variety of minicomputers). Additional packages that are in wide use and widely valued include MINITAB and SPSS. There are many other packages, some specially designed for particular areas of statistics (such as design of experiments). It is good to bear in mind that quality varies widely; SAS is felt by many to be the "gold standard" of such packages.

For details of SAS, see SAS Institute, Inc. (1982). For BMDP, see Dixon (1983). For STATPRO, see Pinsky (1983). For LABONE, see Levy and Dumoulin (1984). In each case, a telephone call will bring current information regarding which computers the package is available for, as well as licensing information.

Section 10, under Computer Applications and Quality Systems, presents additional information on statistical packages. The graphics available with these packages (such as SAS/GRAPH with SAS) are of such a quality that they would often justify the expenditure for the package to management. The American Society for Quality annually publishes a "Directory of Software for Quality Assurance and Quality Control" (see, for example, ASQC 1996).

Coding of Data.   Suppose that we have five observations, $X_1, \ldots, X_5$ as in Table 44.11 and wish to compute the mean and standard deviation. Then on a pocket calculator (such as the Texas Instruments TI-55) or on a mainframe computer, we find

$$\sum_{i=1}^{5} X_1 = 49345 \qquad \sum_{i=1}^{5} X_i^2 = 4.8698581 \times 10^8$$

$$\overline{X} = 9869 \qquad\qquad s^2 = 0.985 \qquad s = 0.992$$

The only problem with these answers is that they are *wrong*. For example, 9869 is less than all the observations; hence it cannot be the mean. And the standard deviation is a measure of the spread in the data; that spread from largest to smallest is 0.00008; hence 0.992 is much too large. The problem that has led to this inaccuracy is that the computers used keep only about eight decimal places of accuracy, and this results in discarding digits that are needed for accurate calculation. If it can be so troublesome to calculate the mean and standard deviation of five numbers accurately, clearly, problems of meaningful size require careful analysis of numerical inaccuracy, as discussed above, and for this reason, software should not be trusted without a careful analysis of its capabilities. The four packages suggested are of high quality.

If one must use untested software, it is recommended that one *code* the data; that is, calculate using $Y_1, \ldots, Y_5$, where $Y_i = a(X_i + b)$ for some a and b. For example, if we choose $a = 10^5$ and $b = -9869$, we will have $Y_1 = 13$, $Y_2 = 7$, $Y_3 = 15$, $Y_4 = 8$, and $Y_5 = 9$. For these we calculate (on the same computers)

$$\sum_{i=1}^{5} Y_i = 52 \qquad \sum_{i=1}^{5} Y_i^2 = 588 \qquad \overline{Y} = 10.4 \qquad s_Y^2 = 11.8 \qquad s_Y = 3.4351$$

which are exactly correct. Now it can be shown that the relation between $\overline{X}, s_X^2$ and $\overline{Y}, s_Y^2$ is

$$\overline{X} = \frac{1}{a}\overline{Y} - b \qquad s_X^2 = \frac{1}{a^2} s_Y^2$$

TABLE 44.11   Five Data Points

$X_1 = 9869.00013$
$X_2 = 9869.00007$
$X_3 = 9869.00015$
$X_4 = 9869.00008$
$X_5 = 9869.00009$

Hence we find (exactly again)

$$\overline{X} = 10.4 \times 10^{-5} + 9869 = 9869.000104$$

$$s_X^2 = 11.8 \times 10^{-10} \text{ (hence } s_X = 0.000034)$$

This method of *coding the data* will preserve accuracy in many other, more complex statistical calculations (such as regression) and is in fact done internally by many of the high-quality statistical computer packages. Thus it should be used whenever you are using a package other than one of the high-quality ones listed earlier. In addition, many absurd results from inaccurate software will be detected early if one observes the cardinal rule of statistics, namely, "Look at the data." (It is all too common to have the data gathered and analyzed via computer without a careful look at them with the measures recommended in this section, and this has led to many costly problems for many companies.)

In terms of the choice of *a* and *b* for the coding, the best values to use are $a = 1/s_X$ and $b = -\overline{X}$. If these values cannot be calculated in a trustworthy manner by the software, the simple estimates of the next paragraph may be used instead.

Simple Estimates of Location and Dispersion.   Simple estimates of the center and the spread of a set of data are often desired (e.g., for use in coding of data, as discussed earlier, and also for rapid analysis of a data set under time pressure). Two simple measures for the center are the median ($\widetilde{X}$) and the midrange, expressed as

$$\frac{\text{Maximum } (X) + \text{minimum } (X)}{2}$$

A simple measure for the variability is

$$\frac{\text{Maximum } (X) - \text{minimum } (X)}{4}$$

For the data of Table 44.11, the true value was $\overline{X} = 9860.000104$. The two simple methods yield 9869.00009 and 9869.000110, respectively. Similarly, the true value of the standard deviation was $s_X = 0.000034$, and the simple estimate yields 0.000020. (If we use Table A in Appendix II and take the range divided by d_2 instead of the range divided by 4, we will have a better estimate. With five data points, $d_2 = 2.326$, so our estimate of s_X is then $0.000080/2.326 = 0.000034$.)

PROBABILITY MODELS FOR EXPERIMENTS

A distinction is made between a sample and a population (or *universe*). A *sample* is a limited number of measurements taken from a large source. A *population* is a large source of measurements from which the sample is taken. (Note that a population may physically exist, such as all stereo sets in a certain lot. It also may be conceptual, as all experiments that might be run.)

A *probability distribution* is a mathematical formula that relates the values of the characteristic with their probability of occurrence in the population. Figure 44.7 summarizes some distributions. When the characteristic being measured can take on any value (subject to the fineness of the measuring process), its probability distribution is called a *continuous* probability distribution. For example, the probability distribution for the resistance data of Table 44.7 is an example of a continuous probability distribution because the resistance could have any value, limited only by the fineness of the measuring instrument. Experience has shown that most continuous characteristics either follow one of several common probability distributions, the *normal* distribution, the *exponential* distribution, and the *Weibull* distribution, or can be fitted with an empirical estimate, as discussed later in this section. These distributions find the probabilities associated with occurrences of the actual

values of the characteristic. Other continuous distributions (e.g., t, F, and chi square) are important in data analysis but do not provide probabilities of occurrence of actual values.

When the characteristic being measured can take on only certain specific values (e.g., integers 0, 1, 2, 3, etc.), its probability distribution is called a *discrete* probability distribution. For example, the distribution for the number of defectives r in a sample of five items is a discrete probability distribution because r can only be 0, 1, 2, 3, 4, or 5. The common discrete distributions are the Poisson, binomial, negative binomial, and hypergeometric (see Figure 44.7).

The following paragraphs explain how probability distributions can be used with a sample of observations to make predictions about the larger population.

Sample Space.   Statistics deals with the *outcomes of experiments.* When an experiment is performed, some outcome results; let us denote a typical outcome by the symbol e. Such an outcome is called a *simple event.* If we list all the possible outcomes of the experiment of interest to us, that set is called the *sample space* of the experiment.

As an example, if we perform the experiment of tossing three coins and observing for each coin whether it lands heads (H) or tails (T), the sample space will contain the eight possible outcomes

$$\text{HHH} \quad \text{HHT} \quad \text{HTH} \quad \text{THH} \quad \text{HTT} \quad \text{THT} \quad \text{TTH} \quad \text{TTT}$$

For simplicity of notation, let us denote these simple outcomes, respectively, by e_1, e_2, e_3, e_4, e_5, e_6, e_7, and e_8.

We associate a number called *probability* with each of the simple events. We think of this number as representing the proportion of times each simple event would occur in a very large number of experiments of this type. For example, the probability of HHH in our experiment of tossing three coins is usually taken to be $1/8 = 0.125$ because it typically occurs in about one-eighth of a large number of experiments where three coins are tossed. We denote the probability of a simple event e by $P(e)$; thus we usually have $P(\text{HHH}) = 1/8$.

Since some outcome occurs in each experiment, when we add up the proportion of times that each e in the sample space occurred, we must obtain a sum of 1. Since probabilities represent what those proportions would be in a large number of experiments, we also must have *probabilities* that *sum to 1 when all outcomes are accounted for.* For example, in our example with three coins,

$$P(e_1) + P(e_2) + P(e_3) + P(e_4) + P(e_5) + P(e_6) + P(e_7) + P(e_8) = 1$$

Events.   Very often we are interested not in a simple event but in a combination of them, called a *composite event.* For example, the event "more heads than tails" occurs if and only if one of the simple events e_1, e_2, e_3, e_4 (i.e., the simple events HHH, HHT, HTH, THH) occurs in our example of tossing three coins. The frequency with which we find "more heads than tails" will be the sum of the relative frequencies of e_1, e_2, e_3, and e_4. Thus we say the probability of the event "more heads than tails" is the sum of the probabilities of the simple events that comprise the event "more heads than tails":

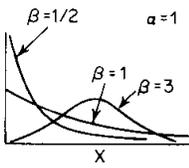
$$P \text{ (more heads than tails)} = P(e_1) + P(e_2) + P(e_3) + P(e_4)$$

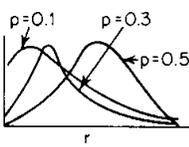
To make this simpler to write, we often denote the event of interest by a symbol, such as A for the event "more heads than tails." Then

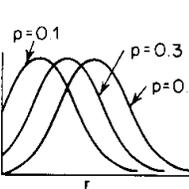
$$P(A) = P(e_1) + P(e_2) + P(e_3) + P(e_4)$$

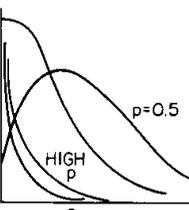
Thus *the probability of a composite event is the sum of the probabilities of all the simple events that comprise it.* (Note that simple events are always mutually exclusive.) Since in the example with three coins we have $P(e_1) = P(e_2) = \dots = P(e_8) = 1/8$, we find

$$P(A) = 1/8 + 1/8 + 1/8 + 1/8 = 1/2$$

DISTRIBUTION	FORM	PROBABILITY FUNCTION	COMMENTS ON APPLICATION
NORMAL		$y = \dfrac{1}{\sigma\sqrt{2\pi}}\,e^{-\frac{(X-\mu)^2}{2\sigma^2}}$ μ = Mean σ = Standard deviation	Applicable when there is a concentration of observations about the average and it is equally likely that observations will occur above and below the average. Variation in observations is usually the result of many small causes.
EXPONENTIAL		$y = \dfrac{1}{\mu}\,e^{-\frac{x}{\mu}}$	Applicable when it is likely that more observations will occur below the average than above.
WEIBULL		$y = \alpha\beta\,(X-\gamma)^{\beta-1}e^{-\alpha(X-\gamma)^{\beta}}$ α = Scale parameter β = Shape parameter γ = Location parameter	Applicable in describing a wide variety of patterns of variation, including departures from the normal and exponential.
POISSON*		$y = \dfrac{(np)^r\,e^{-np}}{r!}$ n = Number of trials r = Number of occurrences p = Probability of occurrence	Same as binomial but particularly applicable when there are many opportunities for occurrence of an event, but a low probability (less than 0.10) on each trial.
BINOMIAL*		$y = \dfrac{n!}{r!(n-r)!}\,p^r q^{n-r}$ n = Number of trials r = Number of occurrences p = Probability of occurrence $q = 1-p$	Applicable in defining the probability of r occurrences in n trials of an event which has a probability of occurrence of p on each trial.
NEGATIVE BINOMIAL*		$y = \dfrac{(r+s-1)!}{(r-1)!(s!)}\,p^r q^s$ r = Number of occurrences s = Difference between number of trials and number of occurrences p = probability of occurrence $q = 1-p$	Applicable in defining the probability that r occurrences will require a total of $r+s$ trials of an event which has a probability of occurrence of p on each trial. (Note that the total number of trials n is $r+s$.)
HYPERGEOMETRIC*		$y = \dfrac{\binom{d}{r}\binom{N-d}{n-r}}{\binom{N}{n}}$	Applicable in defining the probability of r occurrences in n trials of an event when there are a total of d occurrences in a population of N.








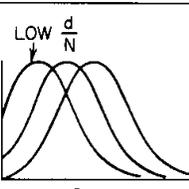


FIGURE 44.7 Summary of common univariate probability distributions. (Asterisks indicate that these are discrete distributions, but the curves are shown as continuous for ease of comparison with the continuous distributions.)

i.e., we expect to find more heads than tails (when three coins are tossed) in about 50 percent of such experiments.

In the example with three coins, we have *equally likely simple events,* i.e., $P(e_i) = P(e_j)$ for all i, j. When this is true, it follows that for any composite event A we have

$$P(A) = \frac{\text{number of simple events in } A}{\text{number of points in the sample space}}$$

In the case of the three coins, this yields the same answer obtained before, namely, $P(A) = 4/8 = 1/2$.

We say two composite events A_1 and A_2 are *mutually exclusive* if no e_i is in both A_1 and A_2. For example, if A_1 is the event "2 heads" and A_2 is the event "more tails than heads," then A_1 and A_2 are mutually exclusive because $A_1 = \{e_2, e_3, e_4\}$ and $A_2 = \{e_5, e_6, e_7, e_8\}$ have no point in common. We often express the fact that A_1 and A_2 are mutually exclusive in shorthand by writing

$$A_1 A_2 = \phi$$

If A_1 and A_2 are mutually exclusive, then for the event "A_1 or A_2" (which occurs if and only if at least one of A_1, A_2 occurs), *we have*

$$P(A_1 \text{ or } A_2) = P(A_1) + P(A_2)$$

This follows because $P(A_1 \text{ or } A_2)$ equals the number of e_i in either A_1 or A_2 divided by the total number of simple events; since there are no points in both A_1 and A_2, this is the same as taking the number of points in A_1 and adding to it the number in A_2 and then dividing by the total number of simple events. In our example, $P(A_1 \text{ or } A_2) = P(A_1) + P(A_2) = 3/8 + 4/8 = 7/8$.

In our example so far, we have discussed the events

A: "more heads than tails"

A_1: "2 heads"

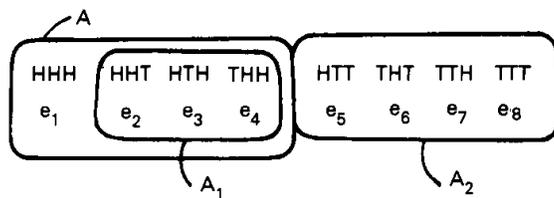
A_2: "more tails than heads"


FIGURE 44.8   Events and sample space, experiment of tossing 3 coins.

These are shown on the sample space in Figure 44.8. Here A and A_1 are not mutually exclusive, so the simple addition of the probabilities does not hold for them, since $P(A) + P(A_1) = 4/8 + 3/8 = 7/8$ counts the points e_2, e_3, e_4 twice as to their probabilities. Thus we see that a correct equation for $P(A \text{ or } A_1)$ will need to subtract this overcounting part, which is $P(A \text{ and } A_1)$, i.e., the probability that we have an experimental outcome where both A and A_1 occur, which is $P(A$ and $A_1) = 3/8$ in this example. Thus we have reasoned to the fact that *for any events A and A_1 the addition rule is*

$$P(A \text{ or } A_1) = P(A) + P(A_1) - P(A \text{ and } A_1)$$

For mutually exclusive events, the $P(A$ and $A_1)$ would be 0 so that this would reduce to simple addition of $P(A)$ and $P(A_1)$ in that case.

Rules of Probability, Combinatorics.

Probability theory underlies all decisions that are based on sampling. As we have seen, probability is expressed as a number that lies between 1.0 (certainty that an event will occur) and 0.0 (impossibility of occurrence), and the most intuitive definition of probability is one based on a frequency interpretation. In the simple case when an event A can occur in s cases out of a total of n possible and equally probable cases, then the probability that the event will occur is

$$P(A) = \frac{s}{n} = \frac{\text{number of successful cases}}{\text{total number of possible cases}}$$

Counting s and n can be complex, in which case it is called a problem of *combinatorics.*

Example: A lot consists of 100 parts. A single part is selected *at random,* which means that each of the 100 parts has an equal chance of being selected. Suppose a lot contains a total of 8 nonconforming parts. Then the probability of drawing a single part that is non-conforming is 8/100, or 0.08.

The following theorems are useful in solving problems involving probability:

Theorem 1: If $P(A)$ is the probability that an event A will occur, then the probability that A will not occur is $1 - P(A)$.

Theorem 2: If A and B are two events, then the probability that either A or B occurs is

$$P(A \text{ or } B) = P(A) + P(B) - P(A \text{ and } B)$$

A special case of this theorem occurs when A and B cannot occur simultaneously (i.e., A and B are "mutually exclusive"). Then the probability that either A or B occurs is

$$P(A \text{ or } B) = P(A) + P(B)$$

Example: The probabilities of r defectives in a sample of six units from a 5 percent defective lot are found below by the binomial. The probability of zero defectives is 0.7351; the probability of one defective is 0.2321. The probability of zero or one defective is then $0.7351 + 0.2321$, or 0.9672.

Theorem 3: If A and B are two events, then the probability of the joint occurrence of both A and B is

$$P(A \text{ and } B) = P(A) \times P(B|A)$$

where $P(B|A) = $ probability that B will occur assuming A has already occurred.

A special case of this theorem occurs when the two events are *independent*; i.e., when the occurrence of one event has no influence on the probability of the other event. If A and B are independent, then the probability of both A and B occurring is

$$P(A \text{ and } B) = P(A) \times P(B)$$

Example: A complex system consists of two major independent subsystems. The probability of successful performance of the first subsystem is 0.95; the corresponding probability for the second subsystem is 0.90. Both subsystems must operate successfully to achieve total system success. The probability of the successful operation of the total system is therefore $0.95 \times 0.90 = 0.855$.

The preceding theorems have been stated in terms of two events but can be expanded for any number of events.

Conditional Probability; Bayes' Theorem.

In *conditional probability,* we seek an answer to such questions as, "If I know that A_2 has occurred, then on those trials of the experiment where A_2 has occurred, how often does A_1 occur?" We use a special shorthand symbol for this conditional probability:

$$P(A_1|A_2)$$

which is read as "the probability of A_1, given that A_2 is known to have occurred" and is calculated from the formula

$$P(A_1|A_2) = \frac{P(A_1 \text{ and } A_2)}{P(A_2)}$$

If $P(A_1|A_2) > P(A_1)$, we say A_2 carries "positive information" about A_1.

If $P(A_1|A_2) < P(A_1)$, we say A_2 carries "negative information" about A_1.

If $P(A_1|A_2) = P(A_1)$, we say A_2 carries no information about A_1 or that A_1 and A_2 are "independent events." In this last case, knowing that A_2 has (or has not) occurred does not change the chances of A_1 occurring.

The powerful *conditional probability reversal formula,* namely,

$$P(A_1|A_2)P(A_2) = P(A_1 \text{ and } A_2) = P(A_2 \text{ and } A_1) = P(A_2|A_1)P(A_1)$$

is the basis of Bayes' theorem. In the simplest setting, this states that

$$P(A_2|A_1) = \frac{P(A_1|A_2)P(A_2)}{P(A_1|A_2)P(A_2) + P(A_1|\text{not } A_2)P(\text{not } A_2)}$$

(Here, "not A_2" is the event that A_2 does not occur.) For worked solutions of problems in probability, see Dudewicz (1993).

The techniques presented under Tests of Hypotheses in this section consist of analyzing a sample of observations and reaching a conclusion (with defined sampling risks) to accept or reject a hypothesis. The experimenter considers the consequences of drawing incorrect conclusions and, to a lesser degree, the likelihood that extreme values of the population parameter will occur. However, this is usually done on a qualitative basis and involves judgment. In practice, a sample size is limited by economics, and the experimenter defines the type I error (usually 0.05 or 0.01) in numerical terms and then must accept the type II error that results with the sample size fixed by economics. There is a methodical way of defining the consequences of the type I and type II errors and the likelihood of extreme values. The approach involves Bayes' theorem and statistical decision theory.

Statistical Decision Theory.   This concept requires two items of information not formally used in classic analysis:

1. The economic consequences of making type I or type II errors.

2. The probabilities that different values of the population parameter will occur. (The classical approach has no assumption concerning different values of the population parameter.)

Statistical tables and sampling plans based on Bayes' theorem or statistical decision concepts are not common, but the concepts can have a significant effect, and therefore development work seems imminent and worthwhile. Oliver and Springer (1972) give an example of Bayesian acceptance sampling tables. Hadley (1967) provides background material including examples on tests of hypotheses, confidence limits, and acceptance sampling plans. Lenz and Rendtel (1984) compare the performance of MIL-STD-105D, Skip Lot, and Bayesian sampling plans. See also the discussion in Section 46, under Bayesian Procedures.

Simpson's Paradox.   What is called *Simpson's paradox* was discovered in 1951 by E. H. Simpson. Since then, it has been found to have many important implications in industry, medicine, and many other fields; a discussion is given in Dudewicz and Mishra (1988, pp. 55–57) and examples are given in Wardrop (1995) and its references. I will give an example to illustrate the problem and discuss how to avoid it.

Suppose that a company has two plants in different parts of the world. Both make a state-of-the-art product that is not yet fully understood (and hence much rework or scrap results). A new process modification is to be tried in both plants, head to head with the present method. The results of the trial come back and are summarized for management as follows: 46 percent successes (on 11,000

units made) with the new method but only 11 percent successes (on 10,100 units made) with the present method. Do you have enough information, and if so, what decision do you make on selection of a method to use in the future?

It is tempting to decide to use the new process; after all, it had over four times the success rate of the present process with a substantial number of trials. However, suppose we ask for more than the executive summary report, namely, for results in both the plants. In fact, it may be the case that the present method was substantially superior in *both* the plants, as illustrated in Table 44.12. There we see that the new method decreased the success rate in Plant 1 from 10 to 5 percent and in Plant 2 from 95 percent with the present method to 50 percent with the new method. Thus the present method was substantially superior in both plants (both Plant 1, which operates in adverse conditions and has a correspondingly lower success rate, and Plant 2, which has a higher success rate and thus received 10,000 of the new materials to test with).

This is paradoxical because the present method does better in both plants, but when one sums over plants, it does worse. In fact, people often think that this is impossible before studying a numerical example such as we have provided. To avoid erroneous decisions (such as selection of the inferior method), there are a number of actions one can take. First, in the design of trials that will take place in different facilities, assign the same number of test cases to each facility. (This is not always possible, since facilities may vary in size, prior commitments, etc.) Second, when assessing results that come from several (two or more) locations, machines, technicians, states, etc., insist that more than the overall summary of successes by method be provided (namely, one also needs to see the successes by location, machine, technician, state, etc.). This should allow one to avoid errors due to Simpson's paradox (and in addition will allow one to detect possibly important nonuniformity in success rates at different locations, machines, etc. that might otherwise go undetected).

DISCRETE PROBABILITY DISTRIBUTIONS

Discrete probability distributions are used to model situations where the outcome of interest can take on only a few discrete values (such as 0 or 1 for failure or success or 0, 1, 2, 3,…as a number of occurrences of some event of interest). Below I give the model leading to the most commonly occurring such distributions and consider where one can obtain numerical values of their probabilities, and their uses in quality control.

The Discrete Uniform Distribution.   If each of the values $x_1,…, x_n$ is equally likely to occur as the result of an experiment, then we say the value obtained has the uniform distribution on the set of values $x_1,…, x_n$. In this case the probability of x_i is $1/n$. Since the probabilities are so simple, no special tables are needed.

Model Leading to a Uniform Distribution.   The model leading to a uniform distribution is random selection from a finite population in which each value occurs the same number of times. (This makes values equally likely to occur in the sample.)

Uses of Random Choices.   Random choices are often used in sampling inspection. For example, suppose that a lot of 1000 items is sequentially numbered from 500 through 1499. Then the chance

TABLE 44.12   Simpson's Paradox with Two Methods in Two Locations

		Plant 1	Plant 2
Present method:	Successes	1000	95
	Failures	9000	5
New method:	Successes	50	5000
	Failures	950	5000

that an item selected at random from the lot will have number i (for any i between 500 and 1499) is $1/1000 = 0.001$. The probability that such an item will have a serial number at least 1400 is $100/1000 = 0.10$.

The Binomial Distribution.   If the probability of occurrence p of an event is constant on each of n independent trials of the event, then the probability of r occurrences in n trials is

$$\frac{n!}{r!(n-r)!} p^r q^{n-r}$$

where $q = 1 - p$.

In practice, the assumption of a constant probability of occurrence is considered reasonable when the population size is at least 10 times the sample size (under this circumstance, the change in probability from one trial to the next due to depletion of the population is negligible).

Table F in Appendix II provides partial tables for the binomial and gives references for more complete tables. King (1971, chaps. 20 through 22) discusses binomial probability.

Model Leading to a Binomial Distribution.   When n independent trials of an experiment each have a constant probability p of occurrence of an event of interest (commonly termed a *success*), then the number of occurrences follows a binomial distribution. The name comes from the fact that the factor

$$\frac{n!}{r!(n-r)!}$$

in the probabilities is called a *binomial coefficient* in mathematics.

Binomial Probabilities and Uses.   A lot of 100 units of product is submitted by a vendor whose past quality has been about 5 percent nonconforming. A random sample of six units is selected from the lot. The probabilities of various sample results are given in Table 44.13.

In using the formula, note that $0! = 1$. Table F in Appendix II lists binomial probabilities in cumulative form, i.e., the probability of r or fewer occurrences in n trials. For the preceding example, the probability of 1 or fewer nonconforming items in a sample of 6 can be read from the table as 0.9672. Note that this is the sum of the probabilities for $r = 0$ and $r = 1$, i.e., $0.7351 + 0.2321 = 0.9672$.

The Hypergeometric Distribution.   Occasionally, the assumptions of the Poisson (see below) or binomial cannot be met even approximately. Subject only to the assumption of a random

TABLE 44.13   Table of Binomial Probabilities

r	P (exactly r defectives in 6) $=$ $[6!/r! (6 - r)!](0.05)^r(0.95)^{6-r}$
0	0.7351
1	0.2321
2	0.0306
3	0.0021
4	0.0001
5	0.0000
6	0.0000

sample, the hypergeometric gives the probability of exactly r occurrences in n trials from a lot of N items having d defectives as

$$\frac{\begin{pmatrix} d \\ r \end{pmatrix} \begin{pmatrix} N-d \\ n-r \end{pmatrix}}{\begin{pmatrix} N \\ n \end{pmatrix}}$$

where $\begin{pmatrix} N \\ n \end{pmatrix}$ is the "combinations" of N items taken n at a time and is equal to $N!/[n!(N-n)!]$, where $N! = [N(N-1)(N-2)\cdots 1]$ and $0! = 1$. The calculations can be avoided by using tables such as those prepared by Lieberman and Owen (1961). Duncan (1974) compares the results of Poisson, binomial, and hypergeometric distributions.

Model Leading to a Hypergeometric Distribution.   The hypergeometric distribution is appropriate when independent trials are conducted, but the probability of occurrence of the event of interest changes from trial to trial because of depletion of a finite population. Because of their simpler form, in this situation one often uses the binomial or Poisson distributions if their assumptions are approximately met.

Hypergeometric Probabilities and Uses.   A lot of 100 units is submitted by a vendor whose past quality has been about 5 percent nonconforming. A random sample of 20 units is selected from the lot. To calculate the probability of 0 nonconforming in 20, note that the lot has 5 nonconforming items and 95 conforming. Then

$$P(0 \text{ in } 20) = \frac{\begin{pmatrix} 5 \\ 0 \end{pmatrix} \begin{pmatrix} 95 \\ 20 \end{pmatrix}}{\begin{pmatrix} 100 \\ 20 \end{pmatrix}} = \frac{\left[\dfrac{5!}{0!(5-0)!} \right]\left[\dfrac{95!}{20!(95-20)!} \right]}{\dfrac{100!}{20!(100-20)!}} = 0.319$$

Repeat substitutions into the formula are made to find $P(r \text{ in } 20)$, where r in this example is 0, 1, 2, 3, 4, and 5.

The Poisson Distribution.   In practice, the most important discrete distribution is the Poisson. It is an approximation to more exact distributions (the hypergeometric and the binomial) and applies when the sample size is at least 16, the population size is at least 10 times the sample size, and the probability of occurrence p on each trial is less than 0.1. (These conditions are often met.)

Figure 44.7 states the Poisson probability function, but the real work is done by cumulative probability tables.

Model Leading to a Poisson Distribution.   As well as being an approximation to more exact distributions, the Poisson is the exact distribution when certain assumptions are met. These assumptions are that events occur at random (in time, or in space, or in location, for example) with a probability of occurrence roughly proportional to the length of time (or volume of space, or area) and that there is no "clumping." [For details, see Dudewicz (1976, Section 3.2).] For example, if a target 0.1 mi^2 in size is known to be contained in an area 10 mi^2 in size, and this area is shelled at random (one shell at a time so there will be no clumping), the probability of a hit will be $0.1/10 = 0.01$. The number of hits will follow a Poisson distribution, and the number of shells fired may be set so that the probability of eight or more hits on the target will be at least 0.95; this is often done in practice when it is known that eight or more hits will effectively destroy the target and a 95 percent kill probability is desired.

Poisson Probabilities and Uses.   A lot of 300 units of product is submitted by a supplier whose past quality has been about 2 percent nonconforming. A random sample of 40 units is selected from the

lot. Table E in Appendix II provides the probability of *r* or fewer defectives in a sample of *n* units. (The application of these probabilities is explained in Section 46, under Operating Characteristic, OC, Curve.) Entering the table with a value of *np* equal to 40(0.02), or 0.8, gives Table 44.14. Individual probabilities can be found by subtracting cumulative probabilities. Thus the probability of exactly two defectives is 0.953−0.809, or 0.144.

The Negative Binomial Distribution.   The negative binomial distribution is one of the most commonly occurring distributions in situations where the sample size is not set in advance but rather is determined as the experiment proceeds.

Model Leading to a Negative Binomial Distribution.   If the probability of occurrence of an event is constant from trial to trial and we make trials until we find *m* occurrences, then the probability that *r* trials will be needed is

$$\frac{(r-1)!}{(m-1)!(r-m)!} \, p^m (1-p)^{r-m}$$

where *r* can be *m, m+1, m+2,....*This equation is equivalent to the more complex one listed in Figure 44.7. Other situations leading to a negative binomial distribution are discussed in Chapter 5 of Johnson and Kotz (1969). Tables are available in Williamson and Bretherton (1963) in case direct calculation is burdensome; Johnson and Kotz (1969) give references to additional tables.

Negative Binomial Probabilities and Uses.   A large lot is inspected until the first defective ($m = 1$) is found; if this occurs in the first five trials, the lot is rejected. Hence the lot will be accepted if no defective is found in the first five trials (and thus trials 6, 7,… need not be performed—we will never inspect more than five items with this scheme). If the lot is 10 percent nonconforming, then from Table

TABLE 44.14   Table of Poisson Probabilities

r	Probability of *r* or fewer in sample
0	0.449
1	0.809
2	0.953
3	0.991
4	0.999
5	1.000

TABLE 44.15   Table of Negative Binomial Probabilities ($m=1, p=0.10$)

r	Probability *r* trials are needed to find $m = 1$ defectives
1	0.10
2	0.09
3	0.081
4	0.0729
5	0.06561
6	0.059049
7	0.053144
8	0.047830

44.15 we see that the probability the lot is accepted is $1 - (0.10 + 0.09 + 0.081 + 0.0729 + 0.06561)$ $= 0.59049$.

The Multinomial Distribution.   The discrete probability distributions discussed up to this point (the uniform, binomial, hypergeometric, Poisson, and negative binomial) all relate to situations that are *univariate,* that is, where the outcome of interest relates to one variable's value (such as the number of defectives in a sample of size n in the binomial case). However, there are important cases where the outcome is *multivariate.* One such example is that where in a sample of size n one observes both the number needing rework and the number to be scrapped, since there are two quantities, this is called a *bivariate* situation. The multinomial distribution can be used when there are any number of categories into which the items may be classified.

Model Leading to a Multinomial Distribution.   If exactly one of the events $E_1,\dots, E_k$ occurs on each of n independent trials and the probabilities of occurrence of the events are respectively $p_1,\dots,$ p_k (with $p_1 + \dots + p_k = 1$ so that one of them must occur), then the probability that E_1 occurs x_1 times and E_2 occurs x_2 times,$\dots$, and E_k occurs x_k times (where $x_1 + x_2 + \dots + x_k = n$ since there are n trials and one of $E_1,\dots, E_k$ must occur on each trial) is

$$\frac{n!}{x_1!x_2!\dots x_k!} \, p_1^{x_1} p_2^{x_2} \cdots p_k^{x_k}$$

Tables are not widely available, and calculations are usually done directly from the probability formula, or (if n is large) the multivariate normal distribution (a continuous multivariate distribution discussed later in this section) is used as an approximation.

Multinomial Probabilities and Uses.   Suppose that $n = 5$ large assemblies are manufactured and inspected each day. The results of each inspection are either pass, rework, or scrap. Past results have shown that 80 percent pass, 15 percent need rework, and 5 percent need to be scrapped. What are the probabilities of the various possible outcomes of one day's output?

Figure 44.9 shows the probabilities of the outcomes, calculated directly from the basic formula. Note that once the number to be reworked (e.g., 1) and the number to be scrapped (e.g., 0) are specified, the number passed is determined (e.g., $5 - 1 - 0 = 4$). We have had to use the multinomial probability distribution because the categories are not independent (an item cannot be both passed and scrapped).

Selecting a Discrete Distribution.   Selection of which discrete distribution to use is usually made either by knowledge of the underlying situation or by fitting a model from relative frequency probability. In either case, a test of the model selected is desirable to check its validity.

Selection from a Model of Reality.   In many cases one will know (or assume) that the model that leads to one of the distributions we have discussed underlies the practical situation. For example, if one draws 50 items at random from a large lot with $100p$ percent defective, one will assume the binomial model with $n = 50$ and probability p of a defective on each trial.

(Chi Square) Test of Model Validity.   To test the validity of an assumed discrete model, where cell i should occur with probability p_i, one compares the observed cell totals with those predicted by the model using the chi square test discussed later (Test 12*b*). Such a confirmatory test can be omitted only if one is willing to run the risk of assuming a model that in fact may have little basis in reality. [See Section 9.12 of Dudewicz and Mishra (1988) and especially Problem 9.12.2 on p. 532.]

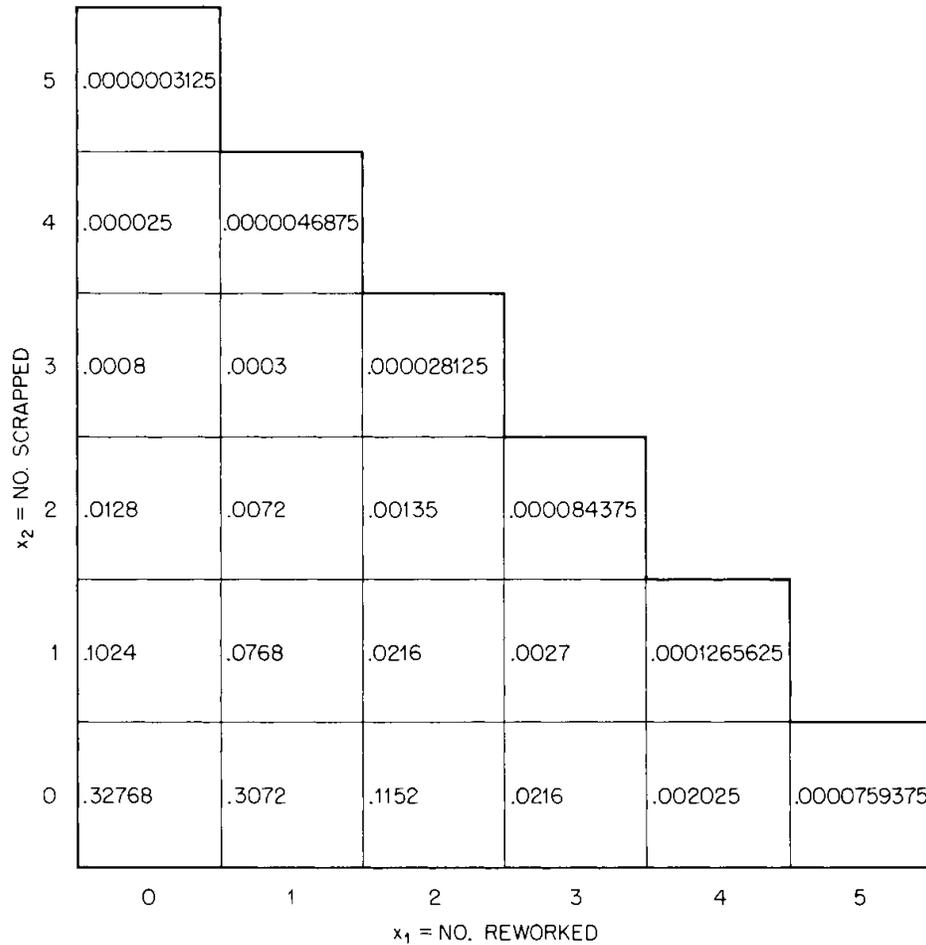
Empirical Models via Relative Frequency Probability.   If there is little or no reason to lead to the adoption of one of the specific models discussed, a model can be fitted to the data using the relative frequencies observed in the past. For example, if one has observed that in 100 items produced in the


FIGURE 44.9 Table of multinomial probabilities, $k = 3$ Categories, $n = 5$, $p_1 = P(\text{Rework}) = 0.15$, $p_2 = P(\text{Scrap}) = 0.05$, $p_3 = P(\text{Pass}) = 0.80$.

past there have been blemishes present in the numbers given in Table 44.16, one would estimate the probability of r blemishes as its relative frequency in the past work, i.e., as in Table 44.17. Such a model should be tested by taking a new sample and performing a chi square test as previously discussed. See also Bootstrap Methods later in this section.

CONTINUOUS PROBABILITY DISTRIBUTIONS

Continuous probability distributions are used to model situations where the outcome of interest can take on values in a continuous range (such as all values greater than zero for the failure time of a motor that is run continuously). Below I give the model leading to the most commonly occurring such distributions and consider where one can obtain numerical values of their probabilities and their uses in quality control.

The Continuous Uniform Distribution. If all values between a and b ($a < b$) are possible, and the chances of the value being in a subinterval are proportional to its length, then the uniform distribution is appropriate. The probability function is flat over the interval (a,b), where $y = 1/(b - a)$. Thus the probability the value is in a subinterval of length c is $c/(b - a)$. Since the probabilities are so simple, no special tables are needed.

Model Leading to a Uniform Distribution.   The model leading to a continuous uniform distribution over the range (a,b) is random selection of a value between a and b. For example, if a valve on a water line is spun at random between pressure 0 lb/in^2 (closed) and 100 lb/in^2 (fully open), then the resulting pressure will be a uniform random variable on (0, 100).

Uses of Random Numbers.   Uniform random variables on the range (0, 1) are called *random numbers.* Such variables are often used to drive digital computer simulation models and are of great importance in simulation studies of quality systems. Full details on sources of high-quality random numbers may be found in Dudewicz and Ralley (1981). Special considerations for simulation uses on microcomputers are given in Dudewicz et al. (1985).

The Exponential Distribution.   The exponential probability function is

$$y = \frac{1}{\mu}\, e^{-X/\mu}$$

Figure 44.7 shows the shape of an exponential distribution curve. Note that the normal and exponential distributions have distinctly different shapes. An examination of the tables of areas shows that 50 percent of a normally distributed population occurs above the mean value and 50 percent below it. In an exponential population, 36.8 percent are above the mean and 63.2 percent below the mean. (This refutes the intuitive idea that the average is always the 50 percent point.) The property of a higher percentage below the average sometimes helps to indicate applications of the exponential. For example, the exponential describes the loading pattern for some structural members because smaller loads are more numerous than larger loads. The exponential is also useful in describing the distribution of failure times of certain complex equipment.

Model Leading to an Exponential Distribution.   It can be shown that the exponential distribution of failure times arises when failures occur "at random" (and are not due to wearout but to such items as random shocks). In fact, the exponential distribution is characterized as the only continuous distribution with the "lack of memory property" that the chances of the item living an additional t_0 time units depend only on the length t_0 and not on how long the item has already been in use [see Dudewicz (1976), pp. 88, 106, for details].

Predictions with Exponential Distributions.   Predictions based on an exponentially distributed population require only an estimate of the population mean. For example, the time between successive failures of a complex piece of equipment is measured, and the resulting histogram is found to

TABLE 44.16   Blemishes per Item in Past Work

No. of blemishes	No. of occurrences
0	50
1	25
2	25

TABLE 44.17   Blemish Probabilities via Relative Frequency Estimation

No. of blemishes	Probability
0	.50
1	.25
2	.25

resemble the exponential probability curve. The results of a sample of measurements indicate that the average time between failures (commonly called *MTBF,* or *mean time between failures*) is 100 h. What is the probability that the time between two successive failures of this equipment will be at least 20 h?

The problem is one of finding the area under the curve beyond 20 h (Figure 44.10). Table C in Appendix II gives the area under the curve beyond any particular ratio X/μ. In this problem,

$$\frac{X}{\mu} = \frac{20}{100} = 0.20$$

and from Table C in Appendix II the area under the curve beyond 20 h is thus 0.8187. The probability that the time between two successive failures is greater than 20 h is 0.8187; i.e., there is about an 82 percent chance that the equipment will operate without failure continuously for 20 or more hours. Similar calculations would give a probability of 0.9048 for 10 or more hours. In Section 48, Reliability Concepts and Data Analysis, this probability is calculated for the specified mission time of a product, and the result is called *reliability.* These analyses also could be made using exponential probability paper.

Example: The Relationship Between Part and System Reliability: It is often assumed that the probability of survival P_s (the system reliability) is the product of the individual reliabilities of the *n* parts within the system: $P_s = P_1 P_2 \ldots P_n$. This is known as the *product rule.* The formula assumes (1) that the failures of any part will cause failure of the system and (2) that the reliabilities of the parts are independent of each other, i.e., that the reliability of one part is not dependent on the reliability of another part. [Evans (1966) gives a good discussion of this and other assumptions in reliability calculations.] A set of lights in series on a Christmas tree demonstrates the product rule. These assumptions are usually not 100 percent correct. However, the formula is a convenient approximation that should be refined as information becomes available on the interrelationships of parts and their relationship to the system. [The redundancy formula (see below under Example: Redundancy) is an example of this.] I will now illustrate the product rule.

Suppose that the following reliability requirements have been set on the subsystems of a communications system:

Subsystem	Reliability (for a 4-h period), %
Receiver	0.970
Control system	0.989
Power supply	0.995
Antenna	0.996

What is the expected reliability of the overall system if the preceding requirements are met?

$$P_s = (0.970)(0.989)(0.995)(0.996) = 0.951$$

The chance that the overall system will perform its function without failure for a 4-h period is 95 percent.

If it can be assumed that each part follows the exponential distribution, then

$$P_s = e^{-t_1 \lambda_1} e^{-t_2 \lambda_2} \cdots e^{-t_n \lambda_n}$$

Further, if t is the same for each part,

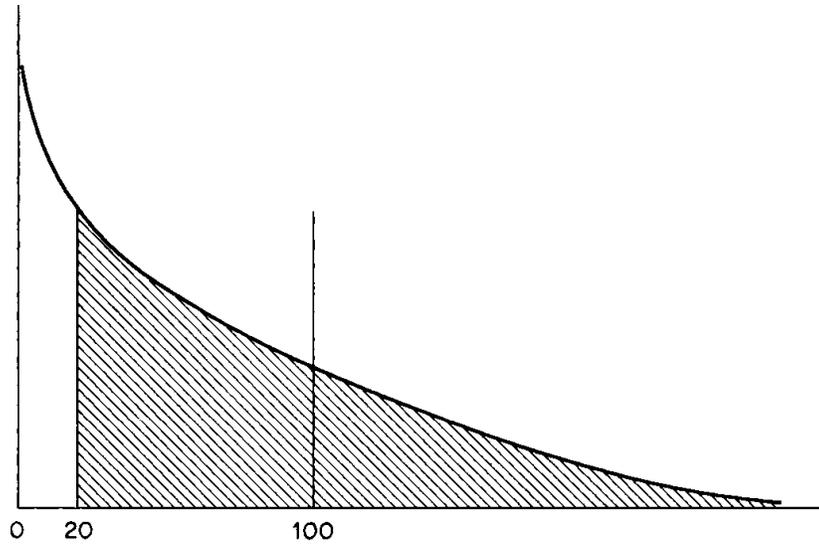
$$P_s = e^{-t \Sigma \lambda}$$


FIGURE 44.10   Distribution of time between failures.

Thus, when the failure rate is constant (and therefore the exponential distribution applies), a "reliability prediction" of a system can be made based on the addition of the part failure rates. This is illustrated in Section 19, under Designing for Reliability, Maintainability, and Availability.

Example: Redundancy: A number of system designs have been devised that attempt to increase system reliability by introducing redundancy. The simplest such system is the *parallel system,* which operates if at least one of its components operates. If each component has reliability $R(t_0)$, then the parallel system consisting of *m* components has reliability equal to [see Dudewicz (1976, p. 39)]:

$$1 - [1 - R(t_0)]^m$$

which is greater than $R(t_0)$.

Many other designs have been introduced, with a view both to reliability and to cost, such as the *k*-out-of-*n* systems. For details on these and other aspects of reliability, see Zacks (1983), Ireson (1982), and Lloyd and Lipow (1982).

The Weibull Distribution.   The Weibull distribution is a family of distributions having the general density function

$$y = \alpha\beta(X - \gamma)^{\beta-1} e^{-\alpha(X-\gamma)^{\beta}}$$

where α = scale parameter, β = shape parameter, and γ = location parameter.

The curve of the function (Figure 44.7) varies greatly depending on the numerical values of the parameters. Most important is the shape parameter β, which reflects the pattern of the curve. Note that when β is 1.0, the Weibull function reduces to the exponential and that when β is about 3.5 (and $\alpha = 1$ and $\gamma = 0$), the Weibull closely approximates the normal distribution. In practice, β varies from about $1/3$ to 5. The scale parameter α is related to the peakedness of the curve; i.e., as α changes, the curve becomes flatter or more peaked.

The location parameter γ is the smallest possible value of *X*. This is often assumed to be zero, thereby simplifying the equation. It is often unnecessary to determine the values of these parameters because predictions are made directly from Weibull probability paper. King (1971, pp. 136–140) gives procedures for graphically finding α, β, and γ.

The Weibull covers many shapes of distributions. This makes it popular in practice because it reduces the problem of examining a set of data and deciding which of the common distributions (e.g., normal or exponential) fits best. In particular, both IFR (increasing failure rate) and DFR (decreasing failure rate) cases are included, respectively, with $\beta > 1$ and $\beta < 1$ [see Dudewicz (1976, pp. 88–89)].

Model Leading to a Weibull Distribution.   It can be shown that a Weibull distribution arises if an exponential variable is raised to a power; i.e., if Y is exponential, then $Y^{1/\beta}$ has a Weibull distribution (Dudewicz 1976, p. 89).

Predictions with Weibull Distributions.   An analytical approach for the Weibull distribution (even with tables) is cumbersome, and the predictions are usually made with Weibull probability paper. For example, five heat-treated shafts were stress tested until each of them failed. The fatigue life (in terms of number of cycles to failure) is

10,263

12,187

16,908

18,042

23,271

The problem is to predict the percentage failure of the population for various values of fatigue life. The solution is to plot the data on Weibull paper, observe if the points fall approximately in a straight line, and if so, read the probability predictions (percentage failure) from the graph.

Although Weibull plotting can follow the mean rank procedure of normal probability paper (see below under Predictions with Normal Distributions), much of the literature on Weibull applications uses "median ranks." Table D in Appendix II gives, for various sample sizes, the values of the median rank. (Note that the mean rank procedure does not require a table.) The median ranks necessary for this particular example are based on a sample size of five failures and are as shown in Table 44.18. (The mean rank estimates are shown for comparison.) The cycles to failure are now plotted on the Weibull graph paper against the corresponding values of the median rank (see Figure 44.11). These points fall approximately in a straight line [King (1971, pp. 126–128) describes how to modify a plot to help obtain a straight line], so it is assumed that the Weibull distribution applies. The vertical axis gives the cumulative percentage of failures in the population corresponding to the fatigue life shown on the horizontal axis. For example, about 50 percent of the population of shafts will fail in less than 17,000 cycles. About 90 percent of the population will fail in less than 24,000 cycles. By appropriate subtractions, predictions can be made of the percentage of failures between any two fatigue life limits.

It is tempting to extrapolate on probability paper, particularly to predict life. For example, suppose the minimum fatigue life were specified as 8000 cycles and the five measurements above were from tests conducted to evaluate the ability of the design to meet 8000 cycles. Since all five tests

TABLE 44.18   Table of Median and Mean Ranks

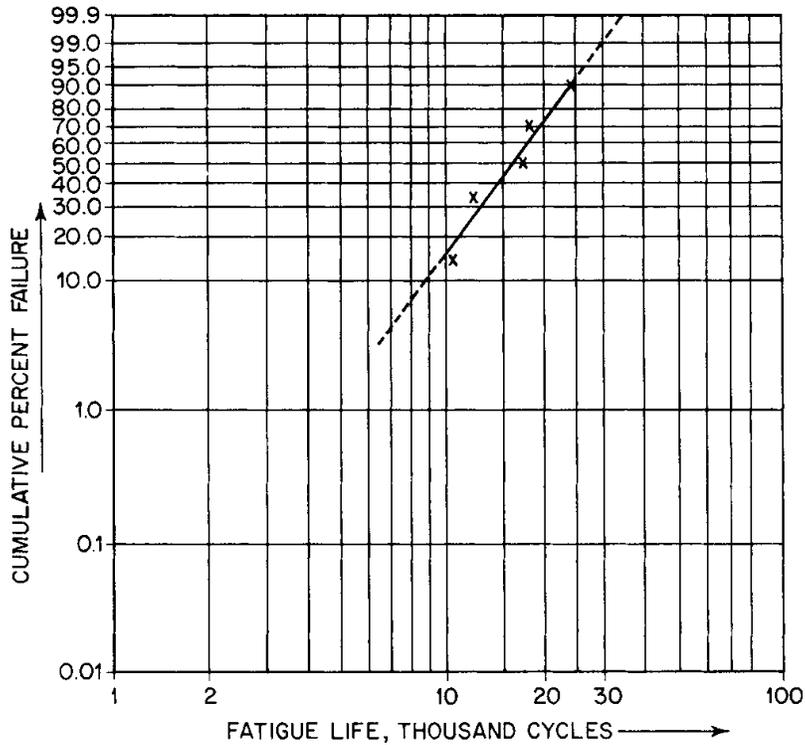
Failure number i	Median rank	Mean rank $= \dfrac{i}{5+1}$
1	0.1294	0.1667
2	0.3147	0.3333
3	0.5000	0.5000
4	0.6853	0.6667
5	0.8706	0.8333


FIGURE 44.11   Distribution of fatigue life on Weibull probability paper.

exceeded 8000 cycles, the design seems adequate and therefore should be released for production. However, extrapolation on the Weibull paper predicts that about 8 percent of the *population* of shafts would fail in less than 8000 cycles. This suggests a review of the design before release to production. Thus the small *sample* (all *within* specifications) gave a deceiving result.

Extrapolation can go in the other direction. Note that a probability plot of life-test data does not require that all tests be completed before the plotting starts. As each unit fails, the failure time can be plotted against the median rank. If the early points appear to be following a straight line, then it is tempting to draw in the line *before* all tests are finished. The line can then be extrapolated beyond the actual test data, and life predictions can be made without accumulating a large amount of test time. The approach has been applied to predicting, *early in a warranty period,* the "vital few" components of a complex product that will be most troublesome. However, extrapolation has dangers. It requires the judicious melding of statistical theory and engineeirng experience and judgment.

Moult (1963) describes the use of a Weibull plot in comparing the suitability of two types of steel for use in bearings. The plot is shown in Figure 44.12. Nelson (1982) discusses Weibull paper. Probability graph paper is available for the normal, exponential, Weibull, and other probability distributions. (A source is TEAM, Technical and Engineering Aids for Management, Box 25, Tamworth, NH 03886.) Although the mathematical functions and tables provide the same information, the graph paper reveals *relationships* between probabilities and values of *X* that are not readily apparent from the calculations. For example, the reduction in percentage defective in a population as a function of wider and wider tolerance limits can be easily portrayed by the graph paper.

The Normal Distribution.   Many engineering characteristics can be approximated by the normal distribution:

$$y = \frac{1}{\sigma\sqrt{2\pi}}\, e^{-(X-\mu)^2/2\sigma^2}$$

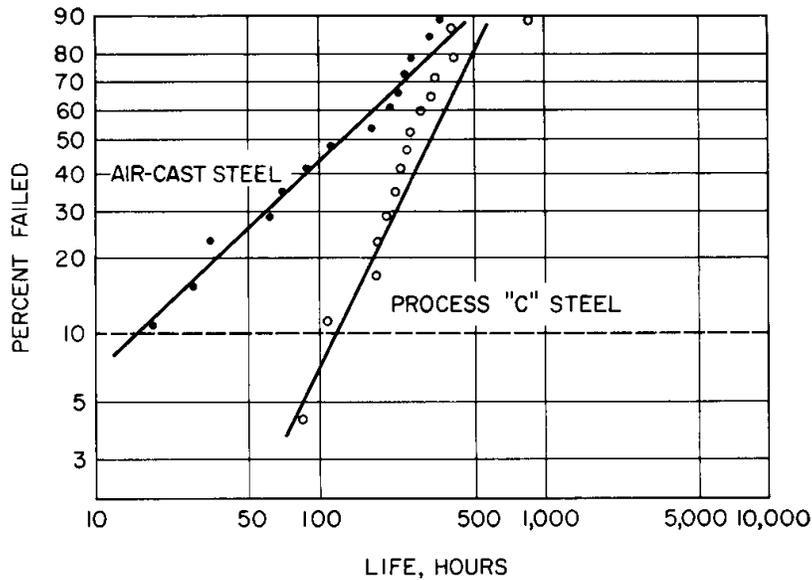
where $e = 2.718$, $\pi = 3.141$, μ = population average, σ = population standard deviation.


FIGURE 44.12   Composite fatigue endurance—process "C" vacuum degassing versus air cast AISI 8620.

Problems are solved with a table, but note that the distribution requires estimates of only the average μ and standard deviation σ of the population (unless otherwise indicated, Greek symbols will be used for population values and Roman symbols for sample values) in order to make predictions about the population. The curve for the normal probability distribution is related to a frequency distribution and its histogram. As the sample becomes larger and larger and the width of each cell becomes smaller and smaller, the historgram approaches a smooth curve. If the entire population (in practice, the population is usually considered infinite, e.g., the potential production from a process) were measured, and if it were normally distributed, the result would be as shown in Figure 44.7. Thus the shape of a histogram of sample data provides some indication of the probability distribution for the population. If the histogram resembles the "bell" shape shown in Figure 44.7, this is a basis for assuming that the population follows a normal probability distribution. (It is not necessary that the sample histogram be perfectly normal—the assumption of normality is applied only to the population, and small deviations from normality are expected in random samples.) Hahn (1971) gives a practical discussion of assuming normality. (The name *normal* distribution dates back to a time when all other distributions were erroneously thought to be abnormal. Today, some prefer the name *Gaussian* distribution.)

Model Leading to a Normal Distribution (Additive Errors, Central Limit Theorem).   It can be shown that if a variable Y is the result of adding many other variables and those variables are not highly dependent on each other, then Y will have approximately a normal distribution. [This result is called the *central limit theorem*; see Dudewicz (1976, p. 149).] Statisticians usually recommend that 10 or more terms be added before this result is relied on to produce normality; however, a number of applied studies have shown good results with as few as three terms being added.

Predictions with Normal Distributions.   Predictions require just two estimates and a table. The estimates are

$$\text{Estimate of } \mu = \overline{X} \qquad \text{and} \qquad \text{estimate of } \sigma = s$$

The calculations of the sample $\overline{X}$ and s are made by one of the methods previously discussed.

For example, from past experience, a manufacturer concludes that the burnout time of a particular light bulb it manufactures is normally distributed. A sample of 50 bulbs has been tested and the average life found to be 60 days, with a standard deviation of 20 days. How many bulbs in the entire population of light bulbs can be expected to be still working after 100 days of life?

The problem is to find the area under the curve beyond 100 days (see Figure 44.13). The area under a distribution curve between two stated limits represents the probability of occurrence. Therefore, the area beyond 100 days is the probability that a bulb will last more than 100 days. To find the area, calculate the difference between a particular value X and the average of the curve in units of standard deviation:

$$K = \frac{X - \mu}{\sigma}$$

In this problem, $K = (100 - 60) \div 20 = +2.0$. Table B in Appendix II shows, for $K = 2$, a probability of 0.9773. Applied to this problem, the probability that a bulb will last 100 days or less is 0.9773. The normal curve is symmetrical about the average, and the total area is 1.000. The probability of a bulb's lasting more than 100 days then is $1.0000 - 0.9773$, or 0.0227, or 2.27 percent of the bulbs in the population will still be working after 100 days.

Similarly, if a characteristic is normally distributed, and if estimates of the average and standard deviation of the population are obtained, this method can estimate the total percentage of production that will fall within engineering specification limits.

Figure 44.14 shows representative areas under the normal distribution curve (these can be derived from Table B in Appendix II). Thus 68.26 percent of the *population* will fall between the average of the population plus or minus 1 standard deviation of the population, 95.46 percent of the population will fall between the average $\pm 2\sigma$, and finally, $\pm 3\sigma$ will include 99.73 percent of the population. The percentage of a *sample* within a set of limits can be quite different from the percentage within the same limits in the population. This important fact is crucial in testing hypotheses (covered later in this section).

Another way of making predictions based on a normal distribution employs probability paper. Probability paper is so constructed that data from a particular kind of distribution plots as a straight line; i.e., a sample of data from a normally distributed population plots approximately as a straight line on normal probability paper. (Small deviations from a straight line are expected because the data represent a *sample* of the population.) The following are the steps taken to plot a set of individual observations on probability paper:

1. Arrange the observations in ascending values. The smallest value is given a rank i of 1 and the largest value a rank of n.

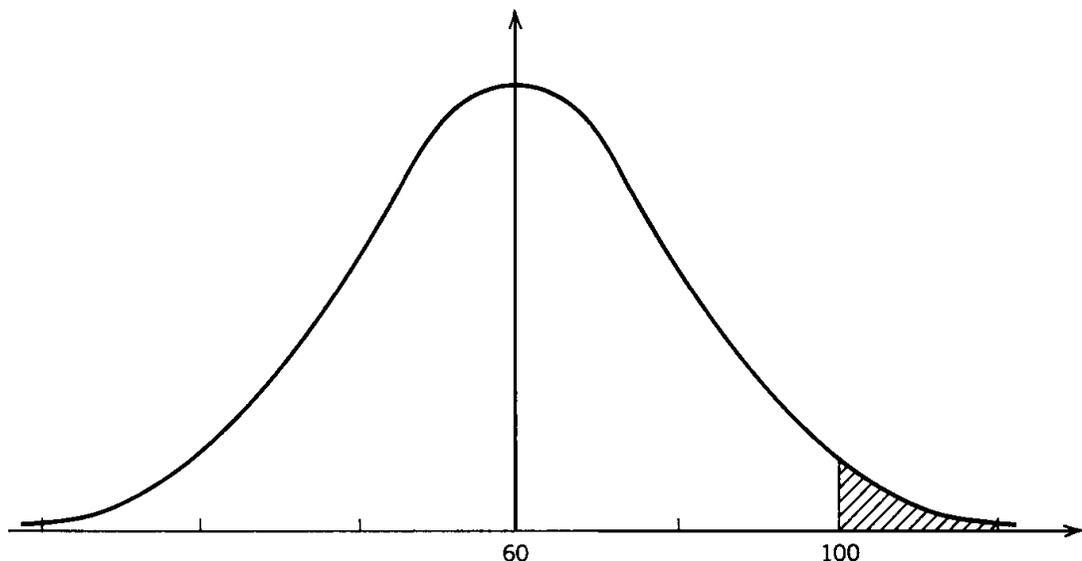
2. For each value, calculate the cumulative frequency.


FIGURE 44.13   Distribution of light bulb life.
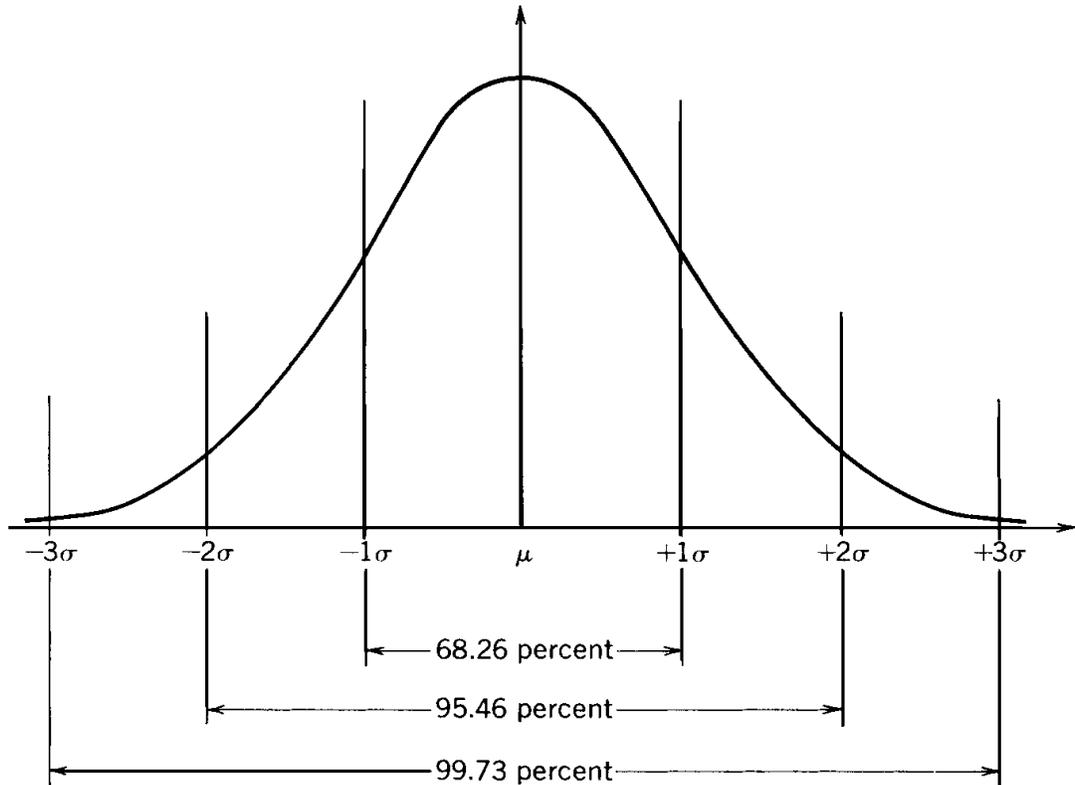

FIGURE 44.14   Areas of a normal curve.

3. For each value, calculate

$$\frac{\text{Cumulative frequency}}{n + 1} \times 100$$

This provides the mean rank probability estimate, in percent, for plotting the data.

4. Plot the observed values against their mean rank probability estimate.

If the observations are in frequency distribution form, the procedure is the same, except that instead of using the observed values, the probability estimates are plotted against the cell boundaries. This is illustrated for the resistance data (see Table 44.19).

The plot is shown in Figure 44.15. Lower cell boundaries are plotted against the last column of Table 44.19 using the upper (Percent Over) scale. The line has been drawn in by eye, and the fit appears reasonable. This line represents an estimate of the population, and predictions like those obtained from the normal probability table can be read directly from the graph. For example, 5 percent of the population of coils will have resistance values greater than about 3.39. Also, 95 percent will have values greater than about 3.29. (Therefore, 95 − 5, or 90 percent, will have values between 3.29 and 3.39.)

Figure 44.16 shows a form that incorporates probability paper plotting with further analysis such as confidence limits and control limits. (This type of form was originally developed by E. F. Taylor.)

King (1971) gives a practical description of probability paper procedures for the normal and other important distributions. While fit is often evaluated by eye when we have clearly good fit (as in Figure 44.15), statistical tests are available and should be used in cases that are not so clearcut; see Iman (1982) for details and graphs on which this analysis can be performed.

The Lognormal Distribution.   If $Y = e^Z$, where Z has a normal distribution, Y is said to have a *lognormal distribution* (since the logarithm of Y has a normal distribution).

TABLE 44.19   Resistance Data

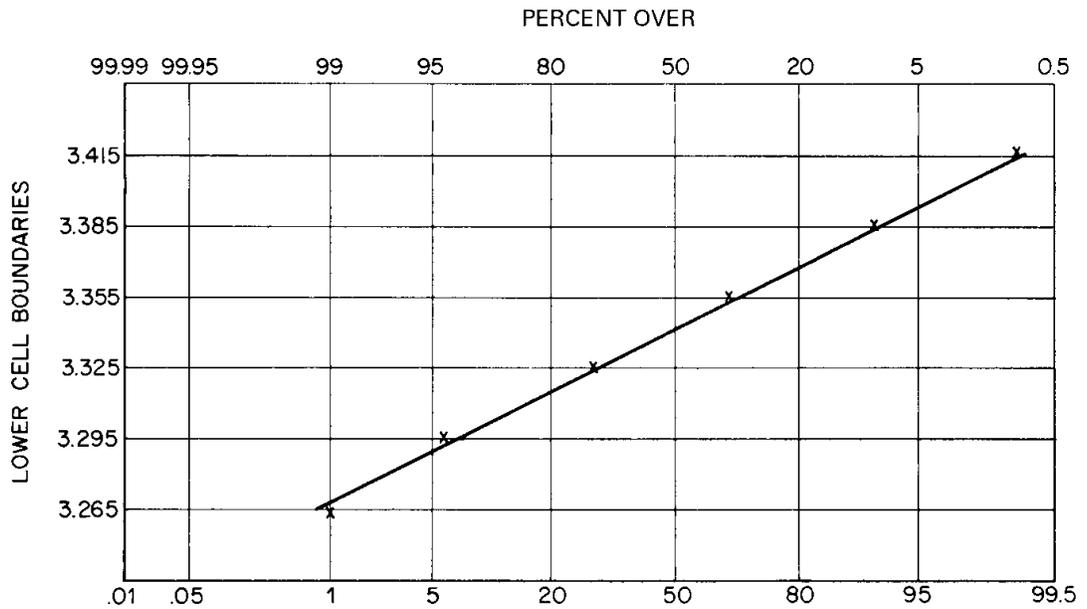
Cell boundaries	Frequency	Cumulative frequency	$\dfrac{\text{Cumulative frequency}}{100 + 1} (100)$
3.415–3.445	1	1	0.99%
3.385–3.415	8	9	8.90
3.355–3.385	27	36	35.60
3.325–3.355	36	72	71.30
3.295–3.325	23	95	94.10
3.265–3.295	5	100	99.00
	100		


FIGURE 44.15   Cumulative probability plot of Table 44.19.

Model Leading to a Lognormal Distribution (Multiplicative or Percentage Effects).   Lognormal variables arise when effects are percentages or multiplicative, which is common in biological and many other applications. For example, if a random percentage of a stock of items goes bad each time period, the percentage still good after a large number (10 or more) of time periods will be lognormally distributed. (This result follows from the central limit theorem already discussed when considering the normal distribution, since the logarithm of a product is the sum of the logarithms of the items in the product.)

Predictions with Lognormal Distributions.   As with the normal distribution, predictions require two estimates. For details, see Cohen and Whitten (1981). Note that the lognormal distribution is positively skewed and is widely employed as a model for distribution of life spans, reaction times, income distributions, and other economic data.

Often the mean, standard deviation, and probabilities of the lognormal variable Y itself are of basic interest; thus, while one can easily estimate these for Z (the logarithm of $Y = e^Z$), this does not answer the real problem. For example, if Y is the lifetime of some system, one may want to estimate the average life of the system—not the mean of the logarithm of Y. This is why the special methods referred to above have been developed for this distribution.

Mixture Distributions. Y is said to have a *mixture distribution* if Y results from source i a percentage $100p_i$ of the time ($i = 1, 2,...$).

FIGURE 44.16 Normal distribution analysis sheet.

44.38

Model Leading to a Mixture Distribution.   When output from several sources is mixed (e.g., output from several suppliers, several plants, several machines, several workers, and so on), the quality characteristics of the resulting mix have mixture distributions. If each of the components coming into the mix has *exactly* the same distribution, then the mix also will have that distribution. However, if the components coming into the mix have different distributions, then the mix will have a *mixture distribution.*

Fitting of Mixtures.   As can be seen from Figure 44.7, the distributions we have considered so far are unimodal (have one peak). When in practice one sees two or more peaks in the histogram, one suspects that a mixture underlies the data. In some cases, this itself leads to a study of the items coming into the mix, often to find a problem in one of the streams of what should be homogeneous product.

   In other cases, the streams coming into the mix cannot be separated (or it is not desired to separate them), but rather one wishes to fit the density of Y as $p_1 f(Z_1) + p_2 f(Z_2) + \ldots + p_k f(Z_k)$ for some k (2 or more). Here the p_i's add to 1 (100 percent of the mix), and often the Z_i's are known to be normal. To fit the distribution of the Y, one must then select $k - 1$ p's (since they add to 1, the last one is then determined), k means, and k variances. This process requires use of modern computer software such as LABONE. As an example, consider the data of Table 44.20. A histogram of these data shows that a mixture (of two terms, since there are two peaks) may be involved. The distributions seem to the eye to be normal. Using LABONE Expert Statistical Programs (ESP), we are able to easily fit a mixture of normal distributions.

The Multinormal Distribution.   The continuous probability distributions discussed up to this point (the uniform, exponential, Weibull, normal, lognormal, and mixture) all relate to situations that are *univariate,* that is, where the outcome of interest has one component (such as lifetime). If there are additional components of interest (such as weight and height), then the outcome is *multivariate* (in this case of three, *trivariate*). The multinormal distribution is appropriate when each of the components has a normal distribution and is the most widely used continuous multivariate distribution.

Model Leading to a Multinormal Distribution.   The same sort of additive process that leads to a univariate normal distribution leads to a multivariate normal distribution when more than one component is being measured.

Predictions with Multinormal Distributions.   Predictions with multinormal distributions require computer packages in most cases. The details, with computer code and examples, are discussed by Siotani et al. (1985).

The Extended Generalized Lambda Distribution.   A one-parameter lambda distribution was proposed in 1960 by J. Tukey, generalized in 1972 and 1974 by J. S. Ramberg and B. Schmeiser,

TABLE 44.20   Data for Mixture Analysis

3.37	3.34	3.48	3.32	3.33	3.38	3.34	3.31	3.43	3.34
3.29	3.46	3.30	3.31	3.43	3.34	3.34	3.46	3.39	3.34
3.45	3.36	3.30	3.42	3.33	3.35	3.45	3.34	3.32	3.48
3.32	3.37	3.44	3.38	3.36	3.47	3.36	3.31	3.43	3.30
3.35	3.43	3.38	3.37	3.54	3.32	3.36	3.42	3.29	3.35
3.48	3.39	3.34	3.42	3.30	3.39	3.46	3.40	3.32	3.43
3.29	3.41	3.37	3.36	3.41	3.47	3.36	3.37	3.43	3.36
3.31	3.43	3.35	3.34	3.45	3.34	3.31	3.46	3.37	3.35
3.50	3.35	3.37	3.42	3.35	3.36	3.48	3.35	3.31	3.44
3.35	3.36	3.49	3.31	3.31	3.40	3.35	3.33	3.45	3.31

and developed and tabled by Ramberg et al. (1979). While it fits a wide variety of curve shapes and can fit any mean and any variance, it cannot fit all combinations of skewness and kurtosis. Thus it is useful when it fits, but for some data sets it does not fit. Recently, Karian et al. (1996) gave an extension called the *extended generalized lambda distribution* (EGLD), which can fit any and all values of the mean, variance, skewness, and kurtosis; tables needed in applications were given in Dudewicz and Karian (1996). Thus now the benefits of this empirical family are available in all univariate data sets. These methods are extended to bivariate GLD cases in Karian and Dudewicz (1999).

Selecting a Continuous Distribution.

Selection of which continuous distribution to use is usually made either by knowledge of the underlying situation or by fitting a model to the histogram (often via plots on probability papers of the most usual distributions). In either case, a test of the model selected is desirable to check its validity.

Selection from a Model of Reality. In many cases one will know (or assume) that the model that leads to one of the distributions we have discussed underlies the practical situation. For example, if the life distribution of the equipment under study has, in the past, always been adequately fitted by a Weibull model (though with parameters that change from application to application), one will usually start with a Weibull assumption.

Testing Distributional Assumptions (Probability Plotting, Tests for Specific Distributions). In practice, a distribution is assumed by evaluating a sample of data. Often it is sufficient to evaluate the shape of the histogram or the degree to which a plot on probability paper follows a straight line. These convenient methods do require judgment (e.g., how "straight" must the line be?) because the sample is never a perfect fit; quantitative tests for probability plots should be used (see Iman 1982). Be suspicious of the data if the fit is "perfect." "Goodness of fit" tests (see Tests of Hypotheses later in this section) evaluate any distribution assumption using quantitative criteria.

Fitting Empirical Probability Distributions. If there is little or no reason to suggest one of the specific models discussed, or if they are rejected (e.g., because of a poor probability paper fit), an alternative is to fit an empirical model. Such models can adapt to a wide range of distributional shapes, including many of those of the specific models discussed above. One of the most widely used empirical families has been the *generalized lambda distribution* (GLD) family. However, as discussed earlier, the new EGLD enhances its capabilities and should be used instead; often the two give the same result, but when the GLD has difficulty, the EGLD can still match the population's sample moments.

As an example, Table 44.21 presents data (from p. 219 of Hahn and Shapiro, 1967) on the coefficient of friction of a metal in 250 samples. Using procedures and tables given in Ramberg et al. (1979), a probability function can be developed.

TABLE 44.21 Coefficient-of-Friction Data

Range	Frequency
Less than .015	1
0.015–0.020	9
0.020–0.025	30
0.025–0.030	44
0.030–0.035	58
0.035–0.040	45
0.040–0.045	29
0.045–0.050	17
0.050–0.055	9
0.055–0.060	4
More than 0.060	4
Total	250

As a check on the goodness of the fit, it is recommended that the probability function always be plotted on the same graph as the histogram for a visual assessment of the fit (which can be supplemented by a chi square test if desired). This is done in Figure 44.17, and we see that the fit is excellent (a chi square test comes to the same conclusion).

Bootstrap Methods. Bootstrap methods suggest that one fit a model such as the EGLD to the data, and then, assuming that the fit passes testing, use that model in a "bootstrapping" analysis. (See The Generalized Bootstrap and Bootstrap Method later in this section.)

STATISTICAL ESTIMATION

In statistical estimation, we make inferences about parameters of a population from data on a sample. For example, if we have a random sample of 100 items from a large lot, information on the sample can be used to infer information about the proportion of defectives p in the lot. This inference takes the form of either a single number (a *point estimate*) or a pair of numbers (an *interval estimate*); there are several types of interval estimates, depending on our goals. If we found that 15 of the 100 items in the sample were defective, we would estimate p as being $15/100 = 0.15$ (point estimate); a typical interval would be to state that we are 95 percent confident that p is between 0.08 and 0.22 (confidence interval estimate). Thus a *confidence interval* sets limits on the unknown parameter, here the proportion p. Two other types of intervals often needed are *prediction intervals* and *tolerance intervals*. Let X denote the number of defectives in a future sample; a prediction interval sets limits on X, such as

$$P[L_1 \leq X \leq U_1] = 0.95$$

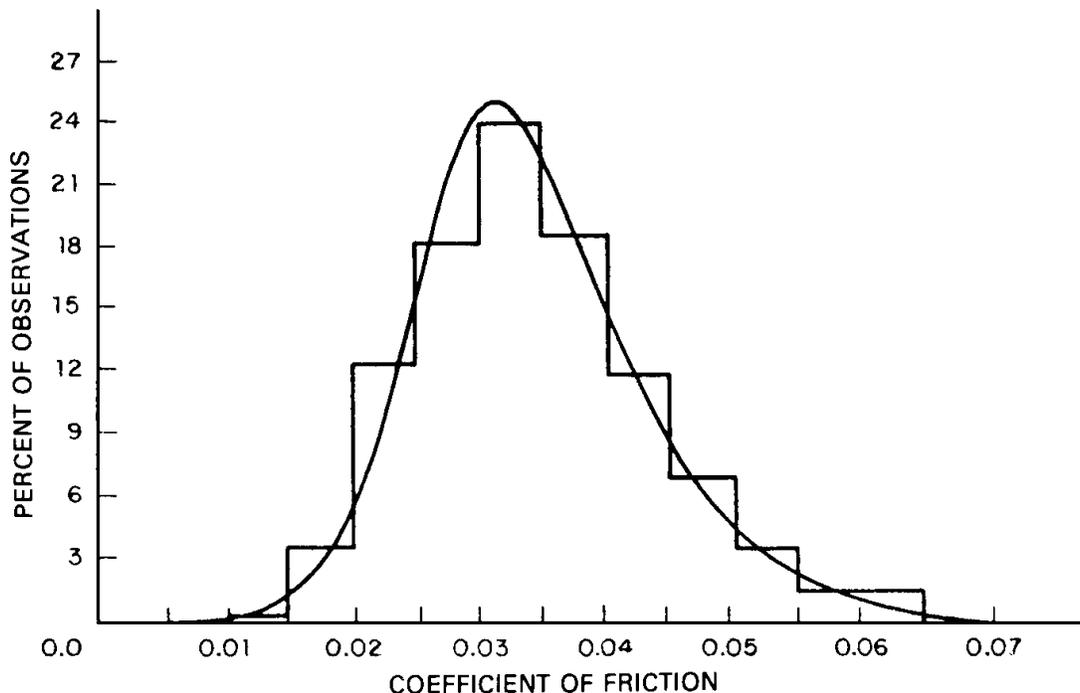
In this example, a *prediction interval* would state that X would be between 5 and 25; these are limits within which one could be 95 percent sure the number of defectives in a future sample of 100 items would lie. A *tolerance interval* sets limits (L, U) such that one can be 95 percent sure that at


FIGURE 44.17 Coefficient of friction relative frequency histogram and the fitted distribution.

least 99 percent of the population will be included within these limits. In this example, the population is all lots of 100 items drawn from the same process; at least 99 percent of the lots will have a proportion of defectives between $L = 0.05$ and $U = 0.25$. These items are discussed in more detail below.

Point Estimates.   Point estimates are customarily the points at which the interval estimates are centered. In many cases, it is preferable to give an interval estimate, since that estimate tells us how much uncertainty is associated with the estimate. For example, if we observe that 15 of 100 items chosen at random from a very large lot are defective, then we will estimate the proportion of defectives in the lot as $15/100 = 0.15$. Similarly, if we observe three defectives in a sample of 20 items, we will estimate the proportion of defectives as $3/20 = 0.15$. However, in the first case the interval estimate (at 95 percent confidence) will be that p is between 0.08 and 0.22, while in the latter case the interval estimate (at 95 percent confidence) will be that p is between 0.00 and 0.31. In either case, if forced to estimate proportion defective in the lot by a single number, that number would be 0.15; however, the uncertainty in that estimate is much greater with the smaller sample size (where as much as 31 percent of the population might be defective) than with the larger sample size (where as much as 22 percent of the population might be defective). The typical point estimates are covered below, as the centers of the respective intervals.

Confidence Interval Estimates.   *Estimation* is the process of analyzing a sample result in order to predict the corresponding value of the population parameter. For example, a sample of 12 insulators has an average impact strength of 4.952 ft·lb (6.7149 N·m). If this is a representative sample from the process, what estimate can be made of the true average impact strength of the entire population of insulators?

1. The *point estimate* is a single value used to estimate the population parameter. For example, 4.952 ft·lb (6.7149 N·m) is the point estimate of the average strength of the population.

2. The *confidence interval* is a range of values that includes (with a preassigned probability called *confidence level*) the true value of a population parameter. *Confidence limits* are the upper and lower boundaries of the confidence interval. Confidence level is the proportion of times in the long run that an assertion about the value of a population parameter is correct.

Duncan (1974) provides a thorough discussion of confidence limits. The explanation here indicates the concept behind the calculations.

If the population mean is μ, the probability that the sample mean will be between

$$\mu \pm 1.96 \frac{\sigma}{\sqrt{n}}$$

is equal to 0.95:

$$P\left(\mu - 1.96 \frac{\sigma}{\sqrt{n}} \leq \overline{X} \leq \mu + 1.96 \frac{\sigma}{\sqrt{n}}\right) = 0.95$$

This is algebraically equivalent to saying that the sample mean plus 1.96 standard deviations of means lies above μ and the sample mean minus 1.96 standard deviations of means lies below μ:

$$P\left(\mu \leq \overline{X} + 1.96 \frac{\sigma}{\sqrt{n}} \text{ and } \overline{X} - 1.96 \frac{\sigma}{\sqrt{n}} \leq \mu\right) = 0.95$$

or

$$P\left(\overline{X} - 1.96 \frac{\sigma}{\sqrt{n}} \leq \mu \leq \overline{X} + 1.96 \frac{\sigma}{\sqrt{n}}\right) = 0.95$$

Or the 95 percent confidence interval on μ is $\overline{X} \pm 1.96\ (\sigma/\sqrt{n})$. Before the sample is taken, this interval has a 0.95 probability of including the population value: 95 percent of the set of such intervals would include the population value. In practice, this is interpreted to mean that there is a 95 percent "confidence" that the limits based on one sample will include the true value.

For the sample of 12 insulators, suppose that $\sigma = 0.25$. Then, the 95 percent confidence limits are

$$\overline{X} \pm 1.96\ \frac{\sigma}{\sqrt{n}} = 4.952 \pm 1.96\ \frac{(0.25)}{\sqrt{12}} = 4.811 \text{ and } 5.093$$

This is interpreted to mean that there is 95 percent confidence that μ is between 4.811 and 5.093. The 95 percent is the confidence level (confidence levels of 90, 95, or 99 percent are usually assumed in practice, and some statisticians call these the "holy" numbers), and 4.811 and 5.093 are the limits of the confidence interval. A confidence level is associated with an assertion based on actual measurements and measures the proportion of times that the assertion will be true in the long run. Confidence limits are limits that include the true value with a preassigned degree of confidence (the confidence level).

Table 44.22 summarizes confidence limit formulas for common parameters. The following examples illustrate some of these formulas.

Example: Sixty-one specimens of brass have a mean hardness of 54.62 and an estimated standard deviation of 5.34. Determine the 95 percent confidence limits on the mean.

Solution:

$$\text{Confidence limits} = \overline{X} \pm t\ \frac{s}{\sqrt{n}}$$

$$= 54.62 \pm 2.00\ \frac{5.34}{\sqrt{61}}$$

$$= 53.25 \text{ and } 55.99$$

There is 95 percent confidence that the true mean hardness of the brass is between 53.25 and 55.99.

Example: A radar system has been operated for 1200 h, during which time eight failures occurred. What are the 90 percent confidence limits on the mean time between failures for the system?

Solution:

$$\text{Estimated } m = \frac{1200}{8} = 150 \text{ h}$$

$$\text{Upper confidence limit} = \frac{2(1200)}{7.962} = 301.4$$

$$\text{Lower confidence limit} = \frac{2(1200)}{26.296} = 91.3$$

There is 90 percent confidence that the true mean time between failures is between 91.3 and 301.4 h. [Epstein (1960) discusses several cases of making estimates from life test data.]

Confusion has arisen on the application of the term *confidence level* to a reliability index such as mean time between failures. Using a different example, suppose the numerical portion of a reliability requirement reads as follows: "The MTBF shall be at least 100 h at the 90 percent confidence level." This means that

1. The minimum MTBF must be 100 h.

TABLE 44.22 Summary of Confidence Limit Formulas and Graphs

Parameters	Formulas
1. Mean of a normal population (standard deviation known)	$\overline{X} \pm K_{\alpha/2} \dfrac{\sigma}{\sqrt{n}}$ where $\overline{X}$ = sample average K = normal distribution coefficient (see Appendix II, Table B) σ = standard deviation of population n = sample size
2. Mean of a normal population (standard deviation unknown)	$\overline{X} \pm t_{\alpha/2} \dfrac{s}{\sqrt{n}}$ where t = Student's distribution coefficient (with n − 1 degrees of freedom) (see Appendix II, Table G) s = estimated σ

3. Standard deviation of a normal population
    a. Using sample standard deviation
    b. Using sample range
	Upper confidence limit = $B_U s$
	Lower confidence limit = $B_L s$
	where B_U and B_L are numerical factors given in Natrella (1963, p. T-34), Dixon and Massey (1969, p. 140)

4. Population fraction defective based on attribute data (fraction defective in sample)	See Appendix II, Chart N
5. Population fraction defective based on variables data ($\overline{X}$ and s in sample)	See Kirkpatrick (1970)
6. Difference between the means of two normal populations (standard deviations σ_1 and σ_2 known)	$(\overline{X}_1 - \overline{X}_2) \pm K_{\alpha/2} \sqrt{\dfrac{\sigma_1^2}{n_1} + \dfrac{\sigma_2^2}{n_2}}$ where K = normal distribution coefficient (see Appendix II, Table B)
7. Difference between the means of two normal populations ($\sigma_1 = \sigma_2$ but unknown)	$(\overline{X}_1 - \overline{X}_2) \pm t_{\alpha/2} \sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}$ $\times \sqrt{\dfrac{\sum (X - \overline{X}_1)^2 + \sum (X - \overline{X}_2)^2}{n_1 + n_2 - 2}}$ where t = Student's distribution coefficient (with degrees of freedom = $n_1 + n_2 - 2$)(see Appendix II, Table G)
8. Difference between the means of two normal populations (σ_1 and σ_2 both unknown)	$(\overline{X}_1 - \overline{X}_2) \pm t_{\alpha/2}^{*} \sqrt{\dfrac{\sum (X - \overline{X}_1)^2}{n_1(n_1 - 1)} + \dfrac{\sum (X - \overline{X}_2)^2}{n_2(n_2 - 1)}}$ where t^{*} = Student's distribution coefficient (with the smaller of $n_1 - 1$ and $n_2 - 1$ as degrees of freedom)

TABLE 44.22 Summary of Confidence Limit Formulas and Graphs (*Continued*)

Parameters	Formulas
9. Mean time between failures (based on an exponential population of time between failures)	Upper confidence limit $= 2T/\chi^2_{\alpha/2}$ Lower confidence limit $= 2T/\chi^2_{1-\alpha/2}$ where $T =$ total test time on all units and DF $= 2r$, where r is a preassigned number of failures and where $\chi^2 =$ chi square distribution coefficient (see Appendix II, Table L)
10. Reliability (based on a Weibull population)	See Thoman, Bain, and Antle (1970)
11. Availability (based on an exponential population of time between failures and log normal population of repair time)	See Gray and Lewis (1967)

2. Actual tests shall be conducted on the product to demonstrate with 90 percent confidence that the 100-h MTBF has been met.

3. The test data shall be analyzed by calculating the observed MTBF and the lower one-sided 90 percent confidence limit on MTBF.

4. The lower one-sided confidence limit must be $\geq$100 h.

The term *confidence level,* from a statistical viewpoint, has great implications on a test program. Note that the observed MTBF must be *greater than* 100 if the lower confidence limit is to be $\geq$ 100. Confidence level means that sufficient tests must be conducted to demonstrate, with statistical validity, that a requirement has been met. Confidence level does *not* refer to the qualitative opinion about meeting a requirement. Also, confidence level does *not* lower a requirement; i.e., a 100-h MTBF at a 90 percent confidence level does not mean that 100 h is desired but that 0.90 $\times$ 100, or 90 h, is acceptable. Such serious misunderstandings have occurred. When the term is used, a clear understanding should be verified and not assumed.

Determination of the Sample Size Required to Achieve a Specified Precision in an Estimate.
Additional tests will increase the precision of the estimates obtained from a test program. The increase in precision usually does not vary linearly with the number of tests—doubling the number of tests usually does not double the precision (even approximately). Further, if the sample is selected randomly and if the sample size is less than 10 percent of the population size, then precision depends primarily on the absolute size of the sample rather than on the sample size expressed as a percentage of the population size. Thus a sample size that is 1 percent of a population of 100,000 may be more precise than a 10 percent sample from a population of 1000 (see Hahn 1972).

The cost of additional tests must be evaluated against the value of the additional precision. Confidence limits can help to determine the size of a test program required to estimate a product characteristic within a specified precision. Suppose it is desired to estimate the true mean life of a battery. The estimate must be within 2.0 h of the true mean if the estimate is to be of any value. The variability is known as $\sigma = 10.0$. A 95 percent confidence level is desired on the confidence statement. The 2.0 h is the desired confidence interval half-width, so

$$2.0 = \frac{(1.96)(10)}{\sqrt{n}} \qquad n = 96$$

A sample of 96 batteries will provide a mean that is within 2.0 h of the true mean (with 95 percent confidence). Notice the type of information required: (1) desired width of the confidence interval

(the precision desired in the estimate), (2) confidence level desired, and (3) variability of the characteristic under investigation. The number of tests required cannot be determined until the engineer furnishes these items of information.

Table 44.23 summarizes formulas and graphs useful in determining the sample size required to estimate a population parameter with a specified precision. The following examples illustrate some of the formulas.

Example: A sample must be selected to estimate the population mean length of a part. It appears reasonable to assume that length is normally distributed. An estimate of the standard deviation is not available, but process knowledge suggests that "almost all" production falls between 2.009 and 2.027 in. As a first approximation, the standard deviation is estimated as $(2.027 - 2.009)$ divided by 6, or 0.003 in. It is desired that the estimate of μ be within 0.001 in of the true μ and that the estimation statement be made at the 95 percent confidence level. Referring to Appendix II, Chart S, $E/s = 0.001/0.003 = 0.33$, and the required sample size is about 37. It is instructive to calculate n for other values of E and s (see Table 44.24). Such a *sensitivity analysis* is helpful in evaluating the cost of extra tests against the value of extra precision.

Example: It is desired to estimate the standard deviation σ of a population within 20 percent of the true value at the 95 percent confidence level. Referring to Appendix II, Chart T, the required degrees of freedom is about 46 and, therefore, the sample size is $46 + 1$, or 47.

TABLE 44.23   Summary of Sample Size Formulas and Graphs

Parameters	Formulas
1. Mean of a normal population (σ known)	$n = \dfrac{K_{\alpha/2}^2 \sigma^2}{E^2}$ where K = normal distribution coefficient E = maximum allowable error in estimate (desired precision)
2. Mean of a normal population (σ estimated)	See Appendix II, Chart S
3. Standard deviation of a normal population	See Appendix II, Chart T
4. Fraction defective of a population	$n \doteq p\,(1 - p)\left(\dfrac{K_{\alpha/2}}{E}\right)^2$ where p = estimate of the population fraction defective. If no estimate of p is available, assume "worst case" of $p = 0.5$

TABLE 44.24   Effect of E and s on n

Maximum error E	Standard deviation s		
	0.002	0.003	0.004
0.0008	27	56	98
0.0010	18	37	64
0.0020	7	12	18

Prediction Intervals.   A prediction interval is used when the desire is not an estimate of population characteristics directly but rather a prediction of what we will find when we take a future item from the population. For example, in the example of $n = 61$ specimens of brass with a mean hardness of 54.62 and an estimated standard deviation of 5.34, we previously found that 95 percent confidence limits on the mean were

$$\overline{X} + t \frac{s}{\sqrt{n}} = 53.25 \text{ and } 55.99$$

Now we ask: What limits can we be 95 percent sure the next item sampled will have its hardness within? The appropriate interval here is

$$\overline{X} + ts \sqrt{1 + \frac{1}{n}} = 54.62 \pm (2.00)(5.34)(1.0082)$$

$$= 43.85 \text{ and } 65.39$$

For further considerations and tables, see Hahn (1970*a*, 1970*b*).

Tolerance Intervals.   *Statistical tolerance limits* are similar to *process capability*; i.e., they show the practical boundaries of process variability (see Section 22, under Operations) and therefore can be a valuable input in the determination of engineering tolerance limits (which specify the allowable limits for product acceptance). Methods for calculating statistical tolerance limits are of two types—those which assume a normal distribution and those which do not require any distributional assumption. Table 44.25 summarizes these methods.

Table 44.26 shows data I will use to illustrate these methods. Five samples of four each were taken and an outside dimension of a cathode pole recorded. A confidence level of 95 percent and a population percentage of 99 percent have been chosen.

Using method 1 and the standard deviation *s,* the statistical tolerance limits are

$$\overline{X} \pm ks = 1.00287 \pm 3.615(0.00034) = 1.00164 \text{ and } 1.00410$$

Using method 2 and the overall range *R* of the combined data, the limits are

$$\overline{X} \pm K_1 R = 1.00287 \pm 1.005(0.00134) = 1.00152 \text{ and } 1.00422$$

Using method 3 and the average of the ranges *R,* the limits are

$$\overline{X} \pm K_2 \overline{R} = 1.00287 \pm 1.783(0.00078) = 1.00148 \text{ and } 1.00426$$

These methods assume that the characteristic is normally distributed. Method 4 is "distribution-free" and assumes only that the distribution is continuous and the sample is a random one (these assumptions apply to all methods). The statistical tolerance limits by this method are simply the extreme observations in the combined sample, i.e., 1.00231 and 1.00365. Appendix II, Table W indicates that at least 78.4 percent of the population will be included within these limits. (Note that Appendix II, Table X provides the sample size required to include 99 percent of the population; i.e., a sample of 473 is needed to be 95 percent confident that the sample extremes would include 99 percent of the population.)

When it is feasible to assume a normal distribution, method 1 is preferred because it usually provides the narrowest set of limits while recognizing the variation in the sample. Methods 2 and 3 are good approximations. If normality cannot be assumed, then method 4 is appropriate but at the cost of a larger sample size. In practice, a partial sample can first be obtained to evaluate the assumption of normality. If normality can be assumed, the partial sample is then used to determine statistical tolerance limits. Otherwise, the full sample should be taken and the distribution-free approach (method 4) applied to determine the limits.

Tolerance intervals also have been developed for other cases, such as where the distribution is exponential. Ranganathan and Kale (1983) give such intervals that are resistant to the presence of an

TABLE 44.25 Methods for Calculating Statistical Tolerance Limits

Method	Distribution assumption	Formula for limits	Source of factor
1. Measure a sample of n items and calculate the average $\overline{X}$ and standard deviation s	Normal	Two-sided limits: $\overline{X} \pm ks$ One-sided limit: $\overline{X} + ks$ or $\overline{X} - ks$	Appendix II, Table V Appendix II, Table V
2. Measure a sample of n items and calculate the average $\overline{X}$ and range R	Normal	Two-sided limits: $\overline{X} \pm K_1 R$	Appendix II, Table U
3. Measure N samples of n items each and calculate the grand average $\overline{\overline{X}}$ and average range $\overline{R}$	Normal	Two-sided limits: $\overline{\overline{X}} \pm K_2 \overline{R}$	Bingham (1962, p. 37)
4. Define the population percentage P which must be included between the tolerance limits. Measure a sample of n and observe the largest and smallest values	None	Two-sided limits: The probability is γ that at least $P\%$ of the population will be between the sample extremes. One-sided limit: The probability is γ that at least $P\%$ of the population will be less than the largest value in the sample (or greater than the smallest value).	Appendix II, Table W Natrella (1963, p. T-76)

TABLE 44.26 Data on Cathode Pole Dimension

	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5	
	1.00263	1.00306	1.00293	1.00291	1.00310	
	1.00298	1.00328	1.00343	1.00247	1.00281	$\overline{X} = 1.00287$
	1.00293	1.00274	1.00239	1.00268	1.00256	$s = 0.00034$ (standard deviation of the
	1.00285	1.00303	1.00274	1.00365	1.00231	20 observations about $\overline{X}$)
$\overline{X}$	1.00285	1.00303	1.00287	1.00293	1.00269	$\overline{R} = 0.00078$
R	0.00035	0.00054	0.00104	0.00118	0.00079	$R = 0.00134$

44.49

outlier in the observations. Their Section 5 includes an example with data on reliability of air conditioning on a Boeing 727 jet aircraft.

All the preceding methods involve two probabilities, i.e., a confidence level γ and the probability P of falling within limits. This is confusing, but these two probabilities are needed to obtain a mathematically correct statement concerning the limits. An approximation uses the sample average $\overline{X}$ and standard deviation s and regards these as highly reliable estimates of μ and σ. If normality is assumed, then 99 percent statistical tolerance limits are calculated as

$$\overline{X} \pm 2.58s$$

where the value of 2.58 is obtained from the normal distribution table (Appendix II, Table B):

$$\overline{X} \pm 2.58 = 1.00287 \pm 2.58 \, (0.000274)$$

$$= 1.00216 \text{ and } 1.00358$$

These limits are then interpreted to mean that 99 percent of the population is within 1.00217 and 1.00357. Another approach sets the limits at simply $\overline{X} \pm 3s$. At best, these are only approximate because $\overline{X}$ and s are not exactly equal to μ and σ. Bingham (1962) discusses the $X \pm 3s$ approximation. (Confidence limit calculations could indicate the size of the possible error.)

Another approach to simplify the probability statement uses the Chebyshev inequality theorem, which holds for any continuous distribution. The theorem states that the probability of obtaining a value that deviates from μ by more than k standard deviations is less than $1/k^2$. For the limits to include 99 percent,

$$0.01 = \frac{1}{k^2}$$

or

$$k = 10$$

The 99 percent limits would be calculated at $\overline{X} \pm 10s$. These limits are distribution-free, and the prediction statement is simple; i.e., at least 99 percent of the population is within $\overline{X} \pm 10s$. However, the multiple of 10 is highly conservative and results in limits much wider than any of the other methods.

For the methods listed in Table 44.25, no provision is made for the division of the remaining $100(1 - P)$ percent between the upper and lower tails of the distribution. Owen and Frawley (1971) give a procedure and tables for setting limits that do provide for controlling the percentage outside each of the two limits.

Statistical tolerance limits are sometimes confused with other limits used in engineering and statistics. Table 44.27 summarizes the distinctions among five types of limits. Hahn (1970*a*, 1970*b*) gives an excellent discussion with examples and tables to illustrate the differences among several types of limits. Also see Harter (1983), under "Tolerance Limits."

Tolerance Limits for Interacting Dimensions.   *Interacting dimensions* are those which mate or merge with other dimensions to create a final result. Setting tolerance limits on such dimensions is discussed in the following paragraphs. Setting tolerance limits on noninteracting dimensions makes use of the methods presented under Statistical Tolerance Limits in this section.

Conventional Method Relating Tolerances on Interacting Dimensions.   Consider the simple mechanical assembly shown in Figure 44.18. The lengths of components *A, B,* and *C* are interacting dimensions because they determine the overall assembly length.

The conventional method of relating interacting dimensions is simple addition. For the example of Figure 44.18,

$$\text{Nominal value of the result} = \text{nominal value}_A + \text{nominal value}_B + \text{nominal value}_C$$

TABLE 44.27 Distinction among Limits

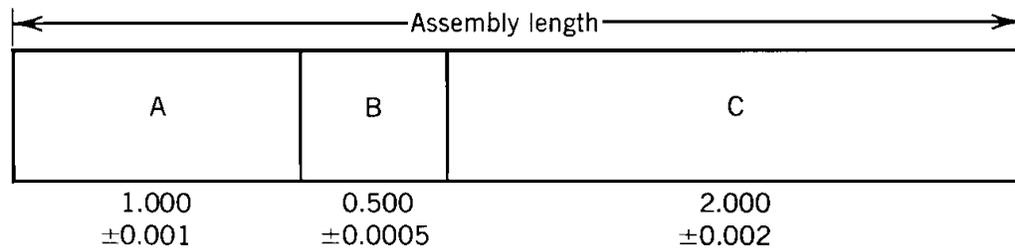
Name of limits	Meaning
Tolerance limits	Set by the engineering design function to define the minimum and maximum values allowable for the product to work properly.
Statistical tolerance limits	Calculated from process data to define the amount of variation that the process exhibits. These limits will contain a specified proportion of the total population.
Prediction limits	Calculated from process data to define the limits which will contain all of k future observations.
Confidence limits	Calculated from data to define an interval within which a population parameter lies.
Control limits	Calculated from process data to define the limits of chance (random) variation around some central value.


FIGURE 44.18 Mechanical assembly.

Tolerance T of the result $= T_A + T_B + T_C$

Nominal value of assembly length $= 1.000 + 0.500 + 2.000 = 3.500$

Tolerance of assembly length $= 0.0010 + 0.0005 + 0.0020 = \pm 0.0035$

This method assumes 100 percent interchangeability of components making up the assembly. If the component tolerances are met, then all assemblies will meet the assembly tolerance determined by the simple arithmetic addition.

The approach of adding component tolerances is mathematically correct but often too conservative. Suppose that about 1 percent of the pieces of component A are expected to be below the lower tolerance limit for component A, and suppose the same for components B and C. If a component A is selected at random, there is, on average, 1 chance in 100 that it will be on the low side, and similarly for components B and C. The key point is this: If assemblies are made at random, and if the components are manufactured independently, then the chance that an assembly will have all three components simultaneously below the lower tolerance limit is

$$\frac{1}{100} \times \frac{1}{100} \times \frac{1}{100} = \frac{1}{1,000,000}$$

There is only about one chance in a million that all three components will be too small, resulting in a small assembly. Thus, setting component and assembly tolerances based on the simple addition formula is conservative in that it fails to recognize the extremely low probability of an assembly containing all low (or all high) components.

Statistical Method of Relating Tolerances on Interacting Dimensions. This method states for the example Figure 44.18:

$$\text{Nominal value of the result} = \text{nominal value}_A + \text{nominal value}_B + \text{nominal value}_C$$

$$\text{Tolerance of the result} = \sqrt{T_A^2 + T_B^2 + T_C^2}$$

Then:

$$\text{Nominal value of the assembly} = 1.000 + 0.500 + 2.000 = 3.500$$

$$T \text{ of the assembly} = \sqrt{(0.001)^2 + (0.0005)^2 + (0.002)^2} = \pm 0.0023$$

Practically all (but not 100 percent) of the assemblies will fall within 3.500 ± 0.0023. This is narrower than 3.500 ± 0.0035 (the result by the arithmetic method).

In practice, the problem often is to start with a defined end result (e.g., assembly length specification) and set tolerances on the parts. Suppose the assembly tolerance was desired to be ± 0.0035. Listed in Table 44.28 are two possible sets of component tolerances that when used with the quadratic formula will yield an assembly tolerance equal to ± 0.0035. The tolerance set using the conventional formula is also shown.

The advantage of the statistical formula is larger component tolerances. With alternative 1, the tolerance for component A has been doubled, the tolerance for component B has been quadrupled, and the tolerance for component C has been kept the same as the original component based on the simple addition approach. If alternative 2 is chosen, similar significant increases in the component tolerances may be achieved. This formula, then, may result in a larger component tolerance with no change in the manufacturing processes and no change in the assembly tolerance. Note that the *largest single* tolerance has the greatest effect on the overall result.

The disadvantage of the quadratic formula is that it involves several assumptions that, even if met, will still result in a small percent (theoretically 0.27 percent) of results not conforming to the limits set by the formula. The assumptions are

1. The component dimensions are independent and the components are assembled randomly. This assumption is usually met in practice.
2. Each component dimension should be normally distributed. Some departure from this assumption is permissible.
3. The actual average for each component is equal to the nominal value stated in the specification. For the original assembly example, the actual averages for components A, B, and C must be 1.000, 0.500, and 2.000, respectively. Otherwise, the nominal value of 3.500 will not be achieved for the assembly, and tolerance limits set about 3.500 will not be realistic. Thus it is important to control the *average* value for interacting dimensions. This means that process control techniques are needed using variables measurement rather than go no-go measurement.

A summary of the two methods of tolerance is given in Table 44.29.

The statistical tolerancing formula applies both to assemblies made up of physically separate components and to a chain of several interacting dimensions within one physical item. Further, the result of the interacting dimensions can be an outside dimension (assembly length) or an internal result (clearance between a shaft and hole).

TABLE 44.28   Comparison of Statistical and Conventional Methods

Component	Statistical		Conventional
	Alternative 1	Alternative 2	
A	± 0.002	± 0.001	± 0.0010
B	± 0.002	± 0.001	± 0.0005
C	± 0.002	± 0.003	± 0.0020

TABLE 44.29 Comparison of Conventional and Statistical Tolerancing

Factor	Conventional	Statistical
Risk of items not interacting properly	No risk; 100% interchangeability of items	Small percent of final results will fall outside limits (but these can sometimes be corrected with selective assembly)
Utilization of full tolerance range	Method is conservative; tolerances on interacting dimensions are smaller than necessary	Permits larger tolerances on interacting dimensions
Special process control techniques	None	Average of each interacting dimension must be controlled using variables measurement
Statistical assumptions	None	Interacting dimensions must be independent and each must be normally distributed
Lot size for components	Any size	Lot size should be moderately large (to assure balancing effect on extreme interacting dimensions)

Further Applications of Statistical Tolerancing.   It is easy to be deceived into concluding that the statistical method of tolerancing is merely a change from an expression of tolerances in the form of limits on each component to a form of

1. Upper and lower limits on the average $\overline{X}$ of the mass of components
2. An upper limit to the scatter σ of the components

The change is much more profound than mere form of the specification. It affects the entire cycle of manufacturing planning, production, inspection, quality control, service, etc. It is, in effect, *a new philosophy of manufacture.*

The first published example of a *large-scale application* of statistical tolerancing appears to be that of the L-3 coaxial system (a broad-band transmission system for multiple telephone or television channels). Dodge et al. (1953) discuss the application.

The general plan was

1. Discovery of the key quality characteristics of each component element of the system.
2. Determination of the precision of measurement to separate measurement variability from process and product variability.
3. Collection of data on process capability for the key qualities, to aid in establishing realistic tolerances.

The foregoing were preliminary to

4. Establishment of tolerances for the key quality characteristics in the dual form of a maximum on the standard deviation σ and limits on the average $\overline{X}$. The limits on X were established as $\pm(^1/_3)\sigma$ around the nominal.
5. Establishment of control procedures.

It was recognized that the limits on σ and $\overline{X}$ required further interpretation if the intent of the designers was to be carried out by the manufacturers. To this end, three forms of product acceptance were established:

1. *Control charts.*   Shewhart control charts for $\overline{X}$ and σ could be used for product acceptance, provided "eligibility" was established (seven consecutive subgroups, of five pieces each, all met the control limits for $\overline{X}$ and σ) and provided subsequent statistical control was maintained (based on chart results plus absence of major changes in process).

2. *Batch control.*   This was based on examination of a sample of (normally) 50 pieces by variables measurements, with limits on $\overline{X}$ and σ appropriate to the sample size of 50. Each batch stood or fell on its own measurements.

3. *Detailed classification.*   Product that did not qualify under 1 or 2 was measured in detail. The resulting conforming units were classified into one of three variable classes. The packaging was then done by selecting classified units in such a way that each package contained an assortment of product which conformed to the intent of the design as to $\overline{X}$ and σ.

Grant and Leavenworth (1980) discuss statistical tolerancing, including an application to shafts and holes. The Western Electric Company, Inc. (1982), in its *Statistical Quality Control Handbook* (pp. 122–127), presents examples and discusses the assumptions. Peters (1970) discusses statistical tolerancing, including a method for recognizing cost differences among components. Choksi (1971) discusses the use of computer simulation to determine optimum tolerances.

The concept may be applied to several interacting variables in an engineering relationship. The nature of the relationship need *not* be additive (assembly example) or subtractive (shaft and hole example). The formula can be adapted to predict the variation of results that are the product and/or the division of several variables. Mouradian (1966) discusses these applications.

Bayesian Estimates.   Bayesian estimation can be used when the parameter to be estimated can be considered to be a random variable for which we know the distribution. For example, in sampling inspection, the proportion of defectives p in a lot may be a random variable about which we can fit a distribution by our sampling inspection over time. If so, then in the future that information can be used to provide quality assurance with less sampling (see Lenz and Rendtel 1984).

When it is not possible to cumulate information about a stable process, some have proposed that we use our "feelings" about the parameter to choose a statistical distribution for it and then proceed as if the parameter were a random variable with that distribution. This is called the *personal probability approach,* and those who use it are called *Bayesians.* Some of the proponents of this approach say that it is the only method that any sensible person should use, and this has been cause for bitter debates and ill-will. In my view, while a person in a management position might find this a reasonable way to express his or her insights quantitatively, in most cases this will be an unscientific way of simply incorporating prejudices into the decision process, resulting in costly errors. This approach is of some use in general statistical decision theory (see Chapter 12 of Dudewicz 1976), but there it is used to generate a set of decision rules that contains all good rules, not just one rule based on one's "feelings." The Bayesian approach should be considered whenever information can be gathered over time on a stable process.

Intervals with Fixed Width and Precision.   The intervals considered up to now typically either had a random width (e.g., parts 7 and 8 of Table 44.22) or required that one know such parameters as variances (e.g., part 6 of Table 44.22). If one can take observations in two stages, then one can control both the width and the confidence. Let me illustrate for two normal means when we do not know the variances (and do not know that they are equal). Here we can proceed in two stages as follows:

Sample n_0 observations from each of $k = 2$ populations (n_0 at least 10 is desirable).

Determine the total sample size for population i as

$$n_i = max \, [n_0 + 1, \, (ws_i)^2] \qquad \text{with } w = h_{n_0} \, (2, \, (1 + P^*)/2)/d$$

where h is from Table 44.30, d is the desired half-width, $k = 2$ populations, and P^* is the confidence desired.

TABLE 44.30 Multipliers $h=h_{n_0}$ $(k, P*)$ Needed for Solving Two-Stage Testing, Confidence Interval, and Selection of the Best Problems*

*The table entries are from Table 4 on pp. 17–23 of "New Tables for Multiple Comparisons with a Control (Unknown Variances)," by E. J. Dudewicz, J. S. Ramberg, and H. J. Chen, *Biometrische Zeitschrift,* vol. 17 (1975), pp. 13–26. Reprinted with the permission of Akademie-Verlag, Berlin.

Take $n_1 - n_0$ more observations on population 1 and $n_2 - n_0$ more on population 2.

Compute the sample means $\overline{X}_1$ of n_1 observations, and $\overline{X}_2$ of n_2 observations and the interval is $\overline{X}_1 - \overline{X}_2 \pm d$ (i.e., we are $100P*$ percent sure that the difference of the population means is within d units of the difference of the sample means). For an example of the calculations involved, see Example of Selection of the Best below.

STATISTICAL TESTS OF HYPOTHESES

A *statistical hypothesis* is an assertion about a population, often about some parameter of a population. *Tests of hypotheses* (also called *tests of significance*) were designed so that experimenters would not ascribe causes to variations in data that were in fact due simply to random variation (and thus did not need a cause to explain them). Thus statistical hypothesis testing is a modern-day version of the medieval Occam's razor principle that "one should not multiply causes without reason." (William of Occam was an English Franciscan philosopher who died about 1349.) For example, if a process has a mean weight of 14.90 lb per item produced, a change is made with a view to increasing the weight per item produced, and a sample of 10 items (taken after the process change) has a mean weight of 15.10 lb, this *does not* necessarily mean that the process mean has been shifted up: It could be that it has remained the same (or has even decreased) and that we are simply seeing the results of the randomness of the process. Making correct inferences in the face of such possibilities is the gist of the area of hypothesis testing.

Basic Concepts, Types of Errors.   *Hypothesis* as used here is an assertion made about a population. Usually the assertion concerns the numerical value of some parameter of the population. For example, a hypothesis might state that the mean life of a population of batteries equals 30.0, written as H:$\mu_0 = 30.0$. This assertion may or may not be correct. A *hypothesis test* is a test of the validity of the assertion and is carried out by analysis of a sample of data.

There are two reasons why sample results must be evaluated carefully. First, there are many other samples that, by chance alone, could be drawn from the population. Second, the numerical results in the sample actually selected can easily be compatible with several different hypotheses. These points are handled by recognizing two types of error which can be made in evaluating a hypothesis:

1. *Reject* the hypothesis when it is *true*. This is called the *type 1 error*; its probability is called the *level of significance* and is denoted by α.

2. *Accept* the hypothesis when it is *false*. This is called the *type II error*; its probability is usually denoted by β (though some authors call it $1-\beta$).

These error probabilities can be controlled to desired values.

The type I error is shown graphically in Figure 44.19 for the hypothesis H:$\mu_0 = 30.0$. The area between the vertical lines represents the *acceptance region* for the hypothesis test: If the sample result falls within the acceptance region, the hypothesis is accepted. Otherwise, it is rejected. Notice that there is a small portion of the curve that falls outside the acceptance region. This portion (α) represents the probability of obtaining a sample result outside the acceptance region, even though the hypothesis is correct.

Suppose it has been decided that the type I error must not exceed 5 percent. This is the probability of rejecting the hypothesis when, in truth, the true average life is 30.0. The acceptance region can be obtained by locating values of average life that have only a 5 percent chance of being exceeded when the true average life is 30.0. Further, suppose a sample n of four measurements is taken and $\sigma = 10.0$.

Remember that the curve represents a population of sample averages because the decision will be made on the basis of a sample average. Sample averages vary less than individual measurements according to the relationship $\sigma_{\overline{X}} = \sigma/\sqrt{n}$.

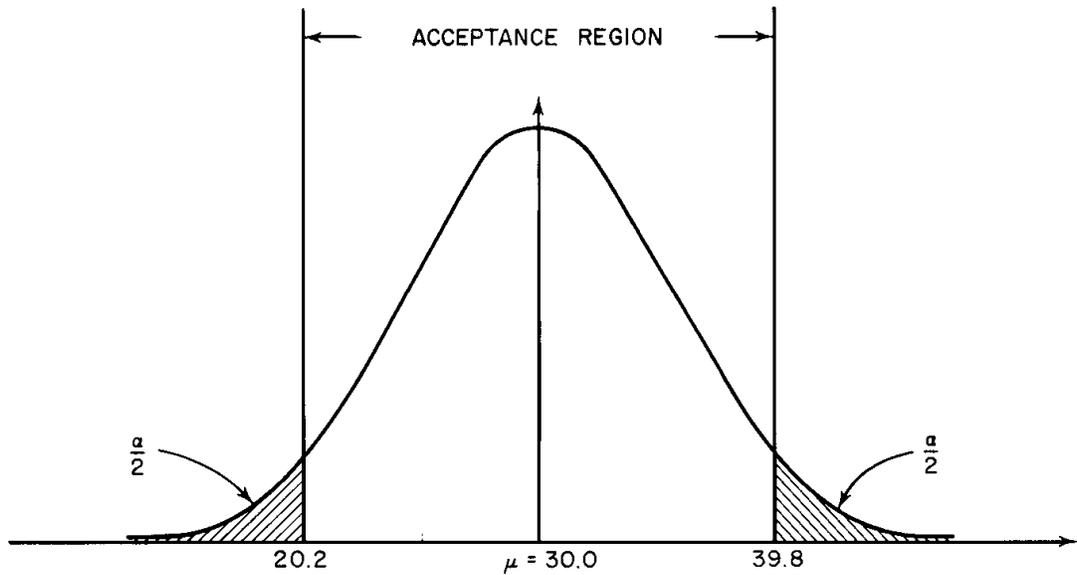
Further, the distribution of sample averages is approximately normal even if the distribution of the individual measurements (going into the averages) is not normal [see Grant and Leavenworth


FIGURE 44.19   Acceptance region for H:μ_0 = 30.0.

(1972, pp. 69–71)]. The approximation holds best for large values of *n* but is adequate for *n* as low as 4.

Table B in Appendix II shows that a 2.5 percent area in each tail is at a limit that is 1.96 standard deviations from 30.0. Then under the hypothesis that μ_0 = 30.0, 95 percent of sample averages will fall within ±1.96$\sigma_{\bar{x}}$ of 30.0, or

$$\text{Upper limit} = 30.0 + 1.96\,\frac{10}{\sqrt{4}} = 39.8$$

$$\text{Lower limit} = 30.0 - 1.96\,\frac{10}{\sqrt{4}} = 20.2$$

The acceptance region is thereby defined as 20.2 to 39.8. If the average of a random sample of four batteries is within this acceptance region, the hypothesis is accepted. If the average falls outside the acceptance region, the hypothesis is rejected. This decision rule provides a type I error of 0.05.

The type II or β error, the probability of accepting a hypothesis when it is false, is shown in Figure 44.20 as the shaded area. Notice that it is possible to obtain a sample result within the acceptance region, even though the population has a true average that is not equal to the average stated in the hypothesis. The numerical value of β depends on the true value of the population average (and also on *n,* σ, and α). This is depicted by an *operating characteristic (OC) curve.*

The problem now is to construct an operating characteristic curve to assess the magnitude of the type II (β) error. Since β is the probability of *accepting* the original hypothesis (μ_0 = 30.0) when it is *false,* the probability that a sample average will fall between 20.2 and 39.8 must be found when the true average of the population is something other than 30.0. This has been done for many values of the true average, and the result is shown in Figure 44.21. [This curve should not be confused with that of a normal distribution of measurements. In some cases the shape is similar, but the meanings of an OC curve and a distribution curve are entirely different; Juran and Gryna (1980, pp. 410–412) give the detailed calculations; also see Dudewicz (1976, pp. 272–275).] Thus the OC curve is a plot of the probability of accepting the original hypothesis as a function of the true value of the population parameter (and the given values of *n,* σ, and α).

Use of the Operating Characteristic Curve in Selecting an Acceptance Region.

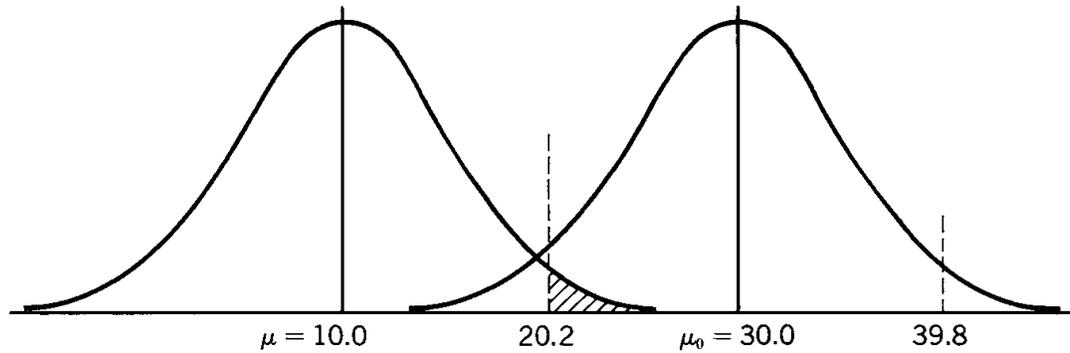
The acceptance region was determined by dividing the 5 percent allowable α error into equal parts


FIGURE 44.20   Type II or β error.
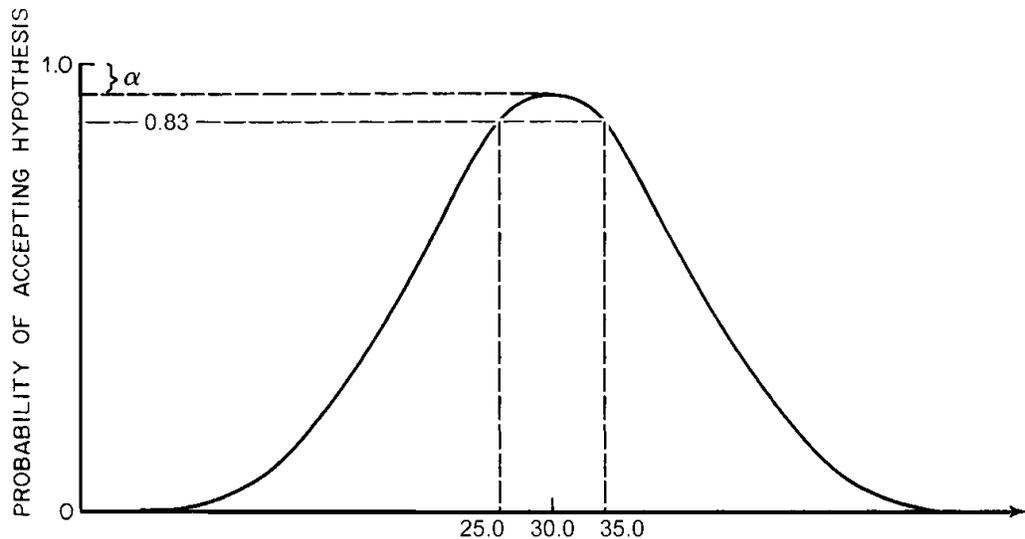

FIGURE 44.21   Operating characteristic curve.

(see Figure 44.19). This is called a *two-tailed test.* The entire 5 percent also could be placed at either the left or the right tail of the distribution curve (Figure 44.22). These are *one-tailed tests.*

Operating characteristic curves for tests having these one-tailed acceptance regions can be developed following the approach used for the two-tailed region. Although the α error is the same, the β error varies for the three tests. (See Figure 9.2-2 on p. 275 of Dudewicz 1976.)

In some problems, knowledge is available to indicate that if the true average of the population is *not* equal to the hypothesis value, then it is on one side of the hypothesis value. For example, a new material of supposedly higher average strength will have an average equal to or *greater than* that of the present material. Such information will help select a one-tailed or two-tailed test to make the β error as small as possible. The following guidelines are based on the analysis of OC curves:

Use a one-tailed test with the entire α risk in the right tail if (1) it is known that (if μ_0 is not true) the true mean is $>\mu_0$ or (2) values of the population mean $<\mu_0$ are acceptable and we are interested only in detecting a population mean $>\mu_0$. [Use a one-tailed test with the entire α risk in the left tail if (1) it is known that (if μ_0 is not true) the true mean is $<\mu_0$ or (2) values of the population mean $>\mu_0$ are acceptable and we are interested only in detecting a population mean $<\mu_0$.]

Use a two-tailed test if (1) there is no prior knowledge on the location of the true population mean or (2) we are interested in detecting a true population mean $<$ or $>$ the μ_0 stated in the original hypothesis. (With a two-tailed test, the hypothesis is sometimes stated as the original hypothesis $H_0: \mu_0 = 30.0$ against the alternative hypothesis $H_1: \mu_0 \neq 30.0$. With a one-tailed test, $H_0: \mu_0 = 30.0$ against the alternative $H_1: \mu_1 < 30.0$ if α is placed in the left tail or $H_1: \mu_1 > 30.0$ if α is placed in the right tail.)

Every test of hypothesis has an OC curve. Duncan (1974) and Natrella (1963) are good sources of OC curves. [Some references present "power" curves, but power is simply $1 -$ (the probability of acceptance) $= 1 - \beta$.]

With this background, our discussion now proceeds to the steps for testing a hypothesis.

Testing a Hypothesis When the Sample Size Is Fixed in Advance.   Ideally, desired values for the type I and type II errors are defined in advance and the required sample size determined (see later discussion on Determining the Sample Size Required for Testing a Hypothesis). If the sample size is fixed in advance because of cost or time limitations, then usually the desired type I error is defined and the following procedure is followed:

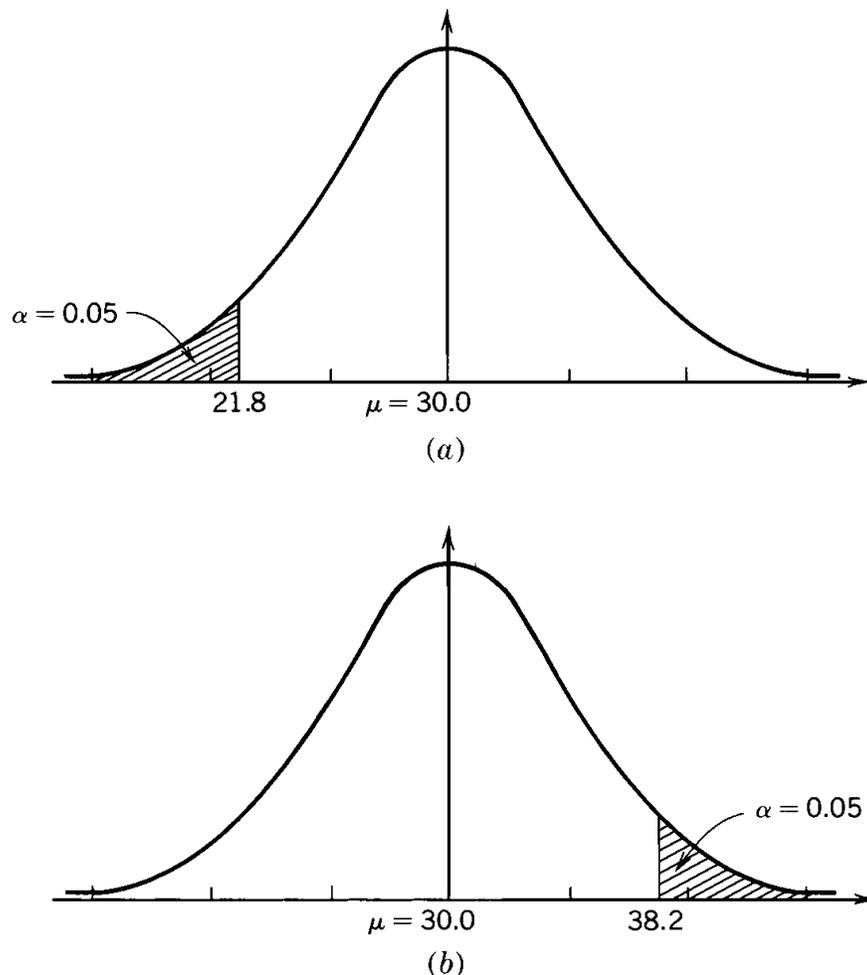
1. State the hypothesis.
2. Choose the type I error. Common values are 0.01, 0.05, or 0.10.
3. Choose the test statistic for testing the hypothesis.
4. Determine the acceptance region for the test, i.e., the range of values of the test statistic that result in a decision to accept the hypothesis.
5. Obtain the sample of observations, compute the test statistic, and compare the value to the acceptance region to make a decision to accept or reject the hypothesis.
6. Draw an engineering conclusion.


FIGURE 44.22   (*a*) Entire 5 percent error on left tail. (*b*) Entire 5 percent on right tail.

In the case of fixed sample size, the hypothesis is said to be "accepted" in the sense that there is insufficient evidence for the hypothesis to be rejected. However, this does not mean that the hypothesis is true. (See the introductory paragraph of Statistical Tests of Hypotheses above and Drawing Conclusions from Tests of Hypotheses below.) For this reason, one often uses the terminology "fail to reject" rather than "accept."

Table 44.31 summarizes some common tests of hypotheses. [These are tests commonly mentioned in the literature and used in practice. A number of them assume a normal distribution, Harter and Dubey (1967) define tests for the mean and variance but assuming a Weibull distribution—which really covers a family of distributions.] The procedure is illustrated through the following examples. Further examples and elaboration of the procedure are provided in Dixon and Massey (1969), Johnson and Leone (1964), Duncan (1974), Dudewicz (1976), and Natrella (1963). Table 44.31 lists a few unique or additional references for certain tests. For nonparametric tests, see especially Gibbons (1997).

Example: Tests on eight units of an experimental engine showed that they operated, respectively, for 28, 26, 31, 29, 25, 27, 28, and 27 min with 1 liter of a certain kind of fuel. A proposed specification states that the engine must operate for an average of at least 30 min. Does the engine meet the requirement? Assume a 5 percent significance level.

Solution: Using Test 1*b* of Table 44.31,

$$H_0: \quad \mu = 30.0$$

$$H_1: \quad \mu < 30.0$$

Test statistic:

$$t_1 = \frac{\overline{X} - \mu_0}{s/\sqrt{n}}$$

Acceptance region:

$$\text{Degrees of freedom DF} = 8 - 1 = 7$$

$$t \geq -1.895$$

A mathematical derivation of *degrees of freedom* is beyond the scope of this handbook, but the underlying concept can be stated. *Degrees of freedom* is a measure of the assurance involved when a sample standard deviation is used to estimate the true standard deviation of a universe. When the true standard deviation is known, DF = ∞. More generally, DF equals the number of measurements used to determine the sample standard deviation minus the number of constants estimated from the data in order to compute the standard deviation. In this example, it was necessary to estimate only one constant (the sample average) in order to compute the standard deviation, therefore DF = 8 − 1.

Analysis:

$$\overline{X} = 27.6 \qquad s = 1.86$$

$$t = \frac{27.6 - 30.0}{\dfrac{1.86}{\sqrt{8}}} = -3.65$$

Conclusion: Reject the hypothesis. There is sufficient evidence to conclude that the engine does not meet the requirement.

TABLE 44.31 Summary Table of Tests of Hypotheses

Test statistic and its distribution	Assumptions	Remarks
Test 1. The mean of a population is equal to μ_0 (H:$\mu = \mu_0$).		
(a) $U = \dfrac{\overline{X} - \mu_0}{\sigma/\sqrt{n}}$ Normal distribution (Appendix II, Table B)	X is distribution-free but should be continuous and have only one mode.	Standard deviation of population is known.
(b) $t = \dfrac{\overline{X} - \mu_0}{s/\sqrt{n}}$ t distribution with DF $= n - 1$ (Appendix II, Table G)	X is normally distributed.	Standard deviation of population is estimated by sample s.
(c) $\tau_1 = \dfrac{\overline{X} - \mu_0}{R}$ τ_1 distribution (Appendix II, Table H)	X is normally distributed.	Dispersion of the population is estimated from sample range.
(d) r = number of occurrences of less frequent sign for a two-tail test (or number of positive or negative signs for a one-tail test) Distribution of r (Appendix II, Table I)	Distribution-free but population should be continuous and symmetrical.	Data are analyzed by evaluating signs of $(X_i - \mu_0)$. (This is a "sign" test; see Gibbons, 1997, p. 112.)

TABLE 44.31 Summary Table of Tests of Hypotheses (*Continued*)

Test statistic and its distribution	Assumptions	Remarks
Test 2. The means of two populations are equal (H:$\mu_1 = \mu_2$).		
(a) $U = \dfrac{\overline{X}_1 - \overline{X}_2}{\sqrt{\sigma_1^2/n_1 + \sigma_2^2/n_2}}$ Normal distribution (Appendix II, Table B)	X_1 and X_2 are distribution-free but should be continuous and have only one mode. If the populations are not normally distributed, sample sizes n_1 and n_2 should be large so that sampling distribution of U is approximately normal.	Standard deviations of populations are known.
(b) $t = \dfrac{\overline{X}_1 - \overline{X}_2}{\sqrt{\dfrac{1}{n_1} + \dfrac{1}{n_2}}\sqrt{\dfrac{[(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2]}{n_1 + n_2 - 2}}}$ t distribution with DF $= n_1 + n_2 - 2$ (Appendix II, Table G)	$\sigma_1 = \sigma_2$. X_1 and X_2 are normally distributed.	Standard deviations of populations are estimated by sample s_1 and s_2.
(c) $\tau_d = \dfrac{\overline{X}_1 - \overline{X}_2}{0.5(R_1 + R_2)}$ Distribution of τ_d (Appendix II, Table J)	X_1 and X_2 are normally distributed.	Dispersions of populations are estimated by sample ranges.

44.64

TABLE 44.31 Summary Table of Tests of Hypotheses *(Continued)*

Test statistic and its distribution	Assumptions	Remarks
Test 2. The means of two populations are equal ($H: \mu_1 = \mu_2$).		
(d) $t' = \dfrac{\bar{X}_1 - \bar{X}_2}{\sqrt{s_1^2/n_1 + s_2^2/n_2}}$ t distribution with DF = $\min(n_1 - 1, n_2 - 1)$ (Appendix II, Table G)	X_1 and X_2 are normally distributed.	Standard deviations of populations are estimated by sample s_1 and s_2 (no assumption that $\sigma_1 = \sigma_2$).
(e) $t = \dfrac{\bar{d}}{s_d/\sqrt{n}}$ t distribution with DF = number of pairs − 1 (Appendix II, Table G)	Populations are normally distributed.	Data are taken in n pairs, and difference d within each pair is calculated.
(f) r = number of occurrences of less frequent sign for a two-tail test (or number of positive or negative signs for a one-tail test) Distribution of r (Appendix II, Table I)	n_1 and n_2 each ≥ 6. Populations must be continuous and symmetrical; each of the two observations in a pair has been obtained under similar conditions.	Data are analyzed by evaluating signs of ($X_1 - X_2$). (This is a "sign" test.) Distribution of r (Appendix II, Table I)
Test 3. Two characteristics on one product have specified population means ($H: \mu_X = \mu_{X_0}$ and $\mu_Y = \mu_{Y_0}$) (Johnson and Leone, 1964).		
$T^2 = \dfrac{s_Y^2}{s_X^2 s_Y^2 - s_{XY}}(X - \mu_{X_0})^2 - \dfrac{2s_{XY}}{s_X^2 s_Y^2 - s_{XY}} \cdot$ $(X - \mu_{X_0})(Y - \mu_{Y_0}) + \dfrac{s_X^2}{s_X^2 s_Y^2 - s_{XY}}(Y - \mu_{Y_0})^2$ where $s_{XY} = \dfrac{n\Sigma(XY) - \Sigma X\Sigma Y}{n(n-1)}$ where critical value for $T^2 = \dfrac{2(n-1)F}{n-2}$ and where the F distribution has $DF_1 = 2$; $DF_2 = n - 2$ (Appendix II, Table K)	Bivariate normal distribution.	Population standard deviations are estimated by s_X and s_Y (T^2 is called Hotelling's T^2).

TABLE 44.31 Summary Table of Tests of Hypotheses (*Continued*)

Test statistic and its distribution	Assumptions	Remarks
Test 4. The standard deviation of a population is equal to σ_0 (H:$\sigma = \sigma_0$).		
$\chi^2 = \dfrac{(n-1)s^2}{\sigma_0^2}$ Chi-square distribution with DF $= n - 1$ (Appendix II, Table L)	Population is normally distributed.	Standard deviation of population is estimated by sample s.
Test 5. The standard deviations of two populations are equal (H:$\sigma_1^2 = \sigma_2^2$).		
$(a)\ F = \dfrac{s_1^2}{s_2^2}$ F distribution with DF$_1 = n_1 - 1$ and DF$_2 = n_2 - 1$ (Appendix II, Table K)	Populations are normally distributed.	Standard deviations of populations are estimated by sample s_1 and s_2.
$(b)\ F' = \dfrac{R_1}{R_2}$ Distribution of F' (Appendix II, Table M)	Distribution-free but X_1 and X_2 should be continuous.	Dispersions of populations are estimated by sample ranges.
Test 6. The proportion of a population exhibiting a certain characteristic is p_0 (H:$p = p_0$).		
$(a)\ U = \dfrac{X - np_0}{\sqrt{np_0(1 - p_0)}}$ Normal distribution (Appendix II, Table B)	$n \geq 100$. Only for large sample sizes.	Proportion of population is estimated by sample proportion.
(b) Determine confidence limits (Appendix II, Table N) and observe if p_0 falls within the limits		Proportion of population is estimated by sample proportion (useful when $n < 100$).

TABLE 44.31 Summary Table of Tests of Hypotheses *(Continued)*

Test statistic and its distribution	Assumptions	Remarks

Test 7. The proportions in two populations are equal ($H: p_1 = p_2$).

Test statistic and its distribution	Assumptions	Remarks
$U = \dfrac{X_1/n_1 - X_2/n_2}{\sqrt{\hat{p}(1-\hat{p})(1/n_1 + 1/n_2)}}$ where $\hat{p} = \dfrac{X_1 + X_2}{n_1 + n_2}$ Normal distribution (Appendix II, Table B)	$np > 5$ for each population. Sample sizes n_1 and n_2 must be large so that sampling distribution of U is approximately normal.	Proportions in populations are estimated by sample proportions.

Test 8. Proportion of correct decisions on a sensory evaluation is p_0 ($H: p = p_0$).

Test statistic and its distribution	Assumptions	Remarks
(a) $U = \dfrac{X/n - 0.50}{\sqrt{0.25/n}}$ Normal distribution (Appendix II, Table B)	$p = 0.5$, n should be $>$ 30.	Judge is asked to identify which of two specimens is the same as a control specimen originally given to him or her. (This is a "duo-trio" test.)
(b) $U = \dfrac{X/n - 0.33}{\sqrt{0.22/n}}$ Normal distribution (Appendix II, Table B)	$p = 0.33$, n should be $>$ 30.	Judge is asked to identify which of three specimens is different from the other two. (This is a "triangle" test.)

TABLE 44.31 Summary Table of Tests of Hypotheses (*Continued*)

Test statistic and its distribution	Assumptions	Remarks
Test 9. Samples are from identically distributed populations [H:$F(X_1) = F(X_2)$ where $F(X)$ = distribution function] (Johnson and Leone, 1964).		
(*a*) For evaluation of means T' = sum of ranks in smaller sample Distribution of T' (Appendix II, Table O)	Distribution-free; if $n_1 > 8$ and $n_2 > 8$, the distribution of statistic T' can be closely approximated by normal.	Data are evaluated by ranking the combined observations from the two samples (1 for the smallest, 2 for the next smallest, etc.). Then calculate the sum of the ranks in the smaller sample. A rejected hypothesis leads to the conclusion that the means are different. (This is a "rank sum" test.)
(*b*) For evaluation of standard deviations T' = sum of ranks in smaller sample Distribution of T' (Appendix II, Table O)	Distribution-free; if $n_1 > 8$, and $n_2 > 8$, the distribution of statistic T' can be closely approximated by normal.	Data are evaluated by ranking the combined observations but ranking assigns 1 to smallest observation, 2 to largest observation, 3 to next smallest, etc. The sum of the ranks for the smaller sample is calculated. A rejected hypothesis means that the standard deviations are different. (This is a "rank sum" test.)

44.68

TABLE 44.31 Summary Table of Tests of Hypotheses *(Continued)*

Test statistic and its distribution	Assumptions	Remarks
Test 10. The observations in a sample have been randomly drawn from a single population (Bennett and Franklin, 1954, and Dixon and Massey, 1969).		
(a) u = number of runs Distribution of runs (Appendix II, Table P)	$n_1 \geq 10$, $n_2 \geq 10$.	Data are evaluated in terms of number of sequences or "runs" above and below the median. (This is a "runs" test.)
(b) $M = \dfrac{\sum\limits_{i=1}^{n-1}(X_{i+1} - \overline{X}_i)^2}{\Sigma(X_i - \overline{X})^2}$ $U = \dfrac{1 - M/2}{\sqrt{(n-2)/[(n-1)(n+1)]}}$ Normal distribution (Appendix II, Table B)	1. $n \geq 4$. 2. Normal population.	Data are evaluated in terms of differences between successive observations in a sequence $(X_{i+1} - X_i)$. (This is the "mean square successive difference, M, test.")
Test 11. An observation does not belong to the same population as the other observations in a sample (Dixon and Massey, 1969; Grubbs, 1969).		
Both X_1 and X_2 are to be evaluated if extreme observations in either direction are undesirable. n r $3 \leq n \leq 7$ $r_{10} = \dfrac{X_2 - X_1}{X_n - X_1}$ $8 \leq n \leq 10$ $r_{11} = \dfrac{X_2 - X_1}{X_{n-1} - X_1}$ $11 \leq n \leq 13$ $r_{21} = \dfrac{X_3 - X_1}{X_{n-1} - X_1}$ $14 \leq n \leq 25$ $r_{22} = \dfrac{X_3 - X_1}{X_{n-2} - X_1}$ Distribution of r (Appendix II, Table Q)	X is normally distributed. Population mean and standard deviation are unknown.	Data are evaluated by arranging data in order of magnitude and comparing the distance of one extreme observation from other observations with a measure of variability. (This is an outlier test.)

44.69

TABLE 44.31 Summary Table of Tests of Hypotheses (*Continued*)

Test statistic and its distribution	Assumptions	Remarks
Test 12. A sample of data comes from a population with the specified probability function.		
(a) D = largest deviation of actual % cumulative frequency from theoretical % cumulative frequency Distribution of D (Gibbons, 1997, Table C)	Distribution should be continuous.	Data are evaluated by first plotting on probability paper. The largest deviation of a plotted point from a straight line is then evaluated. This test applies particularly where $n < 30$. (This is the "Kolmogorov-Smirnov goodness-of-fit test.")
(b) $\chi^2 = \Sigma \dfrac{(f_a - f_e)^2}{f_e}$ Distribution DF Normal Number of cells minus 3 Exponential Number of cells minus 2 Weibull Number of cells minus 4 Poisson Number of cells minus 2 Binomial Number of cells minus 2 Test statistics for all distributions follow the chi square distribution (Appendix II, Table L)	$n > 30$ and preferably > 100.	Data are evaluated by first constructing a frequency distribution. Theoretical frequencies (based on the distribution assumption) are calculated for each cell. The actual (f_a) and theoretical (f_e) frequencies are then compared. This test can be used for continuous and discrete distributions. If any theoretical frequency is less than 5, the cell involved should be combined with one or more adjacent cells. (This is the x^2 goodness-of-fit test.)

Example: *Solve the previous example using the range instead of the standard deviation.*

Solution: *Using Test 1c of Table 44.31,*

$$H_0: \quad \mu = 30.0$$

$$H_1: \quad \mu < 30.0$$

Test statistic:

$$\tau_1 = \frac{\overline{X} - \mu_0}{R}$$

Acceptance region:

$$\tau_1 \geq -0.230$$

Analysis:

$$\tau_1 = \frac{27.6 - 30.0}{6} = -0.40$$

Conclusion: Reject the hypothesis. There is sufficient evidence to conclude that the engine does not meet the requirement.

Example: Solve the previous example using the sign test.

Solution: Using Test 1d of Table 44.31,

$$H_0: \quad \mu = 30$$

$$H_1: \quad \mu < 30$$

Test statistic: Number of positive signs r.

Acceptance region:

$$r > 1 \text{ (one-tailed test)}$$

Analysis:

X	$X - \mu_0$	
28	−	
26	−	
31	+	
29	−	$r = 1$
25	−	
27	−	
28	−	
27	−	

Conclusion: Reject the hypothesis. There is sufficient evidence to conclude that the engine does not meet the requirement.

Example: Five batches of rubber were made by each of two recipes and tested for tensile strength with the following results:

Recipe 1	*Recipe 2*
3067	3200
2730	2777
2840	2623
2913	3044
2789	2834

Test the hypothesis that average strength is the same for the two recipes. Assume a 5 percent significance level.

Solution: First, Test 5a of Table 44.31 tests the assumption of equal variances. The outcome of this is used to decide whether to use Test 2b or 2d to evaluate the question about average strength.

$$H_0: \quad \sigma_1^2 = \sigma_2^2$$

$$H_1: \quad \sigma_1^2 \neq \sigma_2^2$$

Test statistic:

$$DF_1 = 5 - 1 = 4 \qquad DF_2 = 5 - 1 = 4$$

$$F = \frac{(s_1)^2}{(s_2)^2}$$

Acceptance region:

$$\frac{1}{9.60} \leq F \leq 9.60$$

Analysis:

$$s_1^2 = 16{,}923.7$$

$$s_2^2 = 51{,}713.3$$

$$F = \frac{16{,}923.7}{51{,}713.3} = 0.33$$

Conclusion: Accept the hypothesis. This is used to satisfy the assumption of equal variances in the following test of hypothesis. Now, using Test 2b,

$$H_0: \quad \mu_1 = \mu_2$$

$$H_1: \quad \mu_1 \neq \mu_2$$

Test statistic:

$$t = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\frac{1}{n_1} + \frac{1}{n_2}} \sqrt{\frac{[(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2]}{n_1 + n_2 - 2}}}$$

Acceptance region:

$$DF = 5 + 5 - 2 = 8$$

$$-2.306 \le t \le +2.306$$

Analysis:

$$t = \frac{2867.8 - 2895.6}{\sqrt{\frac{1}{5} + \frac{1}{5}} \sqrt{\frac{(5-1)16{,}923.7 + (5-1)51{,}713.3}{5+5-2}}} = -0.2373$$

Conclusion: Accept the hypothesis. There is insufficient evidence to conclude that the recipes differ in average strength.

Example: Solve the previous example using ranges instead of standard deviations.

Solution: First, Test 5b of Table 44.31 tests the assumption of equal variances.

$$H_0: \quad \sigma_1^2 = \sigma_2^2$$

$$H_1: \quad \sigma_1^2 \ne \sigma_2^2$$

Test statistic:

$$F' = \frac{R_1}{R_2}$$

Acceptance region:

$$0.32 < F' < 3.2$$

Analysis:

$$R_1 = 3067 - 2730 = 337$$

$$R_2 = 3200 = 2623 = 577$$

$$F' = \frac{337}{577} = 0.58$$

Conclusion: Accept the hypothesis. This is used to satisfy the assumption of equal variances in the following test of hypothesis. Now, using Test 2c,

$$H_0: \quad \mu_1 = \mu_2 \quad H_1: \quad \mu_1 \ne \mu_2$$

Test statistic:

$$\tau_d = \frac{\overline{X}_1 - \overline{X}_2}{0.5(R_1 + R_2)}$$

Acceptance region:

$$-0.493 \le \tau_d \le +0.493$$

$$R_1 = 3{,}067 - 2{,}730 = 337$$

$$R_2 = 3{,}200 - 2{,}623 = 577$$

Analysis:

$$\tau_d = \frac{2867.8 - 2895.6}{0.5(337 + 577)} = -0.061$$

Conclusion: Accept the hypothesis. There is insufficient evidence to conclude that the recipes differ in average strength.

Testing a Hypothesis When the Sample Size Is Not Fixed in Advance.   As noted earlier under Testing a Hypothesis When the Sample Size Is Fixed in Advance, ideally the desired values of type I and type II errors are defined in advance and the required sample size determined. However, if the sample size is fixed in advance, this cannot be done in most cases, and one can control only the type I error (not the type II error). One can control both when the sample size is not fixed in advance, as illustrated now for the case of testing if the means of two populations are equal ($H : \mu_1 = \mu_2$).

For type I error equal to α and type II error equal to β when the means differ by δ^* (a positive number) in absolute value, one proceeds as follows:

Sample n_0 observations from each of the ($k = 2$) populations (it is desirable that n_0 be at least 10 if possible).

Determine the total sample size for population i as

$$n_i = max[n_0 + 1, (ws_i)^2]$$

where w solves the equation (solve by trial and error)

$$P_{n_0}(-h - \delta^* w) + P_{n_0}(-h + \delta^* w) = \beta$$

where $h = h_{n_0}(2, 1 - \alpha/2)$ is found from Table 44.30, and $P_{n_0}(t)$ is tabled in Table 44.32.

Take $n_1 - n_0$ more observations from population 1 and $n_2 - n_0$ more observations on population 2.

Reject the hypothesis that the means are equal if the sample means (based on all the data) differ by more than h/w.

As an example, suppose we have an initial sample size of $n_0 = 15$ and desire type I error $\alpha = .05$ and type II error $\beta = .10$ when the means differ by $\delta^* = 4.0$. Then from Table 44.30, $h = h_{n_0}(2, 1 - \alpha/2) = h_{15}(2, .975) = 3.02$. We find the w that solves

$$P_{15}(-3.02 - 4w) + P_{15}(-3.02 + 4w) = .10$$

in two steps. First, we find w approximately by solving $P_{15}(-3.02 + 4w) = .10$ using Table 44.32. Since Table 44.32 has entries of .4999 and larger, we first convert the equation using the fact that $P_{n_0}(-v) = 1 - P_{n_0}(v)$ for all v, obtaining

$$1 - P_{15}(3.02 - 4w) = .10 \qquad or \qquad P_{15}(3.02 - 4w) = .90$$

Since $P_{15}(1.9) = .8968$ and $P_{15}(2.0) = .9079$, w will (to a first approximation) be in the range of the solutions of

$$3.02 - 4w = 1.9 \qquad and \qquad 3.02 - 4w = 2.0$$

namely, $w = (3.02 - 1.9)/4 = 0.28$ and $w = (3.02 - 2.0)/4 = 0.255$. Thus let us try a value of $w = 0.255$. For this value,

$$P_{15}[-3.02 - (4)(0.255)] + P_{15}[-3.02 + (4)(0.255)] = P_{15}(-4.04) + P_{15}(-2.0) = 1 - P_{15}(4.04)$$

$$+ 1 - P_{15}(2.0) = 1 - .9946 + 1 - .9079 = .0054 + .0921 = .0975 = .10$$

TABLE 44.32 Probabilities $P_{n_0}(t)$ Needed for Testing if Two Means Are Equal in Two Stages*

*The table entries are from p.52 of E.J. Dudewicz and S.R. Dalal (1975), "Allocation of Observations in Ranking and Selection With Unequal Variances." *Sankhyā*, vol. 73B, pp.28-78. Acknowledgment is made to the Indian Statistical Institute for permission to reproduce these tables.

(The approximation process could be carried further, but for most practical purposes this w will suffice.) Then, if $s_1 = 17.3$, we will need a total sample of size

$$n_1 = \max\{15 + 1, [(0.255)(17.3)]^2\} = \max(16, 19.46) = 20$$

(since sample sizes must be integers, we round up). Since we already have 15 observations, $20 - 15 = 5$ more will be required from population 1. Similarly, if $s_2 = 10.4$, we will need a total sample of size

$$n_2 = \max\{15 + 1, [(0.255)(10.4)]^2\} = \max(16, 7.03) = 16$$

Since we already have 15 observations from population 2, $16 - 15 = 1$ more will be required. If the sample means based on all the data are $\overline{X}_1$ and $\overline{X}_2$, we reject the hypothesis that $\mu_1 = \mu_2$ if the sample means differ by more than

$$\frac{h}{w} = \frac{3.02}{0.255} = 11.84$$

For example, if $\overline{X}_1 = 38.3$ and $\overline{X}_2 = 50.2$, the sample means differ by 11.9, and we reject the null hypothesis that the means are equal.

Drawing Conclusions from Tests of Hypotheses.   The payoff for these tests of hypotheses comes from reaching useful conclusions. The meaning of "Reject the hypothesis" or "Accept the hypothesis" is shown in Table 44.33 along with some analogies to explain subtleties of the meanings.

When a hypothesis is rejected, the practical conclusion is that "the parameter value specified in the hypothesis is wrong." This conclusion is made with strong conviction—roughly speaking at a confidence level of $100(1-\alpha)$ percent. The key question then is: Just what is a good estimate of the value of the parameter for the population? Help can be provided on this question by calculating the "confidence limits" for the parameter discussed under Statistical Estimation: Confidence Interval Estimates.

TABLE 44.33   The Meaning of a Conclusion from Tests of Hypotheses

	If hypothesis is rejected	If hypothesis is accepted
Adequacy of evidence in the sample of observations	Sufficient to conclude that hypothesis is false	Not sufficient to conclude that hypothesis is false; hypothesis is a reasonable one but has *not* been proved to be true
Difference between sample result (e.g., $\overline{X}$) and hypothesis value (e.g., μ_0)	Unlikely that difference was due to chance (sampling) variation	Difference could easily have been due to chance (sampling) variation
Analogy of guilt or innocence in a court of law	Guilt has been established beyond a reasonable doubt	Have not established guilt beyond a reasonable doubt
Analogy of a batting average in baseball	If player got 300 base hits out of 1000 times at bat, this is sufficient to conclude that the overall batting average is about 0.300	If player got 3 hits in 10 times, this is not sufficient to conclude that the overall average is about 0.300

When a hypothesis is accepted, the numerical value of the parameter stated in the hypothesis has not been proved, but it has not been disproved. It is *not* correct to say that the hypothesis has been proved as correct at the 100 (1 − α) percent confidence level. Many other hypotheses could be accepted for the given sample of observations and yet only one hypothesis can be true. Therefore, an acceptance does *not* mean a high probability of proof that a specific hypothesis is correct. (All other factors being equal, the smaller the sample size, the more likely it is that the hypothesis will be accepted. Less evidence certainly does not imply proof.) For this reason, often today the wording used is "the hypothesis was not rejected at level of significance α" rather than "the hypothesis was accepted at level α." Only when the sample size is not fixed in advance do we have an indication that the true value does not differ from the hypothesized value by more than δ* with risk β.

With an acceptance of a hypothesis, a key question then is: What conclusion, if any, can be drawn about the parameter value in the hypothesis? Two approaches are suggested:

1. Calculate confidence limits on the sample result (see the previous topic of Statistical Estimation). These confidence limits define an interval within which the true population parameter lies. If this interval is small, then an acceptance decision on the test of hypothesis means that the true population value is either equal to or close to the value stated in the hypothesis. Then it is reasonable to act as if the parameter value specified in the hypothesis is in fact correct. If the confidence interval is relatively wide, then this is a stern warning that the value stated in the hypothesis has not been proved and that the true value of the population might be far different from that specified in the hypothesis.

2. Construct and review the operating characteristic curve for the test of hypothesis. This defines the probability that other possible values of the population parameter could have been accepted by the test. Knowing these probabilities for values relatively close to the original hypothesis can help draw further conclusions about the acceptance of the original hypothesis. For example, Figure 44.21 shows the OC curve for a hypothesis that specified that the population mean is 30.0. Note that the probability of accepting the hypothesis when the population mean μ is 30.0 is 0.95 (or 1 − α). Also note that if μ really is 35.0, then the probability of accepting μ = 30.0 is still high (about 0.83). If μ really is 42.0, the probability of accepting μ = 30.0 is only about 0.33.

Care must always be taken in drawing engineering conclusions from the statistical conclusions, particularly when a hypothesis is accepted. [Rutherford (1971) discusses a procedure for drawing conclusions which requires that a choice be made between two policies for drawing conclusions, i.e., conservative and liberal.]

Determining the Sample Size Required for Testing a Hypothesis.   The previous subsections assumed that the sample size was fixed by nonstatistical reasons and that the type I error only was predefined for the test. The ideal procedure is to predefine the desired type I and type II errors and calculate the sample size required to cover both types of errors.

The sample size required will depend on (1) the sampling risks desired (α and β), (2) the size of the smallest true difference that is to be detected, and (3) the variation in the characteristic being measured. The sample size can be determined by using the "operating characteristic" curve for the test. Table 44.34 summarizes methods useful in determining the sample size required for two-sided tests of certain hypotheses. [Further sources of OC curves are Duncan (1974) and Natrella (1963).]

Suppose it were important to detect the fact that the average life of the batteries cited previously was 35.0. Specifically, be 80 percent sure of detecting this change (β = 0.2). Further, if the true average was 30.0 (as stated in the hypothesis), there should be only a 5 percent risk of rejecting the hypothesis (α = 0.05). In using Appendix II, Chart R, d is defined as

$$d = \frac{\mu - \mu_0}{\sigma} = \frac{35.0 - 30.0}{10} = 0.5$$

Entering with $d = 0.5$ and $P_a = 0.2$ (the β risk), the curves indicate that a sample size of about 30 is required.

TABLE 44.34 Summary of Sample Size Graphs and Tables

Hypothesis	Graph or table
1. Mean of a population = μ_0 (σ known)	Appendix II, Chart R
2. Mean of a population = μ_0 (σ estimated by s)	Duncan (1974, p. 539)
3. Means of two populations are equal (σ_1 and σ_2 known)	Natrella (1963, pp. T-16, T-17)
4. Means of two populations are equal ($\sigma_1 = \sigma_2$ but estimated by s_1 and s_2)	Natrella (1963, pp. T-16, T-17)
5. Standard deviation of a population = σ_0	Duncan (1974, p. 324)
6. Standard deviations of two populations are equal	Duncan (1974, p. 572)

Duncan (1974) discusses the calculation of the sample size required to meet the type I and II errors. In practice, however, one is often not sure of desired values of these errors. Reviewing the operating characteristic curves for various sample sizes can help to arrive at a decision on the sample size required to reflect the relative importance of both risks. It is especially important to consider β as well as α, lest meaningless results be obtained. (Note that randomizing so as to reject H_0 100α percent of the time yields a test with level of significance α. That in itself, without consideration of β, is trivial.)

Relation to Confidence Intervals.   Confidence limits provide a set of limits within which a population parameter lies (with specified probability). Tests of hypotheses evaluate a specific statement about a population parameter. These procedures are related, and most hypothesis tests also can be made using confidence limit calculations.

Example: A sample of 12 insulators has an average strength of 4.95 ft·lb (6.7149 N·m). The standard deviation of the population is known to be 0.25 ft·lb (0.34 N·m). It is desired to test the hypothesis that the population mean is 5.15 ft·lb (6.9834N·m).

Solution using tests of hypotheses: Table 44.31 defines the test statistic 1*a* and $U = (\overline{X} - \mu_0)/(\sigma/\sqrt{n})$, and U is normally distributed. If $\alpha = 0.05$, the acceptance region is a U between ± 1.96. Then

$$H_0: \quad \mu = \mu_0 = 5.15$$

$$H_1: \quad \mu \neq \mu_0$$

$$U = \frac{4.95 - 5.15}{0.25/\sqrt{12}} = -2.75$$

Since the sample index is outside the acceptance region, the hypothesis is rejected. The procedure using confidence limits is:

1. State the hypothesis concerning the value of a population parameter.

2. Obtain a sample of data and calculate confidence limits for the population parameter.

3. If the hypothesis value falls within the confidence limits, accept the hypothesis. If the hypothesis value falls outside the confidence limits, reject the hypothesis.

Solution using confidence limits: From Table 44.22, parameter 1, the confidence limits are

$$\overline{X} \pm K_{\alpha/2} \frac{\sigma}{\sqrt{n}}$$

The 95 percent confidence limits are $4.95 \pm 1.96 \, (0.25/\sqrt{12}) = 4.81$ and 5.09. As the hypothesis value falls outside the confidence limits, the hypothesis is rejected. This is the same conclusion reached by using the hypothesis testing procedure.

Confidence limit concepts and tests of hypotheses are therefore alternative approaches to evaluating a hypothesis. [For certain hypotheses, these two approaches will result in slightly different type I errors (see Barr 1969).] As discussed under Drawing Conclusions from Tests of Hypotheses, confidence limits are a valuable supplement to the test of hypothesis procedure. For example, in the preceding example, not only do confidence limits tell us that μ is not 5.15, they also tell us that μ is between 4.81 and 5.09.

Standard Cases.   Some of the most important practical cases have been covered in Table 44.31, namely:

Binomial proportion	Tests 6, 8
Two binomial proportions	Test 7
Normal mean	Test 1
Two means	Test 2
Bivariate normal mean	Test 3
One normal standard deviation	Test 4
Two standard deviations	Test 5
Two distributions are equal	Test 9
Random order of observations	Test 10
Test for outliers	Test 11

Many of these problems also can be solved using sequential tests. There, the sample size is not set in advance, but based on the data we decide how many observations are needed. For example, if one decided to inspect a fixed number of items such as 100 items and reject the lot if 15 or more defectives were found, clearly one could stop sampling as soon as the fifteenth defective were found. Similar ideas allow savings in numbers of observations in most of the standard cases listed above and are especially important when sampling is costly or time-consuming. For details, see Govindarajulu (1981).

Paired versus Unpaired Data.   In Test 2*e* of Table 44.31 a test is given that is appropriate when data are taken in pairs and the difference within each pair is used as the basic data. This procedure is often used in order to "wash out" the effects of variables that are believed to have effects but whose effects we do not wish to study.

For example, suppose that there is an effect of the operator of the machine, and we wish to compare two types of operation on that machine—but do not wish to evaluate the size of the operator effect. Then by letting each operator perform both operations and taking the difference, we wash out the effect of the operator. (Whereas if one operator performed all of one procedure and another operator performed all of the other procedure, differences observed might be due not to the procedures but to the operators.)

As another example, in testing of mailing lists to evaluate competing advertising copy, often an "A/B split" is used. That is, one type of copy goes to names 1, 3, 5, 7,…on the list, while the other type goes to names 2, 4, 6, …. Since (on ZIP-code-ordered lists) adjacent listings may be expected to be more similar than entries far apart, this is an appropriate pairing.

This technique of pairing is *not* used when there is no advance pairing of the data. For example, it is an error to pair items by their sequence in a data listing (where often they may be sorted by some other characteristic).

Statistical Significance versus Practical Significance.   Suppose we are using Test 1*a* of Table 44.31 to test the hypothesis that the mean is 30, and wish a two-tailed test with level of sig-

nificance 0.05. Then we will reject H if U is outside the interval $(-1.96, 1.96)$. If we find $U = 3.15$, one way of reporting the result of the test is to state that H was rejected at level 0.05.

Another way of reporting is to find for which level of significance the acceptance interval would be $(-3.15, 3.15)$. From Table B in Appendix II we see that level is $(2) (0.00082) = 0.00164$. This is called the *significance probability* of the test we have conducted. It is the smallest level of significance at which we would reject H for the data we observed.

One advantage of the significance probability is that if we use it, then we can report the significance probability as 0.00164 without choosing a level of significance. Anyone reading our report can use the level of significance he or she believes is appropriate: If theirs is less than 0.00164, they do not reject, while if theirs is equal to or greater than 0.00164, they do reject the hypothesis.

One disadvantage of the significance probability is that it can be very small (indicating, one would think, a "very significant" result) even when the true mean is close to 30. For example, $U = 3.15$ when $\overline{X} = 33.15$ and $\sigma/\sqrt{n} = 1.00$; $U = 3.15$ also when $\overline{X} = 30.0315$ and $\sigma/\sqrt{n} = 0.01$. In each case the significance probability is 0.00164 (i.e., 0.164 percent). In the first case, the confidence interval on the mean at 95 percent confidence runs over $(31.19, 35.11)$, while in the second, the interval runs over $(30.0119, 30.0511)$. In terms of *practical significance,* the latter is much more likely to be a trivial difference to the practitioner than is the former. However, there is no way to tell these two situations apart by using the significance probability. For this reason, it is recommended that instead confidence intervals be computed and presented.

ADDITIONAL STATISTICAL TOOLS

Today, a large number of statistical tools are used in quality control. The statistical tool kit (see Table 44.1) stresses the statistical base of collection, analysis, and interpretation of data. *Transformations,* discussed below, are a method often used to ensure that data will meet the assumptions of statistical procedures, while *Monte Carlo sampling methods* and *clustering and discrimination procedures* are powerful methods whose use in quality control is now growing. They allow analysis with minimal assumptions and analysis of multivariate characteristics, respectively. *Bootstrap methods* are a relatively recent attempt to simplify modeling and analysis; in their *generalized bootstrap* form they achieve this with minimal drawbacks. *Selection of the best* is an alternative goal (versus hypothesis testing or confidence intervals) that should be used when one's experiment has a goal of selection.

Transformations of Data.   Most of the statistical methodology presented in this section assumes that the quality characteristic follows a known probability distribution. The analysis and conclusions that result are, of course, strictly valid only to the extent that the distribution assumption is correct. Under Tests of Hypotheses, a "goodness-of-fit" test was presented for quantitatively evaluating a set of data to judge the validity of a distributional assumption. Moderate deviations of a sample of observations from a theoretical population assumption are to be expected because of sampling variation. The goodness-of-fit test determines whether the deviation of the sample from a theoretical assumption is likely to have been due to sampling variation. If it turns out as unlikely, then it is concluded that the assumption is wrong.

Sometimes a set of data does not fit one of the standard distributions such as the normal distribution. One approach uses "distribution-free" statistical methods for further analysis. Some of these were listed under Tests of Hypotheses, and Natrella (1963) and Gibbons (1997) present further material. However, these methods often require larger sample sizes than conventional methods for equivalent statistical risks. Some other approaches to analysis are

1. Examine the data to see if there is a nonstatistical explanation for the unusual distributional pattern. For example, the output of each of several supposedly identical machines may be normally distributed. If the machines have different means or standard deviations, then the combined output probably has an unusual distribution pattern such as the mixture distribution already discussed in this section. In this case, separate analyses could be made for each machine.

2. Analyze the data in terms of averages instead of individual values. As stated under Basic Concepts, Types of Error, sample averages closely follow a normal probability distribution even if the population of individual values from which the sample averages came is not normally distributed. If it is sufficient to draw a final conclusion on a characteristic in terms of the average value, the normal distribution assumption can be applied. However, the conclusions apply only to the average value and not to the individual values in the population. (Predicting the percentage of a population falling outside engineering limits illustrates the situation where analysis in terms of the average would not be sufficient because engineering limits refer to individual values rather than averages.)

3. Use the Weibull probability distribution. The Weibull distribution is really a group of many continuous distributions with each distribution uniquely defined by numerical values of the parameters of the Weibull probability function (e.g., a beta value of 1.0 indicates an exponential distribution). If a set of data yields an approximate straight-line plot on Weibull paper, the straight line then directly provides estimates of the probabilities for the population. Whether the exact form of the probability distribution is normal, or exponential, or another distribution becomes somewhat secondary because the straight-line plot provides the needed probability estimates.

4. Make a transformation of the original characteristic to a new characteristic that is normally distributed. Figure 44.23 summarizes several of these mathematical transformations. These transformations are useful for (*a*) achieving normality of measured results, (*b*) satisfying the assumption of equal population variances required in certain tests, and (*c*) satisfying the assumption of additivity of effects required in certain tests. Natrella (1963) discusses transformations for all these uses. Romeu and Ozturk (1996) provide graphic tests of normality (even in multivariate cases).

The most common transformations for achieving normality are

$$\xi_1(X_1) = \sqrt{X_1 - a}$$

$$\xi_2(X_1) = X_1^{1/3}$$

$$\xi_3(X_1) = \log_{10}(X_1)$$

$$\xi_4(X_1) = \arcsin \sqrt{X_1}$$

$$\xi_5(X_1) = \sinh^{-1} \sqrt{X_1}$$

If one of these, say, $\xi(X_1)$, is normally distributed, the mean and variance of $Y_i = \xi(X_i)$ may be estimated by

$$\overline{Y} = \sum_{j=1}^{n} \frac{Y_j}{n} \qquad S_Y^2 = \sum_{j=1}^{n} \frac{(Y_j - \overline{Y})^2}{(n-1)}$$

However, interest in many cases is not in the expected value $E\xi(X_1)$ and the variance $\text{Var } \xi(X_1)$ but in the original problem units EX_1 and $\text{Var}(X_1)$. Simply using the inverse transformation—for example, to estimate EX_1 by $\overline{Y}^2 + a$ in the case of ξ_1—results in a biased estimate. Good estimators for the mean of the X's are given in Table 44.35. Good estimators of the variance of the X's allow us to find approximate 95 percent confidence intervals for the mean of the X's; such estimates are given in Table 44.36. For example, when using $\sqrt{X_1 - a}$, a 95 percent confidence interval for the mean of the X's is

$$\overline{Y}^2 + a + \left(1 - \frac{1}{n}\right) s_Y^2 \pm 2\sqrt{\lambda}$$

where

$$\lambda = \frac{4}{n} s_Y^2 \overline{Y}^2 + s_Y^4 \left\{ \left(1 - \frac{1}{n}\right)^2 - \frac{n-1}{n+1} \left[1 - 2\left(1 - \frac{1}{n}\right)^2 + 3\left(1 - \frac{1}{n}\right)^4\right] \right\}$$

Full references are given by Dudewicz (1983), who also covers procedures for dealing with cases where variances are unequal and data are normal. It is standard to recommend that equality of variability should be investigated, even when data are normal. Procedures for dealing with variance inequality when it is found had not been available until recent years. Recently, Dudewicz and Dalal (1983) showed how to compare several new processes with a standard process in this setting; their paper also includes consideration of nonnormality and a data set (their Section 5) with numerical details and normal probability plots for an example arising with solvents.

Monte Carlo Sampling Methods.   Monte Carlo sampling methods are finding increasing and important uses in quality control. For example, Gutt and Gruska (1977) use them to predict quality problems that may result from variation in manufacturing and assembly operations. This method is based on fitting distributions to data (such as the GLD distribution discussed above under Continuous Probability Distributions) and sampling from them using random numbers (also discussed previously), employing the resulting data to assess the performance of the simulated system (which allows optimization of the system before it is built or modified). Other uses occur in optimization (Golden et al. 1984), location modeling (Golden and Eiselt 1992), vehicle routing (Golden 1993), and inventory management (Dudewicz 1997). For example, a recent optimization method called ARSTI that uses random intervals (Edissonov 1994) compares very well with previous methods. Since one can choose to apply more than one method and then take the better result, one can only gain by incorporating such new methods into one's work [which is facilitated by the fact that a FORTRAN computer program for ARSTI is given by Edissonov (1994)].

Bootstrap Methods.   In many quality control problems, full solutions have been developed under the assumption that one knows the underlying probability distribution. Since often one does not have this knowledge in practice, one needs to estimate the probability distribution (see Selecting a Discrete Distribution and Selecting a Continuous Distribution earlier in this section). In the *bootstrap method,* one does not estimate the probability distribution from a set of data like the tensile strengths of five batches of rubber made with recipe 1 used in the illustration of testing average strength: 3067, 2730, 2840, 2913, and 2789. That is, one does not test (for example) normality of the data and (if the test fails to reject) use procedures that assume a normal probability distribution. Instead, the bootstrap method takes samples at random with replacement from the data we have and uses them to try to answer the question of interest. If one is interested, for example, in a 90 percent

confidence interval for the mean tensile strength with recipe 1, then one proceeds as follows: Draw samples of size $n = 5$ repeatedly from the basic data points until one has N such samples (with $N = 500$ being a popular choice—see note 1 below); for each sample, calculate the sample mean, thus obtaining $N = 500$ sample means, say, $\overline{X}_1, \overline{X}_2, \ldots, \overline{X}_{500}$; delete the smallest 25 (5 percent) and largest 25 (5 percent) of these 500 sample means [since $(.10)(500)/2 = 25$]; and state that the mean tensile strength is between the smallest and largest of the remaining 450 sample means.

The bootstrap method is simple and attractive; it seems to yield (without any complicated statistics or mathematics) solutions to difficult problems, i.e., to give us "something for nothing." Since there is no free lunch, we should be suspicious. In fact, the method can behave badly if the sample is not large (and most of the theory is developed as the sample size becomes infinite). For example, suppose that one desires to study the maximum rainfall over 100 years and has data on 5 years. In resampling those 5 years, one will never observe a higher rainfall than the largest of the 5 measurements with the bootstrap method. Clearly, the study will be greatly misled by this (e.g., we may recommend an inadequately sized dam or levee). Thus while the bootstrap method can be useful in some settings, it is fraught with danger. A more robust version (which yields about the same results when the sample sizes are large but is not so fragile when the sample sizes are small) is the generalized bootstrap method discussed below.

The bootstrap type of method was used as early as 1967 but did not gain wide acceptance until it was given the name *bootstrap method* by B. Efron in 1979, after which it experienced an explosion of interest. It in some ways generalizes the method given by Quenouille in 1949, which gained wide acceptance when christened the *jackknife method* by J. Tukey in 1958. History, references, and examples of its flaws (and how to remedy them) are given by Dudewicz (1992) [also see Section 15.6 of Dudewicz and Mishra (1988)].

The Generalized Bootstrap.   The generalized bootstrap was introduced by Dudewicz (1992) as a generalization of the bootstrap method with superior properties in the small-sample (few observations) case. [For a textbook discussion, see Section 6.6 of Karian and Dudewicz (1991).] Basically, with the generalized bootstrap, one takes the observations and fits an appropriate probability distribution from a broad class such as the extended generalized lambda distribution discussed earlier in this section. One's random samples are then taken from the fitted distribution. Thus, in the context of the five rubber batches discussed under Bootstrap Methods earlier, one fits an EGLD to the $n = 5$ data points. Then $N = 500$ random samples of size 5 are drawn from the fitted EGLD (not from the basic 5 data points), and analysis proceeds as in the bootstrap method. This method has been shown to do better when one has few data points (but to do as well when one has many) in recent studies [e.g., Sun and Dietland-Müller (1996) have an excellent exposition with real-data examples].

Bootstrap methods, especially in the form of the generalized bootstrap, would suggest that one fit a model to the data (e.g., a Poisson or other model) and then (assuming the fit passes testing; see Test of Model Validity above) use that model in one's analysis, which can proceed by bootstrapping. (The generalized bootstrap method allows for there being a possibility one could observe three or more blemishes sometime in the future, while the bootstrap method—which is not recommended—always assumes the probability of three or more is zero just because we did not observe three or more in any of the set of data we have.)

Note 1:   The statistical literature recommends the use of at least $N = 200$ replications. Recent work by Sun and Müller-Schwarze (1996, pp. 482–483) suggests that considerable gains in accuracy can be had by requiring at least $N = 500$ replications. The number of replications made with one's data set should not be confused with one's actual data set's size (see Note 2).

Note 2:   Bootstrap methods are widely used for sample sizes that are quite small [such as 9 in Sun and Müller-Schwarze (1996)] due to the need to draw reliable conclusions from small data sets (often gathered over a considerable period at considerable effort, such as 10 years for the Sun and Müller-Schwarze data). I would strongly recommend the generalized bootstrap for cases with fewer than 100 data points.

Clustering and Discrimination.   *Clustering and discrimination* methods are a part of the area of statistics called *multivariate analysis* (Siotani et al. 1985). A typical type of problem where these methods are used in quality control is when several different kinds of malfunctions within a production facility cause product to fall outside engineering limits. It is often difficult to determine the causes of the malfunction in any one case. Then clustering a number of cases may reveal causal links via common factors over the clusters. (That is, this method allows one to ask, "What do the cases with malfunctions of each type have in common?")

   As an example of the power of the "discrimination" method, Fisher (1936) gave the data excerpted in Table 44.37. [A convenient source of the full data set is Dixon (1983, p. 520).]This consists of two length and two width measurements on each of three distinct varieties that might be found in the same location. We wish to know: How well can the varieties (which can be classified by a more involved analysis without error) be classified by just use of the two length and two width measurements? After these data are entered into a computer, program 7M of the BMDP set of programs (Dixon 1983) may be used to answer this question. The program code is given in Figure 44.24. From the resulting output, of key interest are the so-called *canonical variables,* which are the linear combinations of L_1, L_2, W_1, and W_2 that best discriminate among the three groups. In this example, these turn out to be

$$V_1 = 2.10510 + 0.82938L_1 + 1.53447W_1 - 2.20121L_2 - 2.81046W_2$$

$$V_2 = -6.66147 + 0.02410L_1 + 2.16452W_1 - 0.93192L_2 + 2.83919W_2$$

A plot of the (V_1, V_2) values for the 150 data points is given in Figure 44.25, with $T = 1, 2, 3$ cases labeled *A, B, C,* respectively, and shows the excellent results obtained. These results are deemed excellent because they allow us to classify a future observation into the correct group with high probability of being correct. For example, if we find $V_1 = 7.20$ and $V_2 = 1.00$, we are virtually certain that group *A* is involved. (This plot is produced by program 7M.)

Heteroscedastic Discrimination.   Traditional discrimination methods have assumed that one knows that the variances are equal and have not been able to specify that the misclassification proba-

bility will be estimated within .01 (say). However, owing to development of the heteroscedastic method [see Dudewicz (1995) for a review], this is now possible in some cases and expected to become more available in the next few years. In other cases, the goal may be to estimate the overlap (rather than directly discriminate the populations); for some methods here, see Mulekar and Mishra (1997).

Selection of the Best versus Testing Hypotheses.   In hypothesis testing, one may (e.g., in the setting of Test 2 in Table 44.31) assess whether one can reject the assertion that the means of two populations are equal. While this is an appropriate question in some settings, there are

other settings where one knows a priori that one must select one or the other of the two populations and wants to select the one with the larger mean (called the "best" population). Procedures for this setting were first published in 1954 by R. E. Bechhofer, and since that time, over 500 publications and several books have been devoted to the problem. [For a categorized list and reviews, see Dudewicz and Koo (1982).]

Example of Selection of the Best: Suppose we are considering two recipes for rubber and want to select the one with the larger tensile strength. We make $n_0 = 5$ batches with each recipe and test for tensile strength with the following results:

Recipe 1	*Recipe 2*
3067	3200
2730	2777
2840	2623
2913	3044
2789	2834

We desire to be at least 95 percent sure that the one we select has a true mean tensile strength no further than $\delta^* = 120$ units from the best one. We then calculate the $s_1^2 = 16{,}923.7$ and $s_2^2 = 51{,}713.3$ in the first samples and take more observations (since we do not know the variances in advance of the first samples, we are not in a position to know how many total samples we will need). The total sample sizes are to be

$$n_1 = \max[n_0 + 1, (s_1 h/\delta^*)^2] = \max\{5 + 1, [(130.09)(3.11)/120]^2\}$$

$$= \max(6, 11.4) = 12$$

$$n_2 = \max[n_0 + 1, (s_2 h/\delta^*)^2] = \max\{5 + 1, [(227.41)(3.11)/120]^2\}$$

$$= \max(6, 34.7) = 35$$

where $h = h_{n_0}(k, P^*) = h_5(2, 0.95)$ comes from Table 44.30 (with $k = 2$ because we are seeking the best of two populations, $P^* = 0.95$ because we desire 95 percent certainty, and $n_0 = 5$ because the first samples were of five observations). We then take $n_1 - 5 = 12 - 5 = 7$ more observations from recipe 1 and $n_2 - 5 = 35 - 5 = 30$ more observations from recipe 2. We then compute the sample mean $\overline{X}_1$ of all 12 observations from recipe 1 and the sample mean $\overline{X}_2$ of all 35 observations from recipe 2, selecting the recipe that produces the larger of $\overline{X}_1$ and $\overline{X}_2$, asserting that that recipe has the larger mean (or a mean no further than 120 units of tensile strength from the best recipe). For example, if we find $\overline{X}_1 = 3067$ and $\overline{X}_2 = 2895$, we will select recipe 1. We will state that we are at least 95 percent sure that recipe 1 is either the best recipe or (in any case) has a mean tensile strength no further than 120 strength units from the best (if it is not the best).

Procedures are also available for selection of the best of more than two populations [see Section 6.3 of Karian and Dudewicz (1991)]; one can essentially use the same procedure with the appropriate k being used when h is looked up in Table 44.30.

REGRESSION AND CORRELATION ANALYSIS

Many quality control problems require estimation of the relationship between two or more variables. Often interest centers on finding an equation relating one particular variable to a set of one or more variables. For example, how does the life of a tool vary with cutting speed? Or how does the octane number of a gasoline vary with its percentage purity?

Regression analysis is a statistical technique for estimating the parameters of an equation relating a particular variable to a set of variables. (Some authors refer to this as *least squares* or *curve fitting.*) The resulting equation is called a *regression equation.*

Some experimental data for the tool life example are given in Table 44.38 [from Johnson and Leone (1964, p. 380)] and plotted in Figure 44.26. Tool life is the *response variable* (also called the *dependent variable* or the *predictand*), and cutting speed is the *independent variable* (also called the *predictor variable*). In this case, the independent variable is controllable; i.e., it is fixed by the experimenter or the operator of the machine. In the second example, both the octane number and the percentage purity are random. The data for this example (from Volk 1956) are given in Table 44.39 and plotted in Figure 44.27. Since the goal is to predict the octane number, it is regarded as the dependent variable, and the percentage purity is considered as the independent variable. (In many problems there are a number of independent variables, and in some cases this set of independent variables includes both random and controllable variables.)

The computations for two-variable regression problems can be done quite easily on a calculator, but when there are many variables, the number of computations becomes overwhelming. (Even in the two-variable case, many of the computer programs available fail to provide numerically accurate calculations. It is strongly recommended that one *not* write one's own regression program and that only major tested software packages such as SAS, BMDP, and the like be utilized.) With modern digital computer multiple regression programs, the number of variables is not a restriction. To under-

stand and interpret the results of multidimensional problems, a thorough knowledge of the two- and three-variable cases is necessary.

There are many reasons for constructing regression equations. Although the motives do not affect the calculations, they do affect the interpretation of the results. In some cases, regression analysis is used to describe the nature of a relationship in a quantitative manner. Often the *goals* are more specific. In the first example, where the cutting speed is controllable, the objective might be to find the particular value of cutting speed which minimizes tool wear or some cost function based on tool wear. Least squares regression also can be used to determine the important independent variables in a process, e.g., whether process variables such as moisture, pressure, or temperature affect a quality characteristic of the product such as strength.

In other problems, where the independent variable is not controllable, the goal may be to predict the value of the dependent or response variable. This might be done because the independent variable is easier to measure than the dependent variable. Or the independent variable may be available before the dependent variable, and hence it would be desirable to forecast the value of the dependent variable before it occurs. In still other cases it might allow a destructive test to be replaced by a non-destructive test.

The following list includes a number of *uses of regression equations:*

1. Forecasting and prediction
2. Quantitatively describing the relationship between a particular variable and another set of variables
3. Interpolating between values of a function
4. Determining the important independent variables
5. Locating the optimum operating conditions
6. Discriminating between alternative models
7. Estimating particular regression coefficients

For any of these goals stated, the *basic steps in a regression study* are those of the checklist for planned experimentation given at the beginning of this section. A summary, specifically relating the steps to regression, is

1. Obtain a clear statement of the objectives of the study. Determine which variable is to be the response variable and which variables can be included as independent variables. In addition, obtain some measure of the precision of the results required—not necessarily in statistical terminology. (It is important to have a thorough understanding of what use will be made of the regression equation, since this may preclude the use of certain variables in the equation and will also help to give an understanding as to how much effort and money should be devoted to the project.)

2, 3. Specify collection procedures for the data. Collect the data. (The end results can only be as good as the data on which they are based. Careful planning at this stage is of considerable importance and can also simplify the analysis of the data.)

4. Prepare crossplots (plots of one variable versus another) of the data to obtain information about the relationships between the variables; screen the data; calculate the regression equation; and evaluate how well it fits the data (including looking at transformations of variables for a better fit, or the removal of variables from an equation if they do not improve the prediction). Give measures of the precision of the equation and any procedure for using the equation. Also specify procedures for updating the equation and checks to determine whether it is still applicable, including control charts for the residuals (observed value-predicted value). (Section 24, Statistical Process Control, discusses control charts.)

5, 6, 7. As in the checklist for planned experimentation.

A number of texts have been written on regression, including Daniel and Wood (1971) and Draper and Smith (1981). These include computer programs and output. Dudewicz and Karian (1985) also discuss design questions in detail. In addition to regression, other techniques have been devised for the analysis of multivariate data; see Kramer and Jensen (1969, 1970) and Siotani et al. (1985) for details. (One of these techniques is discriminant and cluster analysis, already discussed in this section.)

Our discussion of regression begins with a single predictor problem and then proceeds to problems with more than one predictor variable and a discussion of computer programs and outputs, with their interpretation. While many texts emphasize advanced mathematical aspects of regression, this is not needed for a practical understanding now that high-quality software is available; hence we find no need for such mathematics. This makes this important subject accessible to most quality practitioners.

Simple Linear Regression.   Many problems involve only a single predictor variable *X.* (The dependent variable *Y* is often related to other predictor variables, which have either been held constant during the experiment or their effects judged to be much smaller than that of *X.*) These problems are often referred to as ones of *simple linear regression.*

Graphing the Data.   A first step in any study of relationships between variables is to plot a graph of the data (often called a *scatter diagram*). The convention is to plot the response variable on the

vertical axis and the independent variable on the horizontal axis. A graph can provide a great deal of information concerning the relationship between variables and often suggests possible models for the data. The data plotted in Figure 44.26 suggest that Y is linearly related to X over the range of this experiment. (If this were not the case, various transformations of the data as well as curvilinear relationships could also be considered. Often the relationship can be "linearized" by taking the logarithm of one or both of the variables.)

A graph also can indicate whether any of the observations are outliers, i.e., observations that deviate substantially from the rest of the data. (Outliers may be due to measurement errors or recording errors, in which case they should be corrected or deleted. They may be due to process changes or other causes, and the investigation of these changes or causes may provide more information than the analysis of the rest of the data.) No outliers are apparent in Figure 44.26.

A closer inspection of the graph can give an indication of the variability of Y for fixed X. In addition, it may show that this variability remains constant over all X or that it changes with X. In the latter case the method of weighted least squares (see Draper and Smith 1981) may be preferred to the standard least squares technique discussed here.

The Model.   After graphing the data, we want to obtain an equation relating Y to X. To do this, a model for the data must be postulated. (I emphasize that the proposed model may be modified during the course of the study and is just a starting point.)

A possible model for the data in Figure 44.26 is

$$Y = \beta_0 + \beta_1 X + \epsilon$$

where β_0 and β_1 are the unknown intercept and slope, respectively, of the regression line. The model assumes that Y is a linear function of X plus a random error term, denoted by ϵ. This random error may be due to errors in the measurement of Y and/or to the effects of variables not included in the model, which is called *equation error.* The X's are assumed to be measured with negligible error. For the data in Figure 44.26, the X's are fixed; however, the same model can be used when the X's are random as in Figure 44.27.

Estimating the Prediction Equation.   The objective is to find estimates (b_0, b_1) of the unknown parameters (β_0, β_1) and thus obtain a prediction equation

$$\hat{Y} = b_0 + b_1 X$$

where $\hat{Y}$ is the predicted value of Y for a given value of X.

Least squares provides a method for finding estimates of these parameters from a set of N observations $(Y_1, X_1), \ldots, (Y_N, X_N)$. The estimates are called *least squares estimates* because they minimize the sum of the squared deviations between the observed and predicted values of the response variable $\sum(Y_m - \hat{Y}_m)^2 = \sum(Y_m - b_0 - b_1 X_m)^2$. These ideas are illustrated in Figure 44.28. (For a mathematical derivation of the estimates, see any of the texts mentioned in the introduction.)

If (1) the observations are independent, (2) the variance of the errors is constant over these observations, and (3) the linear model postulated is correct, the least squares estimates are the "best linear unbiased estimates": In the class of linear unbiased estimates of the parameters, the least squares estimates have the smallest variance. (Even if these conditions are not satisfied, the least squares technique can be used, although modifications or other methods may provide better estimates.) Note that no assumption has been made concerning the distribution of the random error, and in particular a normal distribution is not assumed. No assumption on this error term will be required until confidence intervals and tests of hypotheses are constructed.

The least squares estimates for the parameters of the linear model $Y = \beta_0 + \beta_1 X + \epsilon$ are

$$b_1 = \frac{\sum(X_m - \overline{X})(Y_m - \overline{Y})}{\sum(X_m - \overline{X})^2}$$

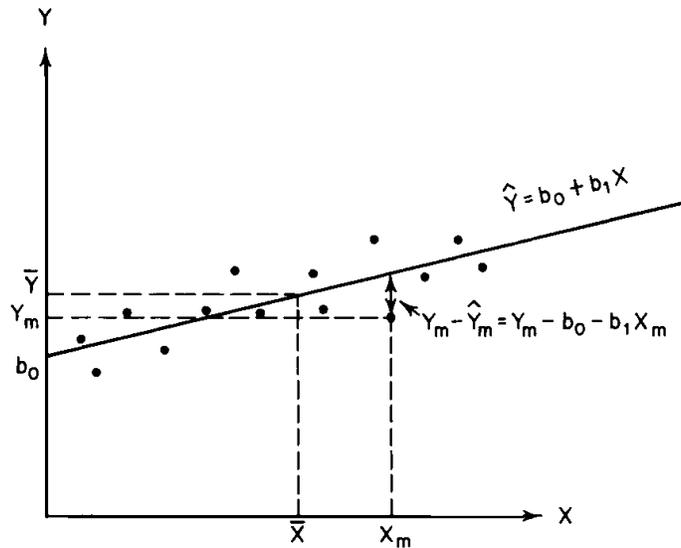
$$b_0 = \overline{Y} - b_1 \overline{X}$$


FIGURE 44.28 Least squares.

where $\overline{X} = \Sigma X_m/N$ and $\overline{Y} = \Sigma Y_m/N$ are sample averages. All these summations range from $m = 1$ to $m = N$. (Except where needed, the additional notation will be omitted for typographic simplicity.)

As can be seen, b_1 is related to the sample correlation coefficient

$$r = \frac{\Sigma(X_m - \overline{X})(Y_m - \overline{Y})}{\sqrt{\Sigma(X_m - \overline{X})^2 \Sigma(Y_m - \overline{Y})^2}}$$

by

$$b_1 = r \sqrt{\frac{\Sigma(Y_m - \overline{Y})^2}{\Sigma(X_m - \overline{X})^2}}$$

However, the concept of correlation is meaningful only when both the variables are random, whereas b_1, the least squares estimate of the rate of change of Y per unit change in X, has meaning for both the case of random X and controllable or fixed X.

The sums, sums of squares, and sum of crossproducts for the data ($N = 16$) given in Table 44.38 are

$$\Sigma X_m = 90 + 90 + \ldots + 110 = 1620$$

$$\Sigma Y_m = 41 + 43 + \ldots + 10 = 369$$

$$\Sigma X_m^2 = 8100 + 8100 + \ldots + 12{,}000 = 164{,}900$$

$$\Sigma Y_m^2 = 1681 + 1849 + \ldots + 100 = 10{,}469$$

$$\Sigma X_m Y_m = 3690 + 3870 + \ldots + 1100 = 36{,}170$$

(Note that calculations for regression are very susceptible to both human and numerical error because of their complexity. Hence good software should be used. The numerical examples in this section can be used both to test one's understanding of that software and to test its accuracy.)

The summary statistics are computed using the following computational formulas:

$$\overline{X} = \Sigma X_m/N = 101.25 \qquad \overline{Y} = \Sigma Y_m/N = 23.06$$

$$\Sigma(X_m - \overline{X})^2 = \Sigma X_m^2 - \frac{(\Sigma X_m)^2}{N} = 164,900 - \frac{(1,620)^2}{16} = 875.00$$

$$\Sigma(Y_m - \overline{Y})^2 = \Sigma Y_m^2 - \frac{(\Sigma Y_m)^2}{N} = 10,469 - \frac{(369)^2}{16} = 1958.94$$

$$\Sigma(X_m - \overline{X})(Y_m - \overline{Y}) = \Sigma X_m Y_m - \frac{\Sigma X_m \Sigma Y_m}{N}$$

$$= 36,170 - \frac{(1620)(369)}{16}$$

$$= -1191.25$$

From these results the least squares estimates can be calculated as

$$b_1 = \frac{-1191.25}{875} = -1.3614$$

$$b_0 = 23.06 - (-1.3614)(101.25) = 160.9018$$

and hence the prediction equation is

$$\hat{Y} = 160.90 - 1.3614X$$

The prediction equation is sometimes written in terms of deviations from averages, i.e., $\hat{Y} = \overline{Y} + b_1(X - \overline{X})$, which for this example becomes

$$\hat{Y} = 23.06 - 1.3614(X - 101.25)$$

Examining the Prediction Equation.   After estimating the coefficients of the prediction equation, the equation should be plotted over the data to check for gross calculation errors. Roughly half the data points should be above the line and half below it. In addition, the equation should pass exactly through the point $(\overline{X}, \overline{Y})$.

A number of criteria exist for judging the adequacy of the prediction equation. One common measure of the adequacy of the prediction equation is the proportion of variation R^2 explained. To compute R^2, the sum of the squared deviations of the Y_m about $\overline{Y}$ is partitioned into two parts, the sum of squares due to regression and the residual sum of squares:

$$\Sigma(Y_m - \overline{Y})^2 = SS(REG) + SS(RES)$$

$$= \Sigma(\hat{Y}_m - \overline{Y})^2 + \Sigma(Y_m - \hat{Y}_m)^2$$

$$= b_1 \Sigma(X_m - \overline{X})(Y_m - \overline{Y}) + \Sigma(Y_m - \hat{Y}_m)^2$$

From this, the proportion of the variation $\Sigma(Y_m - \overline{Y})^2$ explained by the regression is computed as

$$R^2 = \frac{SS(REG)}{\Sigma(Y_m - \overline{Y})^2}$$

$$= \frac{b_1 \Sigma(X_m - \overline{X})(Y_m - \overline{Y})}{\Sigma(Y_m - \overline{Y})^2}$$

$$= \frac{(-1.3614)(-1191.25)}{1958.94} = 0.828$$

Thus in this example the prediction equation explains 82.8 percent of the variation of the tool life.

Another interpretation of R^2 (when both the independent and the dependent variables are random) is as the square of the sample multiple correlation coefficient. When there is only one independent variable, this reduces to the square of the sample correlation coefficient r defined earlier.

Although R^2 is a useful measure of the adequacy of the prediction equation, an estimate of the variability of the Y's about the regression equation is usually more important. Either the sample variance s_e^2 or its square root s_e, called the *standard error of the estimate,* can be used. The latter is often preferred because it is measured in the same units as Y. Both of these, as well as other results, can be obtained from the analysis of variance (ANOVA) given in Table 44.40.

The corrected total sum of squares and the regression sum of squares are calculated from the summary statistics and the estimate of the regression coefficient [some authors include the total sum of squares, uncorrected, in the ANOVA table, partitioning it into two parts—the corrected sum of squares and the sum of squares due to $\overline{Y}$ (or b_0) (see Draper and Smith 1981)]. Although the residual sum of squares can be calculated directly, it is more easily obtained as the difference between the corrected total sum of squares and the sum of squares due to regression. Each of these sums of squares has an associated degrees of freedom (see Testing a Hypothesis When the Sample Size Is Fixed in Advance). The corrected total sum of squares has $N - 1$ degrees of freedom, since one degree of freedom is used in estimating the mean. For this *one*-variable model, there is *one* degree of freedom associated with the regression sum of squares, leaving $(N - 1) - 1 = N - 2$ degrees of freedom associated with the residual sum of squares. The mean squares (MS) are calculated by dividing the sum of squares by their associated degrees of freedom. The estimate of the variance of Y about the regression line is $s_e^2 = \text{MS(RES)}$; hence the standard error of the estimate is $s_e = \sqrt{\text{MS(RES)}}$.

From the mean squares an F statistic can be calculated as

$$F_{\text{CALC}} = \frac{\text{MS(REG)}}{\text{MS(RES)}}$$

If (1) the ϵ's in the original model are normally distributed with a common variance, (2) the observations are independent, and (3) the postulated linear model is correct, then the regression can be tested for significance, i.e., the statistical hypothesis

$$H_0: \quad \beta_1 = 0$$

can be tested against the alternative hypothesis

$$H_1: \quad \beta_1 \neq 0$$

by comparing F_{CALC} with the tabulated F_{TAB} at an appropriate level of significance α. If $F_{\text{CALC}} > F_{\text{TAB}}$, we conclude that the regression is significant and that the prediction equation is a better predictor of Y than $\overline{Y}$. Although it is difficult to check the assumptions stated above, the test is not extremely sen-

TABLE 44.40   ANOVA Table (Linear Model)

2. Residual	$\Sigma(Y_m - \hat{Y}_m)^2$†	$N - 2$	MS (RES) = SS(RES)/$(N - 2)$
3. Total corrected for the mean	$\Sigma(Y_m - \overline{Y})^2$	$N - 1$	

†Obtained by subtracting (1) from (3).

sitive to departures in the distribution of ϵ from normality if the number of observations is relatively large. If the X's are random, this test must be interpreted in a conditional sense, i.e., given the values of the X's.

For the example, the analysis of variance (ANOVA) table is given in Table 44.41. (See Section 26, under Completely Randomized Design: One Factor, k Levels.) The regression is significant at an $\alpha = 0.01$ level ($F_{TAB} = 8.86$) and $s_e = \sqrt{24.08} = 4.91$.

It is important to note that even when the regression is significant, the unexplained variability can still be large, and the prediction equation may not be of any value.

Residuals, Outliers, Confidence and Prediction Bands, Extrapolation; Lack of Fit—Replicated Observations.
If it is feasible to replicate, i.e., take more than one observation of Y at one or more values of X, the adequacy of the model also can be tested. (An estimate of the pure error sometimes may be available from sources outside the immediate experiment.) In this case, the SS(RES) can be partitioned into two parts—that due to pure error, SS(PE), and that due to lack of fit, SS(LF).

Suppose that there are N_m readings $Y_{m1}, Y_{m2},..., Y_{mN_m}$ at x_m, where $m = 1, 2,..., k$. The contribution to the sum of squares due to pure error for X_m is

$$\sum_{j=1}^{Nm} (\hat{Y}_{mj} - \bar{Y}_m)^2 = \sum_{j=1}^{Nm} Y_{mj}^2 - \frac{\left(\sum_{j=1}^{Nm} Y_{mj}\right)^2}{N_m}$$

and the associated degrees of freedom is $N_m - 1$. The SS(PE) is just the sum of these k contributions, and the associated degrees of freedom (DF) is

$$\sum_{m=1}^{k} (N_m - 1) = \sum_{m=1}^{k} N_m - k$$

For the example given in Table 44.38,

X_m		SS(PE)	DF
90	$41^2 + 43^2 + 35^2 + 32^2 - (151)^2/4 =$	78.75	3
100	$22^2 + 35^2 + 29^2 + 18^2 - (104)^2/4 =$	170.00	3
105	$21^2 + 13^2 + 18^2 + 20^2 - (72)^2/4 =$	38.00	3
110	$15^2 + 16^2 + 6^2 + 10^2 - (42)^2/4 =$	41.00	3
	Total	327.75	12

The SS(LF) is found by subtraction as

$$SS(LF) = SS(RES) - SS(PE) = 337.14 - 327.75 = 9.39$$

TABLE 44.41   ANOVA Example

Source	Sum of squares	Degrees of freedom	Mean square	F_{CALC}
1. Due to regression	1621.80	1	1621.80	67.35
2. Residual	337.14	14	24.08	
3. Total corrected for the mean	1958.94	15		

and the lack of fit degrees of freedom is obtained in a similar manner as $14 - 12 = 2$. The mean squares are then found by dividing the sum of squares by the appropriate degrees of freedom and

$$F_{CALC} = \frac{MS(LF)}{MS(PE)}$$

If the F_{CALC} is greater than the tabled F, the lack of fit is "significant," and a better or more complete model is needed (e.g., $Y = \beta_0 + \beta_1 X + \beta_2 X^2$). Plots of the residuals $(Y_m - \hat{Y}_m)$ versus X_m are particularly helpful in suggesting alternative models. Some examples are given in Figure 44.29. [Daniel and Wood (1971, pp. 19–24) present graphs of a number of nonlinear functions and give transformations that "linearize" them.] In each case the model $Y = \beta_0 + \beta_1 X$ was postulated and the plots are of the resulting residuals.

If F_{CALC} is less than the tabled F, the model is accepted. This does not mean that other variables should not be considered in the model, but only that the form of X in the model is adequate.

The calculations for our example are summarized in Table 44.42. The lack of fit is judged not significant at an α level of 0.05 ($F_{TAB} = 3.89$). Hence the postulated model is accepted, and the residual mean square is used as the estimate of the variance.

If replication is not possible, e.g., X is random rather than controllable, the Y values corresponding to X values that are close together can be used to obtain an estimate of the variability and hence judge the lack of fit. [See pp. 123–125 of Daniel and Wood (1971).]

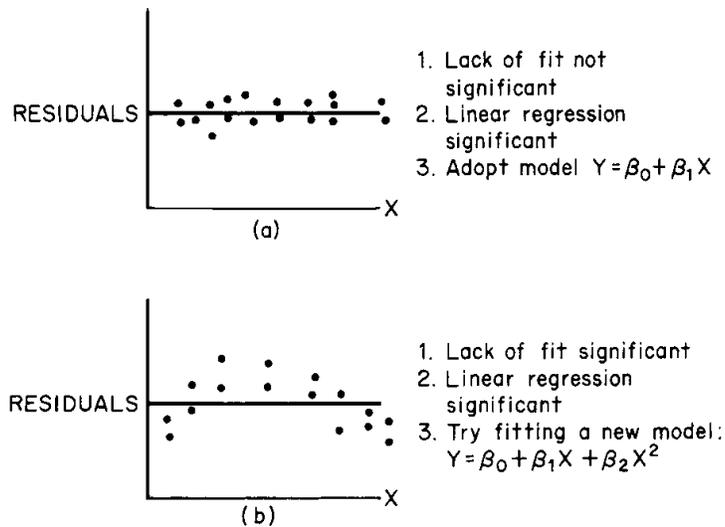
Confidence Intervals.   Both R^2 and s_e^2 provide measures of the reliability or adequacy of a prediction equation. Confidence intervals provide another measure of the reliability of the various


FIGURE 44.29   Residuals and lack of fit.

TABLE 44.42   ANOVA Lack of Fit Example

Source	Sum of squares	Degrees of freedom	Mean square	F_{CALC}

Pure error	327.75	12	27.3125	

*Obtained by subtracting SS(PE) and SS(RES).

estimates. All these confidence intervals are based on the square root of the residual mean square. A $(1 - \alpha)$ two-sided confidence interval for the slope β_1 is given by

$$b_1 \pm \frac{ts_e}{\sqrt{\Sigma(X_m - \overline{X})^2}}$$

where the value t is obtained from Appendix II, Table G, with $N-2$ degrees of freedom. The term in the denominator plays the role that $n^{1/2}$ plays in confidence intervals on population means. For the example, the 0.95 confidence interval on β_1 is

$$-1.36 \pm \frac{(2.145)(4.91)}{\sqrt{875}} = -1.36 \pm 0.356$$

The term $s_e/\sqrt{\Sigma(X_m - \overline{X})^2}$ is often called the *standard error of the regression coefficient.*

In addition to the confidence interval on β_1, more importantly, *confidence intervals* also can be constructed *for the mean of Y at a given value of X.* The $(1 - \alpha)$ confidence interval on the mean of Y at X (or equivalently on $\beta_0 + \beta_1 X$) is

$$b_0 + b_1 X \pm ts_e \sqrt{\frac{1}{N} + \frac{(X - \overline{X})^2}{\Sigma(X_m - \overline{X})^2}}$$

where X is the value at which the confidence interval is being constructed and t again has $N - 2$ degrees of freedom. (By letting $X=0$, a confidence level for β_0 is obtained.)

In addition to the assumptions previously stated, these confidence intervals also require (1) that the independent variable is fixed rather than random and (2) that the errors are normally distributed. However, if the X's are random, confidence intervals can still be calculated, but they must be interpreted in a conditional sense. Confidence intervals are not sensitive to departures from normality if the sample size is reasonably large. This is not the case for the following interval, which is very sensitive to the normality assumption. *Least absolute value* (LAV) and *Chebyshey estimation* are two possible alternatives to least squares estimation, which are less sensitive to model departures than is least squares. For sources of efficient computer algorithms, with a detailed numerical example, see Dielman and Pfaffenberger (1984).

In addition to a confidence interval on the expected value of Y at a given X, there may be a need for *an interval estimate for a future individual observation on Y at X.* [A more complete discussion of confidence intervals is given in Draper and Smith (1981). See Daniel and Wood (1971) for a confidence interval that simultaneously includes the whole line. See Dudewicz (1976, p. 427) for a plot of the interval for all X, called a *prediction band,* and its uses.] In this case the interval also must take into account the variability of Y about $\beta_0 + \beta_1 X$, and the result is

$$b_0 + b_1 X \pm ts_e \sqrt{1 + \frac{1}{N} + \frac{(X - \overline{X})^2}{\Sigma(X_m - \overline{X})^2}}$$

where t has $N - 2$ degrees of freedom. Computations of these intervals for various values of X are given in Table 44.43.

Multiple Regression.
Although there are many problems involving single predictor variables, more often there are many predictor variables. A generalization of the least squares technique, previously discussed, can be used to estimate the coefficients of the multivariable prediction equation. This problem is called *multiple regression.*

The General Model.   For a problem with k predictor variables, the model can be written as

$$Y = \beta_0 + \beta_1 X_1 + \ldots + \beta_k X_k + \epsilon$$

TABLE 44.43 Computation of Confidence Limits

X (1)	$b_0 + b_1X$ (2)	$\dfrac{(X-\overline{X})^2}{\Sigma(\overline{X}_m-\overline{X})^2}$ (3)	$\sqrt{\dfrac{1}{N}+(3)}$ (4)	$ts\times(4)$ (5)	90% confidence limits on the mean of Y at X		$\sqrt{1+\dfrac{1}{N}+(3)}$ (8)	$ts\times(8)$ (9)	90% prediction limits on Y at X

Note: Numbers in parentheses are column numbers. $t_{14,0.95} = 1.761$.

where the β's are unknown parameters and ε is the random error. These variables may be transformations of the original data. For example, in predicting gasoline yields from data on the specific gravity and vapor pressure of crude oil, Y may be the log of the gasoline yield, X_1 the crude oil specific gravity, X_2 the crude oil vapor pressure, and X_3 the product of the crude oil specific gravity with its vapor pressure.

The general model includes polynomial models in one or more variables such as

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1^2 + \beta_4 X_2^2 + \beta_5 X_1 X_2 + \epsilon$$

[which is called the *full quadratic model* of Y on X_1 and X_2 and is of great use in designed experiments (see Dudewicz and Karian 1985)]. This is still a linear model, since the term *linear model* means that the model is linear in the β's. [See Draper and Smith (1981) for a discussion of models which are nonlinear.]

Estimating the Prediction Equation.   The objective now is to find the least squares estimates (b_0, b_1,..., b_k) of the unknown parameters (β_0, β_1,..., β_k) and obtain a prediction equation

$$\hat{Y} = b_0 + b_1 X_1 + \ldots + b_k X_k$$

where $\hat{Y}$ is the predicted value of Y for the given values of X_1,..., X_k. Letting $x_i = X_i - \overline{X}_i$ and using the fact that

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - \ldots - b_k \overline{X}_k$$

this prediction equation can be expressed in the alternative form

$$\hat{Y} = \overline{Y} + b_1 x_1 + \ldots + b_k x_k$$

To simplify the formulas, the observations also can be expressed as deviations from their sample averages; i.e., for the mth observation $x_{im} = X_{im} - \overline{X}_i$ and $y_m = Y_m - \overline{Y}$. Then the least squares estimates of the $k + 1$ parameters of the multivariable linear model $Y = \beta_0 + \beta_1 X_1 + \ldots + \beta_k X_k$ can be obtained by solving the set of $k + 1$ linear equations:

$$b_1 \Sigma x_1^2 m + b_2 \Sigma x_{1m} x_{2m} + \ldots + b_k \Sigma x_{1m} x_{km} = \Sigma x_{1m} y_m$$

$$b_1 \Sigma x_{1m} x_{2m} + b_2 \Sigma x_{2m}^2 + \ldots + b_k \Sigma x_{2m} x_{km} = \Sigma x_{2m} y_m$$

$$\vdots \qquad\qquad\qquad\qquad\qquad\qquad\qquad \vdots$$

$$b_1 \Sigma x_{1m} x_{km} + b_2 \Sigma x_{2m} x_{km} + \ldots + b_k \Sigma x_{km}^2 = \Sigma x_{km} y_m$$

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - b_2 \overline{X}_2 - \ldots - b_k \overline{X}_k$$

(All the above summations are on m and range from 1 to N.)

Solving these "reduced normal" equations simultaneously can be tedious, is error prone, and involves matrix algebra. Many reference works emphasize how to perform these calculations accurately. To the user of modern accurate statistical software, these calculations are of no direct importance: That user can trust that they are being done accurately and concentrate on statistical aspects of model adequacy, interpretation, and use.

Examining the Prediction Equation.   After obtaining (b_0, b_1,..., b_k), an ANOVA table can be constructed and the adequacy of the prediction equation evaluated by a number of criteria. The ANOVA table, which is a generalization of that derived for the single predictor variable, is given in Table 44.44. The third row in Table 44.44 is the same as in Table 44.40. Note that the expressions in the first row reduce to those in the first row of Table 44.40 when $k=1$.

Since there are k variables in the model, the sum of squares due to regression has k degrees of freedom associated with it. In addition, since k coefficients and one intercept have been estimated, the residual sum of squares has $N - (k + 1) = N - k - 1$ degrees of freedom associated with it. The F

TABLE 44.44   ANOVA Table (Linear Model)

Source	Sum of squares	Degrees of freedom	Mean square
1. Due to regression	$b'a$†	k	MS(REG) = SS(REG)/k
2. Residual	$\Sigma(\overline{Y}_m - \hat{Y}_m)^2$‡	$N - k - 1$	MS(RES) = SS(RES)/ $(N - k - 1)$
3. Total corrected for the mean	$\Sigma(Y_m - \overline{Y}_m)^2$	$N - 1$	

†The sum of squares due to regression can be written as $b'a = b_1\Sigma x_{1m}y_m + b_2\Sigma x_{2m}y_m + \cdots + b_k\Sigma x_{km}y_m$. [Note that b' is the transpose of the b vector, i.e., $b' = (b_1\ b_2 \cdots b_k)$. Those not familiar with vector notation can regard $b'a$ as a shorthand for the sum given in this footnote. Since computations are usually done with computer software, details of vector notation are not given and will not be needed by most readers.]

‡Obtained by subtracting (1) from (3).

statistic is calculated as before—i.e., $F = $ MS(REG)/MS(RES)—and $s_e = \sqrt{\text{SS(RES)}/(N-k-1)}$. In this case, the F statistic can be used to test the statistical hypothesis

$$H_0: \quad \beta_i = 0 \qquad (i = 1, 2, \ldots, k)$$

against the alternative statistical hypothesis

$$H_1: \quad \text{Some } \beta_i \neq 0 \qquad (i = 1, 2, \ldots, k)$$

The only change from simple linear regression is in the degrees of freedom used to look up the F_{TAB} ($k, n - k - 1$ versus $1, n - 2$).

The proportion of variation explained by the equation (R^2) can be obtained from the ANOVA table. Note that R^2 does not depend on the number of variables in the equation, but s_e^2 does. In fact, if a new variable is added to the model (and the least squares estimates and ANOVA table are recomputed), the value of R^2 *cannot decrease*. However, s_e^2 can either increase or decrease, since it depends on the residual degrees of freedom in addition to the residual sum of squares, which decreases by one when a new variable is added.

Confidence Intervals.   Confidence intervals for individual β's can be developed as

$$b_i \pm ts_e \sqrt{c_{ii}}$$

where t has $(N - k - 1)$ degrees of freedom, and c_{ii} is defined below. However, since the b_i ($i = 1, \ldots, k$) have a joint distribution and are in general not uncorrelated, care must be taken in the interpretation of sets of these confidence intervals [see, for example, Draper and Smith (1981)].

More usefully, a confidence interval on the regression equation at a point $x = (x_1, \ldots, x_k)$, where $x_i = X_i - \overline{X}_i$ is given by

$$\overline{Y} + b_1 x_1 + \ldots + b_k x_k \pm ts_e \left(\frac{1}{N} + x'Cx\right)^{1/2}$$

where t has $N - k - 1$ degrees of freedom, and $x'Cx$ is a quadratic form that takes into account the covariances and variances of the b's. (Here C is as defined in the next paragraph.)

In a similar manner, an interval for a future Y at X is given by

$$\overline{Y} + b_1 x_1 + \ldots + b_k x_k \pm ts_e \left(1 + \frac{1}{N} + x'Cx\right)^{1/2}$$

where t has $N - k - 1$ degrees of freedom. (Here $C = S^{-1}$, where S is the $k \times k$ matrix whose entry in row i and column j is $\Sigma x_{im}X_{jm}$. In practice, as we will see, these matrix calculations are done by

the computer, and the user need not bother with them—or even understand the concept of a *matrix* and its *inverse.*)

An example: The methods discussed can now be illustrated by an example furnished by Mason E. Wescott (example 5 from *Mimeo Notes,* Mason E. Wescott, Rochester Institute of Technology, Rochester, NY) with $k = 2$ predictor variables. The problem is to relate the green strength (flexural strength before baking) of electric circuit breaker arc chutes to the hydraulic pressure used in forming them and the acid concentration. The data are given in Table 44.45, with hydraulic pressure and green strength given in units of 10 lb/in^2 and the acid concentration given as a percentage of the nominal rate for 20 observations. Two-variable plots of the data are given in Figures 44.30, 44.31, and 44.32. Summary statistics including sums, sums of squares, and crossproducts, both raw and corrected, as well as the sample means, are given in Table 44.46.

The estimates are

$$b_2 = 4.162940$$

$$b_1 = 1.571779$$

$$b_0 = \overline{Y} - b_1\overline{X}_1 - b_2\overline{X}_2 = 16.27475$$

The C matrix is

$$c_{22} = 0.00048916$$

$$c_{12}(=c_{21}) = -0.000058099$$

$$c_{11} = 0.00029787$$

TABLE 44.45   Arc Chute Data

Green strength Y in units of 10 lb/in^2	Hydraulic pressure X_1 in units of 10 lb/in^2	Acid concentration X_2, as % of nominal rate
665	110	116
618	119	104
620	138	94
578	130	86
682	143	110
594	133	87
722	147	114
700	142	106

and hence

$$C = \begin{vmatrix} 297.869 & -58.099 \\ -58.099 & 489.160 \end{vmatrix} \times 10^{-6}$$

The prediction equations can be calculated as

$$\hat{Y} = 16.277 + 1.572X_1 + 4.163X_2$$

$$\hat{Y} = 641.600 + 1.572(X_1 - 131.400) + 4.163(X_2 - 100.600)$$

(The latter form will be used in the remaining computations.)

The ANOVA table (Table 44.47) for the example follows directly from the summary statistics of Table 44.46 and from Table 44.44. The residual mean square error is 228.0, and hence the standard deviation s_e is 15.100.

The 95 percent confidence intervals on β_1 and β_2 are obtained as

$$1.572 \pm 2.110 \times 15.100 \times \sqrt{297.869} \times 10^{-3}$$

$$= 1.572 \pm 0.550 = 1.02 \text{ and } 2.12$$

and

$$4.163 \pm 2.110 \times 15.0997 \times \sqrt{489.16} \times 10^{-3}$$

$$=4.163 \pm 0.705 = 3.46 \text{ and } 4.87$$

Confidence intervals for $\beta_0 + \beta_1 X_1 + \beta_2 X_2$ and for a future observation of Y, at five combinations of X_1 and X_2, are given in Table 44.48. (The five points at which the confidence intervals are computed are also indicated in Figure 44.32.)

An additional excellent example is provided in Golden and Wasil (1992, pp. 227–245), where 37,000 observations gathered from 34 stations in the Chesapeake Bay are used to develop 10 regression models for salinity dynamics. Data quality, model building, model results, and model validation are all discussed.

Computer Programs. Because of the widespread popularity of regression, almost every computer facility has at least one and most have many regression programs. These programs may have been locally written, or they may have been obtained from other sources. In the latter case, the program usually has been modified in some manner so that it can be run on the local computer system and satisfy the needs of the local users.

Studies by Longley (1967) and Wampler (1970) indicate that the user should *strongly* prefer software such as that of SAS and BMDP. One should not presume that the program has been checked just because a sample data problem is given in the program manual. Unfortunately, a number of the algorithms used in these programs are often taken directly from desk calculator instructions. These algorithms are often not good and can produce numerically inaccurate results, even in

TABLE 44.48 Computation of Confidence Intervals

X_1 (1)	X_2 (2)	$\hat{Y}$ (3)	$(x'Cx)$ (4)	$\sqrt{\dfrac{1}{N}+(4)}$ (5)	$ts\times(5)$† (6)	95% confidence limits on the mean of Y at X_1, X_2		$\sqrt{1+\dfrac{1}{N}+(4)}$ (9)	$ts\times(9)$ (10)	95% prediction limits on Y at X_1, X_2	
						Lower (3)−(6) (7)	Upper (3)+(6) (8)			Lower (3)−(10) (11)	Upper (3)+(10) (12)
111.4	90.6	568.53	0.1457*	0.4424	14.10	554.43	582.63	1.0935	34.84	533.69	603.37
111.4	110.6	651.79	0.1922	0.4921	15.68	636.11	667.47	1.1145	35.51	616.28	687.30
131.4	100.6	641.60	0.0	0.2236	7.12	634.48	648.72	1.0247	32.65	608.95	674.25
151.4	90.6	631.41	0.1922	0.4921	15.68	615.73	647.09	1.1145	35.51	595.90	666.92
151.4	110.6	714.67	0.1457	0.4424	14.10	700.57	728.77	1.0935	34.85	679.82	749.52

Note: Numbers in parentheses are column numbers.

*Since $x' = (111.4 - 131.4, 90.6 - 100.6) = (-20, -10)$, then

$$x'Cx = (-20, -10)\begin{bmatrix} 297.869 & -58.099 \\ -58.099 & 498.160 \end{bmatrix} \times 10^{-6} \begin{bmatrix} -20 \\ -10 \end{bmatrix} = (-5,376.39, -3,819.62) \times 10^{-6} \begin{bmatrix} -20 \\ -10 \end{bmatrix} = 0.1457.$$

†t_{TAB} with 17 degrees of freedom is 2.110, $s = 15.100$.

44.106

double precision. For example, Longley found that many of the programs computed the squared deviations of a variable about its mean by the computational formula $\sum X_m^2 - (\sum X_m)^2/N$, rather than by $\sum (X_m - \bar{X})^2$. Since these quantities are the base for most of the regression calculations, numerical errors may be present in all the results.

Since the user may not be able (or simply does not want to invest the time) to check a program, a few simple checks for this purpose are given below. These can be used to gain some idea of the limitations of a program; however, I again strongly recommend against "rolling your own" when SAS, BMDP, and (perhaps) other excellent software is available at reasonable prices and is kept up to date with advances in statistics.

1. Add the residuals about the regression line. They should sum to zero, within rounding error.

2. If the residuals sum to zero, make additional runs of the problem after adding 10, 100, 1000, 10,000, etc. to each variable. The coefficients will begin to change at a point where round-off error occurs.

3. As a check on the accuracy of the inversion routine, run a problem with two variables X_1 and X_2. Then make another run with the same response variable but two new independent variables $X_1^* = X_1 + X_2$ and $X_2^* = X_1 - X_2$. The following results should hold: $b_1 = b_1^* + b_2^*$ and $b_2 = b_1^* - b_2^*$.

Longley (1967) gives some additional checks, and Wampler (1970) lists results on many regression programs.

A write-up is usually available with regression programs; it should include a complete discussion of the *input* required and an explanation of the *output* and *options* available, as well as a complete statement of the calculation formulas and a sample problem. (Although documenting a program is a difficult task, poorly written documentation is often a warning of a poorly or improperly written computer program.)

While the input formats of regression programs vary, most programs have an option that allows the user to specify a variety of transformations of the data, such as logs, powers, and crossproducts. Typical regression outputs include ANOVA tables, residuals plots, and other statistics, in addition to the estimates of the regression coefficients. Although often omitted, an *echo-check*, i.e., a printout of the original and transformed data, is essential. Often "strange" regression results can be traced to a misplaced decimal point in an observation, the wrong variables being read in, or incorrect use of the transformation option. (If this is not available in a program, ask the computer center to modify the program so that it is automatically printed out unless the user deletes it.)

R^2 and C_p Criteria for Model Choice.   In many situations there are a large number of possible variables for a model, and the problem is to select the "vital few" from these "useful many," instead of obtaining the complete regression equation. There are many reasons for not using all the variables. For example, a subset of variables can provide a better prediction equation than the full set, even though the full set has a higher R, since the full set also will include more variability. In addition, equations with fewer variables are easier to understand and hence more likely to gain acceptance and be used.

Unless the data come from a properly designed experiment, there is no simple test for significant variables. Since there are $2^k - 1$ possible prediction equations to evaluate, for large k it is obvious that a brute-force approach is not feasible (e.g., if $k = 20$, then $2^k - 1 = 1,048,575$).

Stepwise regression is a heuristic technique for avoiding this computational problem. It begins by selecting the single independent variable that is the "best" predictor in the sense that it maximizes R^2. Then it adds variables to the equation in a sequential manner, in order of importance. At each step the variable added is the one that increases the regression sum of squares (and hence R^2) or equivalently reduces the residual sum of squares by the largest amount. This procedure not only selects variables but deletes variables previously selected, if at some point they no longer appear important.

Stepwise regression does not guarantee that the "best" set of variables will be included in the final equation. However, it does provide an efficient method for reducing the number of variables k to a manageable size; e.g., if $k = 100$, then stepwise regression can be used to select the best 25 or fewer for more exhaustive study. Stepwise regression programs are widely available; see Draper and Smith (1981).

In addition to stepwise regression, numerous other techniques have been developed. One that seems to have great potential was developed by Hocking and Leslie (1967) and improved by LaMotte and Hocking (1970). Their algorithm finds the "best" subset of variables of size 1, 2,…, k, where k is the total number of variables submitted. Although the computations require more time than the stepwise procedure, this procedure guarantees the best subset in the R^2 sense and in addition gives a number of the "contending" subsets. (Of course, if the number of variables is small, we could compute all regressions.) These "best" regression algorithms are available in BMDP and can handle k up to 20 or 25 without computer time problems.

The set of possible variables should be selected on the basis of preliminary investigations of the factors that influence the response variables. The indiscriminate use of regression analysis to "find" relationships, where no facts suggest the existence of a relationship, often leads to nonsensical results. Unfortunately, this is usually discovered after the prediction equation fails miserably in predicting future observations.

If a large amount of data is available, one portion of it can be used for selecting variables and estimating coefficients, saving the remainder of the data for testing the derived equations. In any case, the equation should be periodically reviewed as new data become available.

A powerful tool in modern regression analysis is the C_p statistic [see, e.g., Dudewicz and Karian (1985, pp. 236, 413)]. While R^2 measures the goodness of the regression equation in predicting the data points in the data set one is using to develop a model, C_p estimates the variance of future predictions made using the model. While adding a variable will increase the R^2 (even if that variable is totally unrelated to what we are trying to predict), C_p typically decreases as variables are added to the model, then increases. Thus, searching for the minimal C_p statistic in all possible regressions is a reasonable approach—though if a large gain in R^2 can be obtained with a modest increase in C_p, it should be taken.

SECTION 45

STATISTICAL PROCESS CONTROL[1]

Harrison M. Wadsworth

INTRODUCTION

This section presents the use of statistical techniques to control processes. Historically, the processes controlled statistically were manufacturing processes; however, in recent years, other processes such as those used by organizations dealing primarily in services have recognized the power of these techniques. The section starts with a few definitions and comments on notation. Where possible, the definitions used are those found in the most common terminology standards.

---

[1]In the Fourth Edition, material for the section on statistical process control was supplied by Dorian Shainin and Peter D. Shainin.

These standards are identified here as American National Standards; however, there are also international standards with the same numerical designations. The standards used are

- ANSI/ISO/ASQC A8402-1994, *Quality Management and Quality Assurance—Vocabulary*
- ANSI/ISO/ASQC A3534-1993, *Statistics—Vocabulary and Symbols*

    Part 1: *Probability and General Statistical Terms*

    Part 2: *Statistical Quality Control*

The reader is referred to these standards for definitions of additional terms. ANSI/ISO/ASQC A8402-1994 has replaced ANSI/ASQC A3 and ANSI/ISO/ASQC A3534-2 has replaced ANSI/ASQC A1 and A2 that were referenced in earlier editions of this handbook.

Definitions

- *Process:* Set of interrelated resources and activities that transform inputs into outputs. [Note: Resources may include personnel, finance, facilities, equipment, techniques, and methods (ANSI/ISO/ASQC A8402-1994, clause 1.2).]

- *State of statistical control:* State in which the variations among the observed sampling results can be attributed to a system of chance causes that does not appear to change with time. [Note: Such a system of chance causes generally will behave as though the results are simple random samples from the same population) (ANSI/ISO/ASQC A3534-2-1993, clause 3.1.5).]

- *Process in control, stable process:* Process in which each of the quality measures (e.g., the average and variability or fraction nonconforming or average number of nonconformities of the product or service) is in a state of statistical control (ANSI/ISO/ASQC A3534-2-1993, clause 3.1.6).

- *Chance causes:* Factors, generally many in number but each of relatively small importance, contributing to variation that have not necessarily been identified. [Note: Chance causes are sometimes referred to as *common causes* of variation (ANSI/ISO/ASQC A3534-2-1993, clause 3.1.9).]

- *Assignable causes:* Factors (usually systematic) that can be detected and identified as contributing to a change in a quality characteristic or process level. [Notes: (1) Assignable causes are sometimes referred to as *special causes* of variation; (2) many small causes of change are assignable, but it may be uneconomic to consider or control them; in this case they should be treated as chance causes (ANSI/ISO/ASQC A3534-2-1993, clause 3.1.8).]

- *Control chart:* Chart with upper and/or lower control limits on which values of some statistical measure for a series of samples or subgroups are plotted, usually in time or sample number order. The chart frequently shows a central line to assist detection of a trend of plotted values toward either control limit. [Note: In some control charts, the control limits are based on the within-sample or within-subgroup data plotted on the chart; in others, the control limits are based on adopted standard or specified values applicable to the statistical measures being plotted on the chart (ANSI/ISO/ASQC A3534-2-1993, clause 3.3.1).]

Notation. The standard statistical notation will be used wherever possible. That is, a measurement of a quality characteristic will be denoted by an *x,* parameters will be denoted by Greek letters, and statistics by Roman letters. An overbar will denote an average, and double overbars will indicate an average of averages. Other symbols will be defined as they are used.

THEORY AND BACKGROUND OF STATISTICAL PROCESS CONTROL

Concern over variation in manufactured products produced by the Western Electric Company and studies of sampling results led Dr. Walter A. Shewhart of the Bell Laboratories to the development

of the control chart as early as 1924. An unpublished memorandum by Shewhart dated May 16, 1924 contains the first known control chart. In subsequent papers, Shewhart developed the concept more completely. See Shewhart (1926a, 1926b, 1927, and 1931) for more details about these early efforts. In 1931 Shewhart published his classic book, *Economic Control of Quality of Manufactured Product.* The first applications of the control chart by Shewhart were on fuses, heat controls, and station apparatus at the Hawthorne Works of the Western Electric Company. By 1927–1928, many other applications throughout the Western Electric Company were initiated by another member of the Quality Assurance Department of Bell Laboratories, Harold F. Dodge. These applications were as an adjunct to sampling inspection plans and as a basic device for demerits-per-unit charts for periodic quality assurance ratings.

In 1935, Dodge prepared the *ASTM Manual on Presentation of Data,* which addresses many types of control charts. This document is currently known as ASTM MNL 7 (1990). It has been used extensively by industry over the years. In 1941–1942, Dodge served as chairman of the American Standards Association Committee Z1, which published ASA standards Z1.1, Z1.2, and Z1.3 on control charts. Widespread use of control charts followed the initial publication of these standards. Revised versions of these three standards are now available from ANSI and ASQ (see ANSI/ASQC 1985a, 1985b, 1985c). Training courses on quality control principles (including the use of control charts and acceptance sampling plans) were sponsored by the Office of Production Research and Development of the War Production Board during World War II as a means for maintaining quality and promoting continual improvement. There have been many extensions and modifications of the basic control charts of Shewhart over the years. Control charts are now widely used in every industry. They are the principal tools of statistical process control (SPC).

In his studies, Shewhart observed that variation occurs in all things in nature as well as in manufactured goods. The study of this variation and its reduction are the principal vehicles of quality improvement. The control chart is the most important tool available to do this. Even though no two items are alike (variation), groups of observations form either predictable patterns or no patterns at all. The latter indicate that process improvement is necessary. This led Shewhart to conclude two important principles: (1) variation is inevitable, and (2) single observations form little or no basis for objective decision making. In order to determine patterns of observations, they may be plotted in several ways. One way is to form a histogram of the observations that presents a picture of the distribution. Another way is to plot the observations in the order in which they were obtained. This forms a line chart and is useful for observing trends or cycles in the data.

Shewhart recommended the use of a line chart to observe the data. He further indicated that there are two causes of variation. One he called *chance causes.* These are events that cause relatively minor fluctuations in the data. Each may be so small that its occurrence is not important or may be uneconomic to correct. Even though each contributes relatively minor fluctuations, together they form a pattern. Shewhart concluded from the central limit theorem and from empirical observations that they often formed approximately a normal distribution. The second cause of variation he called *assignable*; that is, a cause can be assigned for the fluctuations observed. These are sources of variation that cause a significant departure of the data from the pattern formed by the chance causes. The control chart developed by Shewhart contains a set of limits around the hypothesized normal distribution of chance causes. Any observation falling outside these limits indicates the presence of an assignable cause. In addition, because the observations are plotted in order of occurrence, trends or other unnatural patterns may be readily observed.

A control chart, then, is a graphic representation of the variation in the computed statistics being produced by the process. It has a decided advantage over presentation of the data in the form of a histogram in that it shows the sequence in which the data were produced. It reveals the amount and nature of variation by time, indicates statistical control or lack of it, and enables pattern interpretation and detection of changes in the process. The basic charts developed by Dr. Shewhart consisted of charts for averages and standard deviations. Other charts were developed for sample ranges, percentage nonconforming, and number of nonconformities per item or hundred items. Further improvements and modifications to the basic charts also have been made over the years. Such charts as cumulative sum charts and exponentially weighted moving average charts have allowed for quicker detection of small shifts in the parameter being followed. All these types of control charts will be reviewed briefly in this section.

STEPS TO START A CONTROL CHART

1. Choose the quality characteristic to be charted. In making this choice, there are several things to consider:
   a. Choose a characteristic that is currently experiencing a high number of nonconformities or items that do not conform. A Pareto analysis is useful to assist the process of making this choice.
   b. Identify the process variables contributing to the end-product characteristics to identify potential charting possibilities.
   c. Choose characteristics that will provide appropriate data to identify and diagnose problems. In choosing characteristics, it is important to remember that attributes provide summary data and may be used for any number of characteristics. On the other hand, variables data are used for only one characteristic on each chart but are necessary to diagnose problems and propose action on the characteristic.
   d. Determine a convenient point in the production process to locate the chart. This point should be early enough to prevent nonconformities and to guard against additional work on nonconforming items.

2. Choose the type of control chart.
   a. The first decision is whether to use a variables chart or an attributes chart. A variables chart is used to control individual measurable characteristics, whereas an attributes chart may be used with go no-go type of inspection. An attributes chart is used to control percentage or number of nonconforming items or number of nonconformities per item. A variables chart provides the maximum amount of information per item inspected. It is used to control both the level of the process and the variability of the process. An attributes chart often provides summary data that can be used to improve the process by then controlling individual characteristics.
   b. Choose the specific type of chart to be used. If a variables chart is to be used, decide whether the average and range or the average and standard deviation are to be charted. If small shifts in the mean are important, a cumulative sum or exponentially weighted moving average chart may be used. The disadvantage of these two latter charts is that they are more difficult for the practitioner to use and understand. If subgroups are not possible, individual readings may be used, but these are to be avoided if possible. For attributes charts, the percentage nonconforming or number of nonconforming items may be charted. In some cases, the number of nonconformities per inspection item may be preferable. All these charts will be discussed later.

3. Choose the center line of the chart and the basis for calculating the control limits. The center line may be the average of past data, the average of data yet to be collected, or a desired (standard) value. The limits are usually set at ±3 standard deviations, but other multiples of the standard deviation may be used for other risk factors. The use of 3 standard deviations results in a negligible risk of looking for problems that do not exist, i.e., false alarms. However, this multiple may result in an appreciable risk of failing to detect a small shift in the parameter being studied. Smaller multiples increase the risk of looking for a false alarm but reduce the risk of failing to detect a small shift. The fact that it is usually much more expensive to look for problems that do not exist than to miss some small problems is the reason that the ±3σ limits are usually chosen.

4. Choose the rational subgroup or sample. It should be pointed out that the term *sample* is usually used, but *sample* could mean an individual value, and samples of more than one are desirable for control charts if feasible. For variables charts, samples of size 4 or 5 are usually used, whereas for attributes charts, samples of 50 to 100 are often used. Attributes charts in fact may be used with 100 percent inspection as a reflection of the underlying process involved. In addition to the size of the sample, the samples should be selected in such a way that the chance of a shift in the process is minimized during the taking of the sample (thus a small sample should be used); whereas the chance of a shift, if it is going to occur, is at a maximum between samples. This is the concept of *rational subgrouping.* Thus it is better to take small samples periodically than to take a single large sample. Experience is usually the best method for deciding on the frequency of taking samples. That is, the known rate of a chemical change or the known rate of tool wear

should be considered when making these decisions. If such experience is not available, samples should be taken frequently until such experience is gained.

5. Provide a system for collecting the data. If control charts are to become a shop tool, the collection of data must be an easy task. Measurement must be made simple and relatively free of error. Measuring instruments must give quick and reliable readings. If possible, the measuring instrument actually should record the data, since this will eliminate a common source of errors. Data sheets should be designed carefully to make the data readily available. The data sheets must be kept in a safe and secure place, free from dirt or oil.

6. Calculate the control limits and provide adequate instruction to all concerned on the meaning and interpretation of the results. Production personnel must be knowledgeable and capable of performing corrective action when the charts indicate it.

CONSTRUCTING A CONTROL CHART FOR VARIABLES FOR ATTAINING A STATE OF CONTROL (NO STANDARD GIVEN CHARTS)

In this case we assume that we know nothing about the process, but we wish to determine if it is in a state of statistical control, i.e., to see if there are only chance causes of variation present. The procedure for all types of charts is

1. Take a series of 20 to 30 samples from the process.

2. During the taking of these samples, keep accurate records of any changes in the process such as a change in operators, machines, or materials.

3. Compute trial control limits from these data.

4. Plot the data on a chart with the trial limits to determine if any of the samples were out of control, i.e., if any plotted points are outside the control limits.

If none of the plotted points are outside the trial control limits, we can say the process is "in control," and these limits may be used for maintaining control. If, on the other hand, some of the plotted points are outside the trial control limits, we say the process is "not in control." That is, there are assignable causes of variation present. In such a case we must determine, from the records in step 2 above if possible, the cause of each out-of-control point, eliminate these samples from the data, and recalculate the trial control limits. If some points are outside these new limits, this step must be repeated until no points are outside the trial control limits. These final limits may then be used for future control.

$\overline{X}$ **and** R **Charts.**   This set of two charts is the most commonly used statistical process control procedure. It is used whenever we have a particular quality characteristic that we wish to control, since we can use the charts with only one characteristic at a time. In addition, the data must be of a measurement or variables type. Most users of process control are interested in individual items of product and the values of a few quality characteristics on these items. Averages and ranges computed from small samples or subgroups of individual items provide very good measures of the nature of the underlying universe. They permit us to control and otherwise make decisions about the process from which the items came. The chart for averages is used to control the mean or central tendency of the process, whereas the chart for ranges is used to control the variability. In place of the range, the sample standard deviation is sometimes used, but the range (the largest minus the smallest values in the sample) is easier to calculate and is easier to understand by the operators.

Using the convention of control limits set at $\pm 3\sigma$, the control limits for the $\overline{X}$ chart will be set at

$$\mu \pm 3\sigma_{\overline{X}} = \mu \pm 3\sigma/\sqrt{n}$$

where μ = the process mean

σ = the process standard deviation

n = the sample size

Since the parameters μ and σ are unknown, we must estimate them from the data. The best estimate of μ is $\overline{\overline{X}}$, where $\overline{\overline{X}}$ is the average of the sample averages $\overline{X}$, and $\overline{X}$ is calculated as

$$\overline{X} = \sum x/n$$

The process standard deviation may be estimated by a function of the average of the sample ranges $\overline{R}$. The average range provides a good estimate of the standard deviation for small samples, say, less than 12. The estimate of the standard deviation is the average range divided by a constant d_2, where d_2 is a function of the sample size. Thus the control limits for the $\overline{X}$ chart are calculated as

$$\text{UCL}_{\overline{X}} = \overline{\overline{X}} + 3\,\overline{R}/(d_2 \sqrt{n}) = \overline{\overline{X}} + A_2\,\overline{R}$$

$$\text{LCL}_{\overline{X}} = \overline{\overline{X}} - 3\overline{R}/(d_2 \sqrt{n}) = \overline{\overline{X}} - A_2\,\overline{R}$$

where $A_2 = 3/(d_2\sqrt{n})$.

The range chart will be calculated similarly as $\mu_R \pm 3\sigma_R$, where μ_R and σ_R are the mean and standard deviation of the distribution of the sample ranges, respectively. The mean range is estimated by $\overline{R}$, and the standard deviation of the range is $\sigma_R = d_3\sigma \cdot$ This may be estimated by $d_3\overline{R}/d_2$. Therefore, we calculate the control limits for the range chart as

$$\text{UCL}_R = \overline{R} + 3d_3(\overline{R}/d_2) = (1 + 3d_3/d_2)\overline{R} = D_4\overline{R}$$

$$\text{LCL}_R = \overline{R} - 3d_3(\overline{R}/d_2) = (1 - 3d_3/d_2)\overline{R} = D_3\overline{R}$$

where the factors A_2, D_3, and D_4 are functions of the sample size n and are tabulated in Table 45.1 along with d_2, d_3, and some other factors that will be used later in this section. A more extensive table will be found in Appendix II, Table A.

To use these two charts, 20 to 25 samples of the same size n are taken from the process. Samples of 4 or 5 are usually used for these charts. The average and range are calculated for each sample. The 20 to 25 averages and ranges are then averaged to find the grand average and the average range. The upper and lower control limits may then be calculated for each of the charts. It will be noticed in Table 45.1 that for $n = 6$ or less, the value for D_3 is 0. This is so because if the lower control limit were to be calculated, it would be negative. This does not make sense because the range is always positive. The fact that the value for this factor is 0 does not mean that the lower control limit for the range is 0. It means that there is no lower control limit for the range for these small samples.

There are many examples of these charts in the literature. The book *Statistical Quality Control Handbook* (AT&T 1984) contains many illustrations of control charts used by the Western Electric

TABLE 45.1   Control Chart Factors

n	d_2	d_3	c_4	c_5	A	A_2	A_3	B_3	B_4	B_5	B_6	D_3	D_4

Company. Other books with excellent descriptions of control charts and examples of their use are Grant and Leavenworth (1996), Ott and Schilling (1990), and Wadsworth et al. (1986).

Example 45.1:   Figures 45.1 and 45.2 illustrate the use of $\overline{X}$ and R charts. The figures are self-explanatory in that they follow all the procedures outlined earlier. It may be observed that the range chart is in control, but the sequence of points in the $\overline{X}$ chart starts low and after an adjustment exhibits good control for awhile. However, the last eight points are above the center line, and three of these points are above the upper control limit.

***s* Charts.**   The sample standard deviation s may be used with the $\overline{X}$ chart in place of the sample range to measure the process dispersion. In such cases we would calculate the standard deviation of each sample, find the average of the sample standard deviations, and calculate the control limits from the equations below:

$$\text{UCL}_s = B_4\overline{s}$$

$$\text{LCL}_s = B_3\overline{s}$$

where values of B_3 and B_4 may be found in Table 45.1 and in Appendix II, Table A.

The standard deviation has superior mathematical properties over the range, and with present hand calculators and computers, it is relatively simple to calculate. However, the range is much easier for the operator with limited statistical training to understand, and for this reason, the range chart is the most often used chart to control process variability.

INTERPRETATION OF CONTROL CHARTS

It is customary to place the $\overline{X}$ chart directly above the range (or standard deviation) chart. Thus the two statistics computed from each sample are easily located, and the relationship between them is obvious. We look for any unusual points or patterns in the plotted data for either chart. In order to consider this, let us first understand natural patterns for control chart data. A stable process, i.e., one under statistical control, generally will not produce a discernible unnatural pattern. It will produce a random array of data that possesses several underlying characteristics. We have observed previously that the control limits are established at the extremities of the underlying distribution of the statistic being studied. Hence the data from a controlled process should have the following characteristics when plotted on a control chart:

- Most of the plotted points occur near the centerline.
- A few of the points occur near the control limits.
- Only an occasional rare point occurs beyond the control limits.
- The plotted points occur in a random manner with no clustering, trending, or other departure from a random distribution.

Having considered natural patterns, we now consider unnatural patterns of plotted points on a control chart. Certainly, a pattern lacking one or more of the preceding characteristics would be an unnatural pattern, but let us consider each of them in turn and consider possible reasons for data to not behave according to these rules.

Most of the data on an $\overline{X}$ chart may not occur near the centerline for several reasons. If the mean changes from time to time, the data may cluster around two lines above and below the centerline. This might occur when there are, for example, two machines or two persons operating at slightly different levels feeding into the production stream.

The absence of the second of the preceding characteristics of a controlled process, the occurrence of a few points near the control limits of an $\overline{X}$ chart, may be caused by two processes having

FIGURE 45.2 How to construct the Shewhart control chart.

45.9

different means being mixed together in the same sample. The sample averages will then tend to fluctuate about the centerline, but the range of each sample will be inflated, causing the control limits to be spread apart. In this case, the chart for averages might seem to be in very good control, but the range chart will show excessive variation. Data patterns lacking the third of the preceding characteristics, an occasional, rare point beyond the control limits, may indicate either frequent changes in the process average or an increased dispersion.

For the fourth characteristic of natural patterns, examples of unnatural patterns are sudden shifts in level, trends, bunching, or clustering. A detailed discussion of this topic may be found in the AT&T *Statistical Quality Control Handbook* (1984), where a dictionary of control chart patterns is developed.

If the process is "in control," there is approximately a risk of 0.0013, or 0.13 percent, of investigating a change in the process when there is none because a point falls outside one of the control limits. There is an equal risk of a point falling outside the other control limit, making a total risk of 0.0026, or 0.26 percent, of searching for an assignable cause that does not exist. This is often called the *risk of a type I error* or an α risk. It is also called the *producer's risk*. If the process is really out of control, the occurrence of a point outside a control limit is much more likely. How likely depends on how far the process is out of control. The risk of a point not falling outside the control limits and thus failing to detect a shift of a given size is the *risk of a type II error* or a β risk. This risk is also called the *consumer's risk.*

The control limits are usually set for a low α risk. Limits much wider than 3σ would save only a few needless investigations and might cause a delay in investigating out-of-control situations. Limits much narrower would increase the incidence of needless investigations while not appreciably reducing delay in the detection of out-of-control situations. The rule of investigating each point that falls outside the 3σ control limits is therefore a compromise.

Once the control limits have been set, there is information that may be obtained from the chart that is not exploited by the preceding rule. It is rare and about equally likely to have the following events occur when the process is in control:

1. One point outside one of the 3 standard deviation control limits

2. Two of three successive points outside 2 standard deviations

3. Four of five successive points outside 1 standard deviation

4. Eight successive points on the same side of the centerline

Any one of these should be regarded as a signal of an out-of-control condition that requires attention.

The use of all four of the preceding rules is optional and has proved practical in many cases. They were advocated in 1956 in the Western Electric Company's quality control program. The last three apply only to control charts with symmetric limits. Collectively, their use increases the α risk when the process is in control but decreases the β risk when it is not in control.

CONTROL CHARTS FOR INDIVIDUALS

Sometimes it is not practical to take a subgroup from a process. This is particularly true for chemical or other continuous processes or when studying variables such as temperature or pressure. Other situations for which a single observation makes the most sense are accounting data, efficiency, ratios, expenditures, or quality costs. In such a situation, if we took several samples from the process at the same time, we would really only be checking our measuring device and not the manufacturing process itself. In this instance we would only take one observation each time we sample. A control chart based on one observation is called a *chart for individuals* or an *X chart*. Since we are not using sample averages, we do not have the benefit of the central limit theorem, which tells us that the distribution of averages is approximately normal regardless of the underlying distribution. Therefore, an *X* chart is much more sensitive to a lack of normality of the underlying distribution than is an $\overline{X}$ chart.

Since we are only taking one observation, we do not have an obvious source of an estimate of the standard deviation that we can use to determine the control limits for an *X* chart. We have two pos-

sible choices: We can use a moving range, e.g., the difference between two successive observations, or we can calculate the standard deviation of 20 or more successive observations. If the process does not shift, both statistics will give about the same answer. However, if the process does shift, the moving range will minimize the effect of the shift. Therefore, that method is usually used.

The basic procedure for developing X charts is as follows:

1. Select the measurable characteristic to be studied.

2. Collect enough observations (20 or more) for a trial study. The observations should be far enough apart to allow the process to be potentially able to shift.

3. Calculate control limits and the centerline for the trial study using the formulas given later.

4. Set up the trial control chart using the centerline and limits, and plot the observations obtained in step 2. If all points are within the control limits and there are no unnatural patterns, extend the limits for future control.

5. Revise the control limits and centerline as needed (by removing out-of-control points or observing trends, etc.) to assist in improving the process.

6. Periodically assess the effectiveness of the chart, revising it as needed or discontinuing it.

Computing the Control Limits.   Control limits for the X chart are calculated similarly to those for the $\overline{X}$ chart. That is, we set the control limits at the centerline ±3 standard deviations. They would then be set at

$$\mu \pm 3\sigma$$

The average of the observations $\overline{X}$ is commonly used to estimate the process mean μ. For the standards-given case, the known standard deviation would be used in the preceding equation. For the no-standards-given case, we must estimate the standard deviation. As mentioned earlier, we can use either the moving range or the standard deviation for this estimate.

Moving Range.   The moving range is the difference between the largest and smallest of two successive observations. Thus for a total of n observations there will be $n - 1$ moving ranges. We would average the moving ranges to get an average moving range $\overline{R}$. The control limits would thus be set in a similar manner to those for the charts using subgroups as

$$UCL_x = \overline{X} + 3\overline{R}/d_2 = \overline{X} + E_2\overline{R}$$

$$LCL_x = \overline{X} - 3\overline{R}/d_2 = \overline{X} - E_2\overline{R}$$

where values of $E_2 = 3/d_2$ will be found in Appendix II, Table Y. If we employ the common rule of using moving ranges of size 2, E_2 from Appendix II, Table Y, is 3 divided by 1.13, or 2.66. The control limits for the individuals chart would thus be set at

$$UCL_x = \overline{X} + 2.66\overline{R}$$

$$LCL_x = \overline{X} - 2.66\overline{R}$$

Standard Deviation.   As an alternative to the moving range method, the standard deviation s of all the trial observations is sometimes calculated. In this case, the control limits would be set at

$$\overline{X} \pm 3s$$

If the process average shifts, e.g., in the case of a trend, the standard deviation method will tend to overstate the variability. If the process average remains relatively constant, both methods will result in approximately the same control limits.

CONSTRUCTING CONTROL CHARTS FOR VARIABLES WHEN A STANDARD IS GIVEN

If standard values of the parameters are given, we have what is commonly called a *standards-given chart*. In this case, the standard for the mean is denoted as $\bar{X}_0$, and the standard for the standard deviation is denoted as σ_0. The control limits for the $\bar{X}$ chart will be at

$$\bar{X}_0 \pm 3\sigma_0/\sqrt{n} = \bar{X}_0 \pm A\sigma_0$$

where A is a function of the sample size n and is tabulated in Table 45.1 and Appendix II, Table A. In the case of control charts for individuals, the X chart, the control limits would be the same, except that since the sample size is 1, the limits would be merely $\bar{X}_0 \pm 3\sigma_0$.

CONTROL CHARTS FOR ATTRIBUTES

Control charts for variables require actual measurements, such as length, weight, tensile strength, etc. Thus go no-go data cannot be used for such charts. Charts for attributes, on the other hand, can be used in situations where we only wish to count the number of nonconforming items or the number of nonconformities in a sample. There are several advantages of attributes charts over variables charts.

1. Attributes charts can be used to cover many different nonconformities at the same time, whereas a separate chart must be used for each quality characteristic with variables charts.

2. The inspection required for attributes charts may be much easier than that for variables charts. We merely need to know if the item being inspected meets the specified requirements.

3. Attributes charts may be used for visual inspections for such attributes as cleanliness, correct labeling, correct color, and so on.

4. Attributes charts do not depend on an underlying statistical distribution.

On the other hand, variables charts need a much smaller sample size. In the case of the charts discussed earlier, we only used sample sizes of 4 or 5, whereas attributes charts would require sample sizes of at least 50. Attributes control charts are often used for 100 percent inspection, whereas this would be difficult for variables charts. The most common control charts for attributes are the p chart for percentage nonconforming, the np chart for number of nonconforming items, the c chart for number of nonconformities, and the u chart for number of nonconformities per item. We will discuss each of these charts in order.

Control Charts for Percentage Nonconforming (p).   The variable to be controlled here is the percentage or fraction of each sample that is nonconforming to the quality requirements. Thus the number of inspected items containing one or more nonconformities is divided by the number of items inspected. This is the fraction nonconforming. Sometimes this ratio is multiplied by 100, and the variable plotted is the percentage nonconforming. Assuming that the process is constant, the underlying distribution would be the binomial distribution. The details of this distribution are covered in Section 44. For relatively large samples, the binomial distribution can be approximated adequately by the normal distribution, and as with the control charts for variables, virtually all the data should then fall within 3 standard deviations of the mean. If data fall outside these 3 standard deviation limits, this would indicate a lack of statistical control. Therefore, the control limits are set at these values.

Recall that the standard deviation of a binomial variable is

$$\sigma_p = \sqrt{\frac{p(1-p)}{n}}$$

Therefore, the upper and lower control limits for a *p* chart will be at

$$\bar{p} \pm 3 \sqrt{\frac{\bar{p}(1 - \bar{p})}{n}}$$

Although the *p* chart is usually used for go no-go types of inspection, it also may be used for measurement inspection. Here a piece being inspected is considered nonconforming if its measurements are outside a set of specified limits. However, this use of the *p* chart is not recommended because it is less able to diagnose causes of nonconformities. A chart for determining control limits for a *p* chart will be found in Appendix II, Chart Z.

A *p* chart may be used when the sample size is constant or not constant. Since the *n* in the preceding expression for the control limits is the sample size, if *n* varies from subgroup to subgroup, as is often the case when the chart is used to plot 100 percent inspection data, the control limits will vary. They will be wider for small subgroups than for large ones. If the subgroup size varies, we have three possibilities.

1. We can calculate the average size of the subgroups. This is appropriate when the sizes are similar or all data lie near the centerline.

2. We can calculate separate control limits for each subgroup. This might lead to a rather confusing appearing chart.

3. We can find the average subgroup size and use the resulting control limits, but when a point falls near the limits, calculate the actual limits using the actual subgroup size.

The third approach is the recommended one. In using it, we must remember that a subgroup size larger than the average will mean the limits move in toward the centerline, so if a point lies outside the limits based on the average *n,* there is no point in calculating a new limit.

In setting up a *p* chart, we would, as for variables charts, collect 20 to 25 samples over enough time to allow the process to change. If the sample sizes are equal, we would determine the number of nonconforming items in each sample, divide each by the subgroup size, and average them. This is the $\bar{p}$ in the preceding expression for the control limits. In finding this average *p,* we first add all the numbers of nonconforming items and the numbers of items inspected in each subgroup. Then we divide the first total by the second to get the average. This procedure is essential if the subgroup size changes. As an example to show the importance of this procedure, suppose that we have five lots of a finished product as shown in Table 45.2. *N* is the lot size, *x* is the number of nonconforming items in each lot, and *p* is the fraction nonconforming. We are inspecting all items in each lot.

If we simply average the fraction nonconforming values in the right hand column, we would get a value for $\bar{p}$ of 0.590/5 = 0.118. This would give us upper control limits, using the actual lot sizes of 0.161, 0.255, 0.152, 0.215, and 0.197. None of the lots are out of control. However, if we instead find $\bar{p}$ as 90/1600 = 0.056, we get upper control limits of 0.087, 0.154, 0.081, 0.125, and 0.113. In this case, three of the five lots (lots 2, 4, and 5) are above the upper control limit, indicating that this does not represent a stable process. The true average fraction nonconforming is 0.056 not 0.118. The latter gives equal representation to each lot despite their widely differing sizes.

TABLE 45.2   Inspection Results of 5 Lots

Lot	N	x	p
1	500	32	0.064
2	50	10	0.200
3	800	10	0.013
4	100	18	0.180
5	150	20	0.133
Totals	1600	90	0.590

For all types of control charts for attributes, the lower control limit, when calculated using the appropriate expressions, may turn out to be negative. This, of course, makes no sense, so we simply do not have a lower control limit in these cases. In the preceding example, this applies to lots 2, 4, and 5. Note that lot 3 is actually below its lower control limit, which is, in this case, 0.032. This means that the quality, measured in terms of fraction nonconforming, is better than the average of the other lots. Some people use zero as a lower control limit when the calculated limit is negative. This might lead to a mistaken notion that a sample value of zero means that the subgroup is not in control.

Example 45.2:   Table 45.3 and Figure 45.3 illustrate a p chart. Table 45.3 contains the result of final testing of permanent magnets used in electrical relays. There were a total of 14,091 magnets tested, and 1030 were found to be nonconforming. The average number of magnets tested per week was $14{,}091/19 = 741.6$. The average fraction nonconforming was $1030/14{,}091 = 0.073$. Figure 45.3 illustrates the control chart with limits based on these values of $\bar{n}$ and $\bar{p}$. Using the preceding formulas, the upper and lower control limits are set at 0.073 ± 0.0287, or 0.102 and 0.044.

Control Charts for Number of Nonconforming Items (np).

In this case we plot the number of nonconforming items in each subgroup. Since p is x/n, x is *equal to np*, where x is the number of nonconforming items in a sample, and the chart is often called an *np chart*. For this type of chart, we must have a constant subgroup size. In this case the control limits are set at

$$n\bar{p} \pm 3 \sqrt{n\bar{p}(1 - \bar{p})}$$

TABLE 45.3 p Chart Data

or, using $\overline{X}$ as the average number of nonconformities per subgroup, the control limits may be stated equivalently as

$$\overline{X} \pm 3 \sqrt{\overline{X}(1 - \overline{X}/n)}$$

Control Charts for Number of Nonconformities (*c*).   If we wish to plot the number of nonconformities, where each item inspected may have several nonconformities and each nonconformity is counted, we have a *c* chart, where *c* is the number of nonconformities in each sample. In this case, the underlying distribution is the Poisson distribution, discussed in Section 44. Recall that in this distribution the standard deviation is the positive square root of the mean, so if we again take 20 to 25 samples and calculate the average number of nonconformities, $\overline{c}$, the control limits will be set at

$$\overline{c} \pm 3\sqrt{\overline{c}}$$

A chart for determining control limits for a *c* chart will be found in Appendix II, Chart AA.

   A *c* chart requires an *equally large* number of opportunities for a nonconformity to occur in each subgroup inspected. Thus, for example, if we are inspecting the number of defective solder connections in each circuit board, they must all have the same number of connections. If not, we must use the *u* chart, to be discussed next.

Example 45.3:   A control chart for *c* is used to control nonconformities in sheeted material. Table 45.4 shows the results of a series of pinhole tests of paper intended to be impervious to oils. Specimen sheets 11 by 17 inches in size were taken from production, and colored ink was applied to one side of each sheet. Each inkblot that appeared on the other side of the sheet within 5 minutes was counted as a nonconformity.

   The centerline of the chart is set at $\overline{c} = 200/35 = 8.0$ nonconformities per sheet. Control limits are set at $8.0 \pm 3 \sqrt{8} = 8.0 \pm 8.5$, or 0 and 16.5. That is, there is only an upper limit set at 16.5. The resulting *c* chart is found in Figure 45.4.

Control Chart for Number of Nonconformities per Item (*u*).   This chart is sometimes called a *standardized c chart*. It is used when more than one item makes up a sample but each item may have more than one nonconformity. The variable plotted on the chart is the number of nonconformities per item. Thus the number of items in a sample does not need to remain constant, as it does for the *c* chart. The control limits are calculated similarly to those for a *c* chart except that the variable is *c/n*, where *n* is the number of items in the sample. For example, if we are inspecting for defective solder joints on printed circuit boards where the boards have different numbers of solder connections, we would divide the number of nonconforming solder connections on each board by

TABLE 45.4 c Chart Data

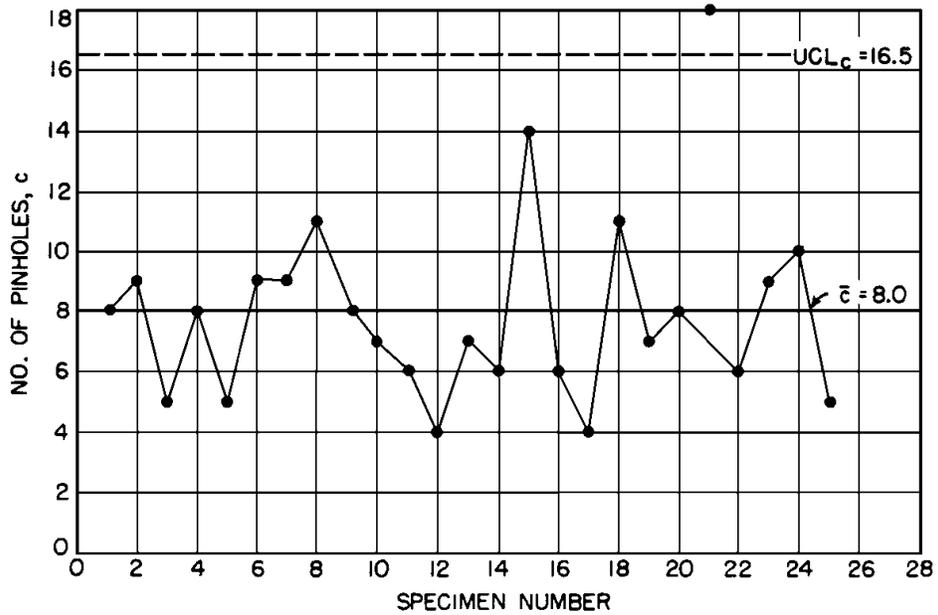
Sheet number	Number of pinholes	Sheet number	Number of pinholes
1	8	14	6
2	9	15	14
3	5	16	6
4	8	17	4
5	5	18	11
6	9	19	7
7	9	20	8
8	11	21	18
9	8	22	6
10	7	23	9
11	6	24	10
12	4	25	5
13	7	Total	200


FIGURE 45.4   c chart for pinholes in paper.

the number of connections on that board.

The control limits for a u chart are set at

$$\bar{u} \pm 3 \sqrt{\bar{u}/n}$$

Example 45.4:   As an example of the use of a u chart, the data in Table 45.5 are the results of the inspection of 10 samples of cloth for imperfections introduced during processing. From the table, we determine that $\bar{u} = 59/1360 = 0.043$. We might then calculate the average sample size as $1360/10 = 136$. Using this figure for n in the preceding expression for the control limits, we get

$$\text{UCL}_u = 0.043 + 3\sqrt{0.043/136} = 0.043 + 0.054 = 0.097$$

$$\text{LCL}_u = 0.043 - 3\sqrt{0.043/136} = 0.043 - 0.054 = <0$$

TABLE 45.5   Inspection Results of Cloth

Square meters of cloth inspected	Nonconformities found	u
200	5	0.025
80	7	0.088
100	3	0.030
300	15	0.050
120	4	0.033
90	6	0.067
250	10	0.040
50	1	0.020
100	6	0.060
70	2	0.029
Totals 1360	59	

There is no lower control limit, and only the second sample is close to the upper control limit; however, since the size of this sample is 80, less than the average sample size of 136, the correct upper control limit will be greater than 0.097, and this sample is in control.

CUMULATIVE SUM (CUSUM) CONTROL CHARTS

Another type of control chart is the *cumulative sum control chart* (often abbreviated as *CUSUM chart*). This chart is particularly useful for detecting small changes (between 0.5σ and 2.5σ) in the parameter being studied. For shifts larger than approximately 2.5σ, the Shewhart-type charts discussed previously are just as good or somewhat better and are easier to understand and use. A CUSUM chart is a plot of the cumulative sum of the deviations between each data point, e.g., a sample average, and a reference value T. Thus this type of chart has a memory feature not found in the previous types of charts. It is usually used to plot the sample average $\overline{X}$, although any of the other statistics, such as s or p, may be used. It is also often used for individual readings, particularly for chemical processes. This section will only discuss the CUSUM chart for averages. For a discussion of other types of CUSUM charts, the reader is referred to Wadsworth et al. (1986). For CUSUM charts, the slope of the plotted line is the important thing, whereas for the previous types of charts it is the distance between a plotted point and the centerline.

CUSUM charts, like other control charts, are interpreted by comparing the plotted points to critical limits. However, the critical limits for a CUSUM control chart are neither fixed nor parallel. A mask in the shape of a V is often constructed. It is laid over the chart with its origin over the last plotted point. If any previously plotted point is covered by the mask, it is an indication that the process has shifted.

Construction of a CUSUM Control Chart for Averages.   The following steps may be followed to develop a CUSUM control chart for averages:

1. Obtain an estimate of the standard error of the statistic being plotted; e.g., $\sigma_{\overline{X}}$ may be obtained from a range chart or from some other appropriate estimator. If a range chart is used, the estimate is $\overline{R}/(d_2\sqrt{n})$ or $A_2\overline{R}/3$.
2. Determine the smallest amount of shift in the mean D for which detection is desired. Calculate $\delta = D/\sigma_{\overline{X}}$.
3. Determine the probability level at which decisions are to be made. For limits equivalent to the standard 3σ limits, this is $\alpha = 0.00135$.

4. Determine the scale factor *k*. This is the change in the value of the statistic to be plotted (vertical scale) per unit change in the horizontal scale (sample number). Ewan (1963) recommends that *k* be a convenient value between $1\sigma_{\bar{X}}$ and $2\sigma_{\bar{X}}$, preferably closer to $2\sigma_{\bar{X}}$.

5. Obtain the lead distance *d* from Table BB in Appendix II using the value of δ obtained in step 2.

6. Obtain the mask angle θ from Table BB in Appendix II by setting *D/k* equal to δ in the table and reading θ from the table. Straight-line interpolation may be used if necessary.

7. Use *d* and θ to construct the V mask.

8. The sample size for a CUSUM chart for averages is usually the same as for the $\bar{X}$ chart. However, Ewan (1963) suggests, for best results, that one use

$$n = 2.25s^2/D$$

where *s* is an estimate of the process standard deviation.

Operation of the CUSUM V Mask.   The mask is placed over the last point plotted. If any of the previously plotted points are covered by the mask, a shift has occurred. Points covered by the top of the mask indicate a decrease in the process average, whereas those covered by the bottom of the mask indicate an increase. The first point covered by the mask indicates the approximate time at which the shift occurred. If no previous points are covered by the mask, the process is remaining in control.

Some Cautions

1. Periodically check the process variability with an *R* or *s* chart before drawing conclusions about the average level of the process.

2. Watch for gradual changes (trends) or changes that come and go in a short period of time. Such changes are not as apparent on a CUSUM chart as they are on an $\bar{X}$ chart.

3. The individual measurements are assumed to follow the normal distribution.

Example 45.5:   The data in Table 45.6 summarize measurements of 20 samples of 4 each taken on the percentage of water absorption in common building brick. A reference value of *T* = 10.0 was used. To illustrate the CUSUM chart, the original data were modified to introduce a decrease in the average level of 2.0 percent, starting with subgroup 11. A range chart shows a value of $\bar{R}$ of 8.08.

1. $\sigma_{\bar{X}}$ is estimated as $\bar{R}/d_2\sqrt{n} = 8.08/2.059 \sqrt{4} = 1.96$.

2. We wish to detect a shift in the process mean of $D = 1\sigma_{\bar{X}}$; therefore, $\delta = 1.96/1.96 = 1.0$.

3. We wish to use α = 0.00135, the value corresponding to the standard control chart.

4. The scale factor *k* is calculated as $2\sigma_{\bar{X}} = 2(1.96) = 3.92 \approx 4$.

5. We enter Table BB in Appendix II to get the lead distance of the mask as *d* = 13.2.

6. We substitute *D/k* = 2/4 = 0.5 for δ in Table BB in Appendix II to get θ = 14°.

Figure 45.5 shows the CUSUM chart with the mask at sample number 17. The mask was moved from left to right with the zero point on the mask over each plotted point. For the first 16 points, the mask did not cover any of the previously plotted points. At point 17 the shift was detected, and the mask indicated that the shift occurred at point 10 or 11.

Figure 45.5 also shows the same data plotted on a standard $\bar{X}$ chart. Such a chart would not have detected the shift based on a single point outside the control limits. However, it would have detected the shift at point 17 based on the fact that four of five successive points were outside the 1σ limits. A comparison of the CUSUM chart and the standard $\bar{X}$ chart usually involves the average run length (ARL). This is the average number of sample points plotted at a specified quality level before the chart detects a shift from a previous level. Ewan (1963) compares the CUSUM and $\bar{X}$ charts for various

TABLE 45.6   Data on Percentage Water Absorption

amounts of shift in the process mean. For shifts between $0.5\sigma_{\bar{X}}$ and $2.0\sigma_{\bar{X}}$ the CUSUM chart detects the shift with many fewer samples than are needed by the $\bar{X}$ chart. For larger shifts there is no longer any advantage to the CUSUM chart. The preceding statement assumes that the $\bar{X}$ chart uses only the one point outside the control limits rule. As indicated in the preceding example, if the other rules for detecting out-of-control conditions are used, the advantage of the CUSUM chart is diminished.

CUSUM Limits Using the Tabulation Method.

For some processes it may not be convenient to use a V mask. An alternative tabulation method may be used that is particularly well suited for computer applications. This method is equivalent to the charting method with the mask. The procedure is as follows:

1. Form the CUSUM as $C_1 = \sum (\bar{X}_i - K_1)$, where $K_1 = T + D/2$, to detect a shift upward.
2. Form the CUSUM as $C_2 = \sum (\bar{X}_i - K_2)$, where $K_2 = T - D/2$, to detect a shift downward.
3. Tabulate these quantities sequentially with $\bar{X}_i$ ignoring negative values of C_1 and positive values of C_2. That is, reset the upper CUSUM to zero when it is negative and the lower CUSUM to zero when it is positive.
4. Watch the progress of the C_1 and C_2 values. When either value equals or exceeds $Dd/2$ in absolute value, a signal is produced.

Example 45.6: We will use the same data as in Example 45.5 to illustrate this technique. Recall that for that example, we had $T = 10.0$, $D = 2$, and $d = 13.2$. Then we have for the preceding steps,

1. $K_1 = T + D/2 = 10.0 + 2/2 = 11.0$ and $C_1 = \sum (\bar{X}_i - 11.0)$
2. $K_2 = T - D/2 = 10.0 - 2/2 = 9.0$ and $C_2 = \sum (\bar{X}_i - 9.0)$
3. Decision limit $= Dd/2 = 13.2$

This procedure is illustrated by Table 45.7.

THE EXPONENTIALLY WEIGHTED MOVING AVERAGE CONTROL CHART

Another type of control chart is the exponentially weighted moving average (EWMA) control chart. It was first introduced by Roberts (1959) and later by Wortham and Ringer (1971), who proposed it for applications in the process industries as well as for applications in financial and management control systems for which subgroups are not practical. Like the CUSUM charts, it is useful for detecting small shifts in the mean. Single observations are usually used for this type of chart. The single observations may be averages (when the individual readings making up the average are not available), individual readings, ratios, proportions, or similar measurements. A brief discussion of the chart is presented here. The interested reader should consult the preceding references or other more recent publications such as Hunter (1986), Lowry et al. (1992), Lucas and Saccucci (1990), Ng and Case (1989), Crowder (1989), and Albin et al. (1997).

The plotted statistic is the weighted average of the current observation and all previous observations, with the previous average receiving the most weight, that is,

$$Z_t = \lambda x_t + (1 - \lambda)Z_{t-1} \qquad 0 < \lambda < 1$$

where Z_0 $= \mu$
  Z_t $=$ the exponentially weighted moving average at the present time t
  Z_{t-1} $=$ the exponentially weighted moving average at the immediately preceding time

x_t = the present observation
λ = the weighting factor for the present observation

The x_t are assumed to be independent, but the sample statistics Z_t are autocorrelated. However, Wortham and Ringer (1971) demonstrated that for large t, the sample statistic is normally distributed when the x_t are normally distributed with mean μ and variance σ^2. That is,

$$E(Z_t) = \mu$$

and

$$\mathrm{Var}(Z_t) = \sigma^2[\lambda/(2-\lambda)][1 - (1 - \lambda)^{2t}]$$

As t increases, the last term bracketed on the right-hand side converges rapidly to one, and the corresponding expression for the variance becomes

$$\mathrm{Var}(Z_t) \approx \sigma^2 \, [\lambda/(2 - \lambda)]$$

By choosing $\lambda = 2/(t + 1)$, the variance approximation becomes

$$\mathrm{Var}(Z_t) = \sigma^2/t \qquad \text{(the variance of averages of sample size } t\text{)}$$

Under these conditions, the control limits become $\hat{\mu} \pm 3 \sqrt{\hat{\sigma}^2/t}$. For other values of λ, the control limits are

$$\mathrm{UCL} = \hat{\mu} + 3\hat{\sigma} \sqrt{\lambda/(2 - \lambda)}$$

$$\mathrm{LCL} = \hat{\mu} - 3\hat{\sigma} \sqrt{\lambda/(2-\lambda)}$$

For the first few observations, the first equation for the variance should be used. This can be illustrated by the following example. If a good estimate of σ is not available, a range chart should be used with $\hat{\sigma}$ estimated by $\overline{R}/d_2$. In the case of individuals, the average moving range can be used as with the control chart for individuals.

Example 45.7:   To illustrate the EWMA control chart, we will use the same data as used in Example 45.5. Recall from that example that we have results of 20 samples of size 4 each taken on the percentage of water absorption in common building brick. The averages are shown in Table 45.6 and again in Table 45.8. The range chart gave us an estimate of $\sigma_{\overline{X}}$ of 1.96. For the first few samples we will use the complete formula for the standard deviation, and we will use the target value of 10 for our estimate of μ. For this example, a λ of 0.2 was used.

The resulting Minitab output with the data plotted is shown in Figure 45.6 It may be observed from the table and the chart that the control limits have stabilized after the eighth or ninth sample. The plot drops below the lower control limit on the sixteenth sample and stays there for the rest of the run.

The design parameters of this chart are the multiple of σ and the value of λ used. It is possible to choose these parameters to closely approximate the performance of the CUSUM chart. There have been several theoretical studies of the average run length of EWMA charts; see, for example, Lucas and Saccucci (1990). They provide average run length tables for a large range of values of λ and control chart widths. In general, Montgomery (1991) recommends values of λ between 0.05 and 0.25, with $\lambda = 0.08$, $\lambda = 0.10$, and $\lambda = 0.15$ being popular choices. Small values of λ should be used to detect small shifts. Three standard deviation limits, as with the Shewhart charts, seem to work well in most cases; however, if λ is less than 0.10, a value of 2.75σ works somewhat better.

Like the CUSUM chart, the EWMA chart is more effective than the $\overline{X}$ chart in detecting small shifts (less than 2.5σ) in the mean; however, both charts perform worse than the $\overline{X}$ chart for larger shifts. In order to overcome this difficulty, some authors have suggested plotting both the Shewhart limits and the EWMA limits on the same chart (see, for example, Albin et al. 1997).

TABLE 45.8   Data and Calculations for EWMA Chart

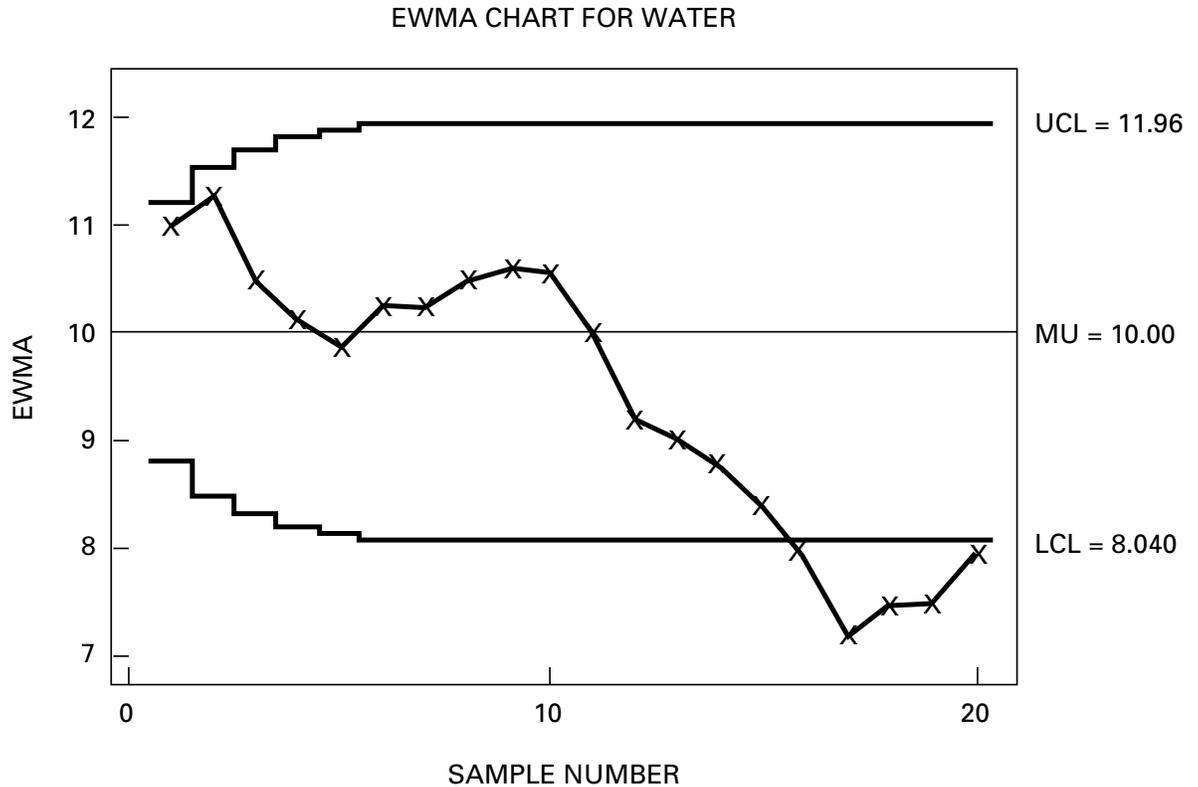
EWMA CHART FOR WATER


FIGURE 45.6   EWMA chart.

SHORT-RUN CONTROL CHARTS

Some processes are carried out in such short runs that the usual procedure of collecting 20 to 30 samples to establish a control chart is not feasible. Sometimes these short runs are caused by previously known assignable causes that take place at predetermined times. Hough and Pond (1995) discuss four ways to construct control charts for such situations:

1. Ignore the systematic variability, and plot on a single chart.
2. Stratify the data, and plot them on a single chart.
3. Use regression analysis to model the data, and plot the residuals on a chart.
4. Standardize the data, and plot the standardized data on a chart.

The last option has received the most consideration. It involves the use of the transformation

$$Z = \frac{X - \mu}{\sigma}$$

to remove any systematic changes in level and variability. This standardization of Shewhart charts has been discussed by Nelson (1989), Wheeler (1991), and Griffith (1996). Control charts of this form have control limits of ±3.0. These charts are sometimes called *Z charts.*

There are several variations of these charts, some of which are as follows:

1. *Difference charts,* in which a constant such as a known mean (μ), an average from past data ($\overline{X}$), a target value (T), or the specification limit is subtracted from each observation. Burr (1989) discussed this chart and included its use to determine process capability.
2. *Standardized charts,* in which a constant as above is subtracted from each observation and the result is divided by a second constant. When the divisor is the standard deviation, the resulting Z values have a standard deviation of 1, and the control limits are ±3 for $\alpha = 0.0027$. The divisor

can be a known standard deviation (σ) or an estimate from past data, such as $\overline{R}/d_2$. Sometimes the divisor is not a standard deviation but some other value. For example, Burr (1989) discussed a measure used at Kodak in which the nominal was subtracted from the observation and the result divided by half the tolerance. This had the advantage of indicating the fraction of the tolerance used by the process as well as the closeness to the nominal.

3. *Short-run $\overline{X}$, R charts,* in which the statistic

$$Z = (\overline{X} - \overline{\overline{X}})/\overline{R}$$

is plotted against control limits for the mean set at $\pm A_2$. The statistic $R/\overline{R}$ is plotted on a range chart with control limits set at D_3 and D_4. The result is a set of dimensionless charts that are suitable for plotting different parts or runs on the same chart.

Another chart for short runs is the Q chart discussed by Quesenberry (1991, 1995a, 1995b). This technique allows the chart to be constructed from initial data without the need of previous estimates of the mean or variance. It allows charting to begin at the start of a production run. Furthermore, the probability integral transformation is used to achieve normality for Q from nonnormal data such as the range or standard deviation. Quesenberry explains how the method may be used for charts for the mean or standard deviation when those parameters are either known or unknown.

To illustrate the Q chart, consider the case where normally distributed measurements are to be plotted when the mean is unknown and the variance is known. The chart for the process location is constructed as follows:

1. Collect individual measurements: $x_1, x_2, x_3, \ldots, x_r$.
2. For the rth point to be plotted, compute

$$Q_r(X_r) = [(r-1)/r]^{1/2}\,[(x_r - \overline{X}_{r-1})/\sigma] \qquad r = 1, 2, 3,\ldots$$

where $\overline{X}_{r-1}$ is the average of the previous $r-1$ points.
3. Plot $Q_r(X_r)$ for each of the data points against control limits of ± 3.0.

The chart for process variation is constructed similarly:

1. Use the same measurements: $x_1, x_2,\ldots, x_r$.
2. For the rth data point to be plotted (plot for only even r)
   a. Compute

$$[(x_r - x_{r-1})^2/2\sigma^2], \qquad r = 2, 4, 6,\ldots$$

   b. Find the percentile of the χ^2 distribution with 1 degree of freedom for the value computed in **a**.
   c. Find the normal deviate value for the percentile determined in **b** and set it equal to $Q(R_r)$.
3. Plot $Q(R_r)$ for even data points against control limits of ± 3.0.

BOX-JENKINS MANUAL ADJUSTMENT CHART

J. S. Hunter has suggested an important addition to the charting tools discussed earlier (Hunter 1997). Whereas the Shewhart, CUSUM, and EWMA charts for variables data *monitor* processes, the charts Hunter calls the *Box-Jenkins Manual Adjustment Charts* may be used to *regulate* them. These charts are based on the early work of Box and Jenkins (1962, 1970). Box and Luceño (1997) have recently published a text with a thorough explanation of these techniques. Hunter (1997) includes a worked example accompanied by many graphs.

The Shewhart, CUSUM, and EWMA charts discussed earlier require an operator to plot the time history of the statistic of interest and to leave the process alone as long as the plotted points fall within the control limits and satisfy the run rules. This assumes that the process mean μ is constant and that departures of the data from the mean are independent and normally distributed with a constant variance σ^2. The charts thus *monitor* the process. The objective is to reduce variability by the elimination of special (assignable) cause events identified by the charts.

The Box-Jenkins manual adjustment charts provide a mechanism to forecast and *regulate* the process after each observation. The procedure assumes the process to be *nonstationary*; i.e., the process level is changing constantly, and the variance is increasing. The objective of the procedure is to keep the variance as small as possible.

It is important to note that if the observed deviations from the mean are independent, this method should not be used, and if it is used, it may tend to inflate the process variance. However, if the deviations are not independent, a Box-Jenkins manual adjustment chart can provide both a forecast and the adjustments necessary to force the process to be on target with minimum variance. For a complete discussion of this technique, the reader is referred to the paper by Hunter (1997).

MULTIVARIATE CONTROL CHARTS

When there are two or more correlated quality characteristics that must be controlled simultaneously, such as both the length and weight of a part, the use of multivariate control charts is necessary. If we construct both the dimensions with separate control charts, the region of control will be rectangular, whereas the region using multivariate methods will be elliptical. This means that some observations will be in control in one case and out of control in the other.

Multivariate control charts are beyond the scope of this section, but the reader is referred to Alt et al. (1998), Jackson (1985), or Woodall and Neube (1985) for a detailed discussion of this topic. Multivariate versions of Shewhart, CUSUM, and EWMA charts are available in the literature. They are all discussed with references in Alt et al. (1998).

PRE-CONTROL

The control charts discussed so far in this section provide limits based solely on the observed variation of the process and therefore provide a means to detect process changes. In some situations it is important to detect the presence of only those changes which might incur the presence of nonconforming items. For such cases, control limits may be derived using a combination of the observed frequency and the product specifications. The process is then permitted to change as long as nonconforming items do not become imminent. The chart gives alarm signals only when nonconforming items threaten. Modified control limits [see Wadsworth et al. (1986, pp. 256–266)] and acceptance control charts are two examples of such charts. Acceptance control charts are described in Section 46. Another example of this approach is the PRE-control technique.

PRE-Control starts with a process centered between the specification limits and detects shifts that might result in making some parts outside of the specification limits. PRE-Control requires no plotting and no computations from the sample data. It only requires the inspection of two items to give control information. It uses the normal distribution to determine significant changes in the process that might result in nonconforming items. The principle of PRE-control assumes that the process uses up the entire tolerance spread. That is, the difference between the upper and lower specification limits is 6σ with the process exactly centered.

Two PRE-control (PC) limits are set one-fourth of the way in from each specification limit, as in Figure 45.7. This results in five regions that are often colored for practical applications. The two regions outside the specification limits are colored red. The two regions between the PC limits and the specification limits are colored yellow, and the middle region between the PC limits is colored

green. If the distribution were as indicated in Figure 45.7a, 86 percent of the parts will be in the green zone, whereas 7 percent or one part in 14 will be in each yellow zone. The probability that two successive parts will fall in the same yellow zone will be 1/14 times 1/14, or 1/196 (approximately 1 in 200). Therefore, we can say that if two parts in a row fall in the same yellow zone, there is a much greater chance (195/196) that the process mean has shifted than not. It is advisable then to adjust the process toward the center.

It is equally unlikely to get one part in one yellow zone and the next in the other yellow zone. This would not indicate that the process has shifted but that some new factor has been introduced that has caused the variability to increase to an extent that nonconforming pieces are inevitable. An immediate study of the process and some corrective action must be made before it is safe to continue its operation.

These principles lead to the following set of rules that summarize the PRE-control procedure:

1. Divide the specification band with PC lines located one-fourth of the way in from each specification limit. If desired, color the zones appropriately, as indicated above, red, yellow, and green.

2. Start the process.

3. If the first piece is in the red (nonconforming) zone, adjust the process.

4. If the first piece is in the yellow (caution) zone, check the next piece.

5. If the second piece is in the same yellow zone, adjust the process toward the center.

6. If the second piece is in the green (good) zone, continue the process, and adjust the process only when two pieces in a row are in the same yellow zone.

7. If two successive pieces are in opposite yellow zones, stop the process and take action to reduce the variability.

8. When five successive pieces fall in the green zone, *frequency gaging* may start and continue as long as the average number of checks to an adjustment is 25. While waiting for five pieces in the green zone, if a piece falls in the yellow zone, restart the count.

9. During frequency gaging, make no process adjustments until a piece exceeds the PC line (yellow zone). If this occurs, check the next piece and continue as in step 6.

10. When the process is adjusted, five successive pieces in the green zone must again be made before returning to frequency gaging.

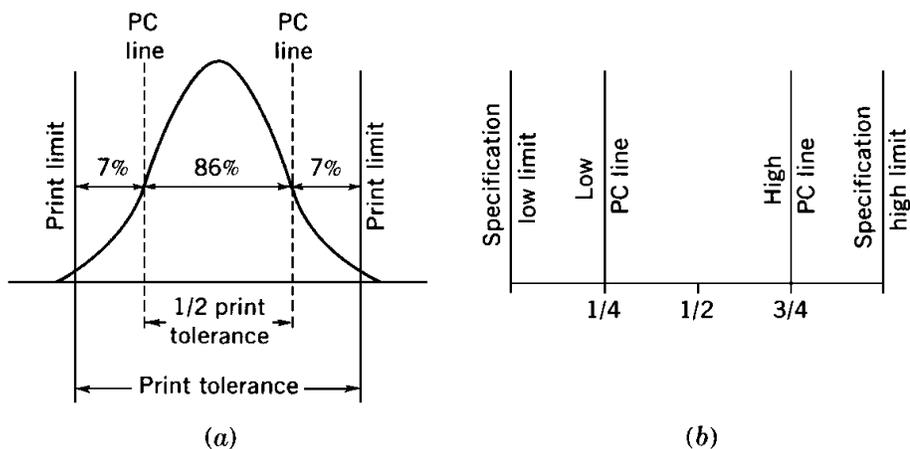
11. If the operator checks more than 25 pieces without having to adjust the process, the frequency of checking may be reduced so that more pieces are produced between checks. If, on the other hand, adjustment is needed before 25 pieces are checked, the frequency of checking should be increased. An average of 25 checks between adjustments is an indication that the frequency is correct.


FIGURE 45.7 (*a*) Assumptions underlying PRE-control. (*b*) Location of PRE-control lines.

For one-sided specification limits, a single PC limit is established halfway between the tolerance and zero (in the case of flatness or concentricity) or one-fourth the distance between the specification limit and the best piece (in the case of a variable like yield or strength). In these cases there is but one yellow zone, one red zone, and one green zone.

The PRE-control technique indicates changes in the process mean or variability. The technique is simple to use and understand, it can make use of go no-go gages, and it can guarantee a certain percentage nonconforming if adjustments are made when indicated. On the other hand, process control techniques such as this, which make use of narrow limit gaging, must be introduced to the shop with care. Unless fully explained, the limits appear to be tightening up the tolerances.

Further discussion of this technique and the statistics behind it may be found in Brown (1966) and Shainin (1984). A comparison of PRE-control with $\overline{X}$ and R charts may be found in Sinibaldi (1985). Ledolter and Swersey (1997) evaluate the PRE-control procedure and conclude that PRE-control "is not an adequate substitute for control charts." They go on to explain that control charts are useful for identifying assignable causes of variation and distinguishing them from chance causes. This is particularly important in the early stages of a process when the process capability is likely to be low ($C_p < 1$). PRE-Control is poorly suited for this situation, and its use is likely to lead to excessive tampering with the process.

STATISTICAL CONTROL OF AUTOMATED PROCESSES

Other sections in this handbook have discussed automated manufacturing processes and the role of computers in both manufacturing and nonmanufacturing processes. The march toward automation has sparked some important innovations in data analysis for the control of processes:

1. Continuous-reading instrumentation that yields large amounts of data on process variables and quality characteristics.
2. Automation of statistical analyses (e.g., calculation of averages, standard deviations, and control limits). This is discussed in the next paragraph.
3. Comparison of process results with preset numerical standards. This comparison may result in
   a. The generation of a document giving pertinent information on a nonstandard condition.
   b. The generation of an error signal that automatically makes a process adjustment.
4. In recent years a great improvement in size control devices has been realized. While an item is being ground, a measuring pair of contacts monitors the change in size and electronically instructs the grinding wheel to prepare to stop as the desired size is being approached.

Software for Statistical Process Control.   Many personal computer programs are available for statistical analysis of data, including all types of control charts. Gages with direct digital output into hand-held data-collection devices are available. These devices will store the gage readings collected on the shop floor and download them into a personal computer in the office. As an alternative, gage readings may be entered into the collection device with its keyboard.

The software will calculate the sample statistics, initial control limits, and the control chart. Control limits may be easily recalculated periodically, and $\pm 2\sigma$ limits can be calculated as an additional guide. Most software will provide additional summaries and analyses such as listing of the raw data, out-of-specification values, histograms, checks for runs and other patterns within control limits, tests for normality, process capability calculations, Pareto charts, and trend analyses.

The relatively low cost of personal computers and the availability of software have contributed substantially to the renewed interest in $\overline{X}$ and R and other control charts. This computer software combination also has made it practical to collect large quantities of data and subject them to complex analyses. However, process improvement still requires the identification of the vital few and often of unexpected variables causing excess variation. Computer analysis of previous data are no substitute for such tools as design of experiments. Computers are most helpful when the diagnostician has created a template for a spreadsheet program and least helpful when a packaged statistical

analysis program is used. Users of such programs are rarely familiar with the detailed logic of the prepackaged programs and can be led to erroneous conclusions.

The American Society for Quality annually publishes a directory of software for process control and other statistical uses (ASQC 1996). In addition, the *Journal of Quality Technology* (ASQ) and *Quality* (Hitchcock Publishing Company) have computer columns describing programs for process control.

SECTION 46

ACCEPTANCE SAMPLING[1]

Edward G. Schilling

INTRODUCTION

Acceptance Sampling—General.   Acceptance sampling refers to the application of specific sampling plans to a designated lot or sequence of lots. Acceptance sampling procedures can, however, be used in a program of *acceptance control* to achieve better quality at lower cost, improved control, and increased productivity. This involves the selection of sampling procedures to continually match operating conditions in terms of quality history and sampling results. In this way the plans and procedures of acceptance sampling can be used in an evolutionary manner to supplement each other in a continuing program of acceptance control for quality improvement with reduced inspection. It is the objective of acceptance control in any application to eventually phase out acceptance sampling in favor of supplier certification and process control. After explaining a variety of specific sampling procedures, this section concludes with suggestions on how and when to progress from sampling inspection toward reliance on process control and check inspection and eventually to no inspection at all, depending on the stage of the life cycle of the product and the state of control.

The disposition of a lot can be determined by inspecting every unit ("100 percent inspection") or by inspecting a sample or portion of the lot. Economy is the key advantage of acceptance sampling as compared with 100 percent inspection. However, sampling has additional advantages:

1. Economy due to inspecting only part of the product
2. Less handling damage during inspection
3. Fewer inspectors, thereby simplifying the recruiting and training problem
4. Upgrading the inspection job from piece-by-piece decisions to lot-by-lot decisions
5. Applicability to destructive testing, with a quantified level of assurance of lot quality
6. Rejections of entire lots rather than mere return of the defectives, thereby providing stronger motivation for improvement

Sampling also has some inherent disadvantages:

1. There are risks of accepting "bad" lots and of rejecting "good" lots.
2. There is added planning and documentation.
3. The sample usually provides less information about the product than does 100 percent inspection.

Acceptance sampling under a system of acceptance control provides assurance that lots of product are acceptable for use. It is assumed that acceptable product is normally being submitted by honest, conscientious, capable suppliers. The plans provide warnings of discrepancies as a means of forestalling use of the product while providing signals of the presence of assignable causes for both the producer and the consumer. If this is not so, other means of dealing with the supplier should be used—such as discontinuance or 100 percent inspection. This is why it is called acceptance sampling.

Why Is Sampling Valid?   The broad scheme of use of sampling is shown in Figure 46.1. It is universally realized that inspection of a sample gives information then and there about the quality of the pieces in the lot. But that is only the beginning. Beyond this, a vast area of knowledge is unfolded because *the product can tell on the process.*

The sample, being the result of the variables present in the process at the time of manufacture, can give evidence as to those variables. Thereby it is possible to draw conclusions as to whether the process was doing good work or bad at the time it produced the samples.

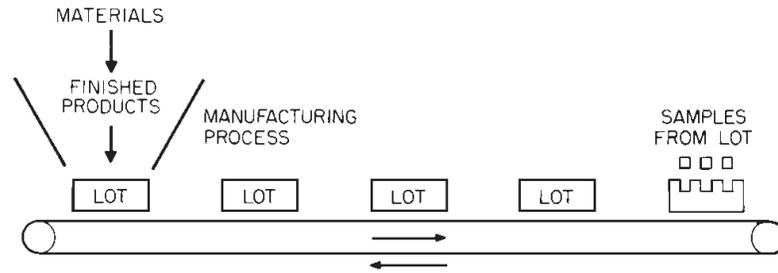
From these conclusions about the process, it is then possible to reverse the reasoning, so that the known *process now can tell on the product.* We already know about the inspected product, but the knowledge of the process gives information about the uninspected pieces. In this way acceptance sampling of a lot is valid not only because the uninspected pieces are neighbors of the inspected


FIGURE 46.1   Measurement of a sample tells (1) whether the pieces in the sample are good or bad; (2) whether the process, at the time the sample was made, was doing good work or bad; (3) whether the uninspected pieces made at the same time by the same process are good or bad (principle of sampling inspection); (4) whether the process is stable; (5) whether the unmanufactured pieces are going to be good or bad (control inspection).

pieces; acceptance sampling is also valid because the uninspected pieces may be derived from the same process which the inspected pieces have labeled as "good."

When we go a step further and examine a series of samples, we learn whether the process is stable or not. Once the series of samples tells on the process by certifying stability, we can use this knowledge of stability to predict the quality of unmanufactured product.

Cowden (1957) has summarized the characteristics of a good acceptance plan. It will:

1. Protect the producer against having lots rejected when the product is in a state of control, and satisfactory as to level and uniformity
2. Protect the consumer against the acceptance of bad lots
3. Provide long-run protection to the consumer
4. Encourage the producer to keep the process in control
5. Minimize sampling costs, inspection, and administration
6. Provide information concerning product quality

Types of Sampling.   Any acceptance sampling application must distinguish whether the purpose is to accumulate information on the immediate *product* being sampled or on the *process* which produced the immediate lot at hand. Accordingly, two types of sampling have been distinguished:

Type A: Sampling to accept or reject the immediate lot of product at hand

Type B: Sampling to determine if the process which produced the product at hand was within acceptable limits

The type of sampling will determine the appropriate probability distribution to be used in characterizing the performance of the plan. In addition, the type of data generated will also play a role. In acceptance sampling, data can be of the following types:

• Attributes—go no-go information

    Defectives—usually measured in proportion or percent defective. This refers to the acceptability of units of product for a wide range of characteristics.

    Defects—usually measured by actual count or as a ratio of defects per unit. This refers to the number of defects found in the units inspected, and hence can be more than the number of units inspected.

• Variables—measurement information

    Variables—usually measured by the mean and standard deviation. This refers to the distribution of a specific measurable characteristic of the product inspected.

Terminology of Acceptance Sampling.   The terminology of acceptance sampling has evolved over the years into a precise and well-directed set of terms defining various properties of acceptance sampling plans and procedures. These are clearly described in the international standard ANSI/ISO/ASQC A3534 (1993), "Statistics—Vocabulary and Symbols."

It is important to distinguish between product which is not fit for use and product which does not meet specification requirements. This is done in ANSI/ISO/ASQC A3534 (1993), Part 2, which uses the term "defect" in relation to the former and "nonconformity" in relation to the latter. These are defined as

Defect: The nonfulfillment of an intended usage requirement.

Nonconformity: The nonfulfillment of a specified requirement.

Clearly a unit of product containing one or more defects or nonconformities is a "defective" or "nonconforming unit."

Since acceptance sampling plans usually relate to requirements imposed by the customer (internal or external), the terms "defect" and "defective" will be generally used here. Furthermore, in referring to the literature of acceptance sampling, the terms "defect" and "defective" will be commonly found. However, in appropriate instances in this section such as variables sampling plans which compare measurements to specifications, the terms "nonconformity" and "nonconforming unit" will be used.

Acceptance Sampling Procedures

Forms of Sampling.   Sampling plans can be classified in two categories: attributes plans and variables plans.

Attributes Plans.   In these plans, a sample is taken from the lot and each unit classified as conforming or nonconforming. The number nonconforming is then compared with the acceptance number stated in the plan and a decision is made to accept or reject the lot. Attributes plans can further be classified by one of the two basic criteria:

1. Plans which meet specified sampling risks provide protection on a lot-by-lot basis. Such risks are
   a. A specified quality level for each lot (in terms of percent defective) having a selected risk (say 0.10) of being accepted by the consumer. The specified quality level is known as the lot tolerance percent defective or limiting quality (p_2); the selected risk is known as the consumer's risk (β).
   b. A specified quality level for each lot such that the sampling plan will accept a stated percentage (say 95 percent) of submitted lots having this quality level. This specified quality level is termed the acceptable quality level (AQL). The risk of rejecting a lot of AQL quality (p_1) is known as the producer's risk (α).
2. Plans which provide a limiting average percentage of defective items for the long run. This is known as the average outgoing quality level (AOQL).

Variables Plans.   In these plans, a sample is taken and a measurement of a specified quality characteristic is made on each unit. These measurements are then summarized into a simple statistic (e.g., sample mean) and the observed value compared with an allowable value defined in the plan. A decision is then made to accept or reject the lot. When applicable, variables plans provide the same degree of consumer protection as attributes plans while using considerably smaller samples.

Attributes plans are generally applied on a percent defective basis. That is, the plan is instituted to control the proportion of accepted product which is defective or out of specification. Variables plans for percent defective are also used in this way. Such plans provide a sensitivity greater than attributes but require that the shape of the distribution of individual measurements must be known and stable. The shape of the distribution is used to translate the proportion defective into specific values of process parameters (mean, standard deviation) which are then controlled.

Variables plans can also be used to control process parameters to given levels when specifications are directed toward the process average or process variability and not specifically to percent defective. These variables plans for process parameter do not necessarily require detailed knowledge of the shape of the underlying distribution of individual measurements.

Sampling plans used in reliability and in the sampling of bulk product are generally of this type. Published plans in the reliability area, however, usually require detailed knowledge of the shape of the distribution of lifetimes. Some of the important features of attributes and variables plans for percent defective are compared in Table 46.1.

The principal advantage of variables plans for percent defective over corresponding attributes plans is a reduction in the sample size needed to obtain a given degree of protection. Table 46.2 shows a comparison of variables sample sizes necessary to achieve the same protection as the attributes plan: $n = 125$, $c = 3$ (sample size of 125 units, allowable number of defectives of 3).

Types of Sampling Plans.   In single-sampling plans, the decision to accept or reject a lot is based on the results of inspection of a single group of units drawn from the lot. In double-sampling plans, a smaller initial sampling is usually drawn, and a decision to accept or reject is reached on the basis of this smaller first sample if the number of defectives is either quite large or quite small. A second sample is taken if the results of the first are not decisive. Since it is necessary to draw and inspect the second sample only in borderline cases, the average number of pieces inspected per lot is generally smaller with double sampling. In multiple-sampling plans, one, or two, or several still smaller samples of n individual items are taken (usually truncated after some number of samples) until a decision to accept or reject is obtained. The term "sequential-sampling plan" is generally used when

TABLE 46.1   Comparison of Attributes and Variables Sampling Plans for Percent Defective

Feature	Attributes	Variables
Inspection	Each item classified as defective or nondefective. Go no-go gages may be employed.	Each item measured. Inspection more sophisticated. Higher inspection and clerical cost.
Distribution of individual measurements	Need not be known.	*Must* be known (normal usually assumed).
Type of defect	Any number of defect types can be assessed by one plan.	Separate plan required for each type of defect.
Sample size	Depends on protection required.	Smaller sample size for same protection as attributes (at least 30% smaller*).
Process information	Percent defective.	Percent defective plus valuable information on process average and variability for corrective action.
Severity	Weights all defectives of a given kind equally.	Weights each unit inspected by its proximity to specifications.
Evidence to supplier	Defectives available as evidence.	Possible for lot to be rejected on sample containing no defectives.
Measurement errors	Measurements not recorded.	Measurements available for review.
Screened lots	No effect on performance of plan.	Screened lots may be rejected in error even though they contain no defectives.

*Bowker and Goode (1952), pp. 32–33. Assumes single sample of one characteristic.

TABLE 46.2   Comparison of Variables and Attributes Sample Sizes*

$p_1 = 0.0109; \alpha = 0.05; p_2 = 0.0535; \beta = 0.10$	
Plan	Sample size
Single-sampling attributes	125
Variables:	
σ known	19
σ unknown (s)	52
σ unknown ($\overline{R}$ of groups of 5)	75
Sequential sampling, σ known (ASN at p_1)	10.3

*Specifications assumed to be $> 6\sigma$ apart if two-sided.

the number of samples is unlimited and a decision is possible after each individual unit has been inspected.

   Sampling Schemes and Systems.   While simple sampling plans are often employed solely in sentencing individual lots, sampling schemes and systems are generally used in acceptance control applications involving a steady flow of product from the producer. The ANSI/ISO/ASQC A3534 (1993) standard defines a sampling plan as "a specific plan which states the sample size(s) to be used and the associated criteria for accepting the lot," and a sampling scheme as "a combination of sampling plans with rules for changing from one plan to another." Finally, it defines an acceptance sampling system as, "a collection of sampling schemes, each with its own rules for changing plans, together with criteria by which appropriate schemes may be chosen." Thus, $n = 134$, $c = 3$ is a sampling plan; Code J, 1.0 percent AQL is a sampling scheme; and ANSI/ASQC Z1.4 (1993) is a sampling system.

Published Tables and Procedures.   From the point of view of ease of negotiation between the producer and the consumer, it is usually best to use the published procedures and standards. This avoids problems of credibility created when one party or the other generates its own sampling plan. Also, the legal implications of using plans which appear in the literature (such as Dodge-Romig plans) or have been subjected to national consensus review (such as ANSI/ASQC Z1.4, 1993) are obvious. Unique plans, specifically generated for a given application, are probably best used internally.

Screening.   In view of advances in automatic inspection equipment and computer integrated manufacturing, 100 percent inspection, or screening, has become more attractive. This is particularly true in the short run; however, dependence on screening may inhibit efforts for continual improvement as a long-term strategy. Screening procedures have been designed to address important considerations such as the selection of a screening variable, prior information on the population, cost, losses due to erroneous decisions, variation in product quality, and environmental considerations. Methods include: statistical models, such as Deming's all-or-none rule, Taguchi's model for tolerance design, and economic and statistical models using correlated variables. Other issues include the possibility of burn-in, group testing, allocation of inspection effort, selection of process parameters, and selective assembly. An excellent systematic literature review will be found in Tang and Tang (1994). An example of the use of a correlated variable to improve 100 percent inspection is given by Mee (1990). Jaraiedi, Kochhar, and Jaisingh (1987) discuss a model for determining the average outgoing quality for product which has been subjected to multiple 100 percent inspections. A computer program for application of their results will be found in Nelson and Jaraiedi (1987).

SAMPLING RISKS AND PARAMETERS

Risks.   When acceptance sampling is conducted, the real parties of interest are the producer (supplier or Production department) and the consumer, i.e., the company buying from the supplier or the department to use the product. Since sampling carries the risk of rejecting "good" lots and of accepting "bad" lots, with associated serious consequences, producers and consumers have attempted to standardize the concepts of what constitutes good and bad lots, and to standardize also the risks associated with sampling. These risks are stated in conjunction with one or more parameters, i.e., quality indices for the plan. These indices are as follows.

Producer's Risk.   The producer's risk α is the probability that a "good" lot will be rejected by the sampling plan. In some plans, this risk is fixed at 0.05; in other plans, it varies from about 0.01 to 0.10. The risk is stated in conjunction with a numerical definition of the maximum quality level that may pass through the plan, often called the acceptable quality level.

    Acceptable Quality Level.   Acceptable quality level (AQL) is defined by ANSI/ISO/ASQC A3534 as follows: "When a continuing series of lots is considered, a quality level which for purposes of sampling inspection is the limit of satisfactory process average." A sampling plan should have a low producer's risk for quality which is equal to or better than the AQL.

Consumer's Risk.   The consumer's risk β is the probability that a "bad" lot will be accepted by the sampling plan. The risk is stated in conjunction with a numerical definition of rejectable quality such as lot tolerance percent defective.

    Lot Tolerance Percent Defective.   The lot tolerance percent defective (LTPD) is the level of quality that is unsatisfactory and therefore should be rejected by the sampling plan. A consumer's risk of 0.10 is common and LTPD has been defined as the lot quality for which the probability of acceptance is 0.10; i.e., only 10 percent of such lots will be accepted. (LTPD is a special case of the concept of limiting quality, LQ, or rejectable quality level, RQL. The latter terms are used in tables that provide plans for several values of the consumer's risk as contrasted to a value of 0.10 for the LTPD.) Limiting quality (LQ) plans will be found in the international standard ISO 2859-2 (1985) and in the U.S. national standard Q3 as well as the LTPD plans in Dodge and Romig (1959).

    A third type of quality index, average outgoing quality limit, is used with 100 percent inspection of rejected lots and will be discussed later in this section.

    The producer's and consumer's risks and associated AQL and LTPD are summarized graphically by an operating characteristic curve.

Operating Characteristic Curve.   The operating characteristic (OC) curve is a graph of lot fraction defective versus the probability that the sampling plan will accept the lot.

    Figure 46.2 shows an ideal OC curve for a case where it is desired to accept all lots 3 percent defective or less and reject all lots having a quality level greater than 3 percent defective. Note that all lots less than 3 percent defective have a probability of acceptance of 1.0 (certainty); all lots greater than 3 percent defective have a probability of acceptance of zero. Actually, however, no sampling plan exists that can discriminate perfectly; there always remains some risk that a "good" lot will be rejected or

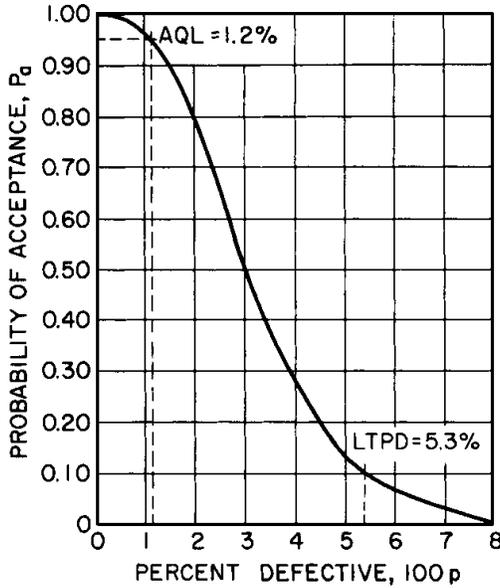
FIGURE 46.2   An ideal sampling plan performance.


FIGURE 46.3 An actual sampling plan performance.

that a "bad" lot will be accepted. The best that can be achieved in practice is to control these risks.

Figure 46.3 shows the curve of behavior that would be obtained if an operator were instructed to take a sample of 150 pieces from a large lot and to accept the lot if no more than four defective pieces were found. Such curves can be constructed from the appropriate probability distribution. For example, using the Poisson table (Appendix II, Table E), we find that for a sample size of 150 ($n = 150$) and 2 percent defective ($p = 0.02$) we would expect $np = 3.0$ defectives in the sample. The table shows for $r = 4$ and $np = 3.0$, the probability of acceptance (for four or fewer defectives) is 0.815.

It is seen from this curve that a lot 3 percent defective has one chance in two of being accepted. However, a lot 3.5 percent defective, though technically a "bad" lot, has 39 chances in 100 of being accepted. In like manner, a lot 2.5 percent defective, though technically a good lot, has 34 chances in 100 of not being accepted.

The effect of parameters of the sampling plan on the shape of the OC curve is demonstrated in Figure 46.4, where the curve for perfect discrimination is given along with the curves for three particular acceptance sampling plans. The following statements summarize the effects:

1. When the sample size approaches the lot size or, in fact, approaches a large percentage of the lot size, and the acceptance number is chosen appropriately, the OC curve approaches the perfect OC curve (the rectangle at p_1).
2. When the acceptance number is zero, the OC curve is exponential in shape, concave upward (see curves 2 and 3).
3. As the acceptance number increases, the OC curve is pushed up, so to speak, for low values of p, and the probability of acceptance for these quality levels is increased, with a point of inflection at some larger value of p (see curve 1).
4. Increasing the sample size and the acceptance number together gives the closest approach to the perfect discrimination OC curve (see curve 1).

It is sometimes useful to distinguish between type A and type B OC curves (see Dodge and Romig, 1959, pp. 56–59). Type A curves give the probability of acceptance for an individual lot that comes from finite production conditions that cannot be assumed to continue in the future. Type B curves assume that each lot is one of an infinite number of lots produced under essentially the same production conditions. In practice, most OC curves are viewed as type B. With the few exceptions noted, this section assumes type B OC curves.

Average Sample Number Curve. The average sample number (ASN) is the average number of units inspected per lot in sampling inspection, ignoring any 100 percent inspection of rejected lots. In single-sampling inspection the ASN is equal to n, the sample size. However, in double- and multiple-sampling plans the probability of not reaching a decision on the initial sample, and consequently being forced to inspect a second, third, etc., sample must be considered. For a double-sampling plan with sample sizes n_1 and n_2, the average sample number, ASN is simply

$$\text{ASN} = n_1 + (1 - P_{a1}) \, n_2$$

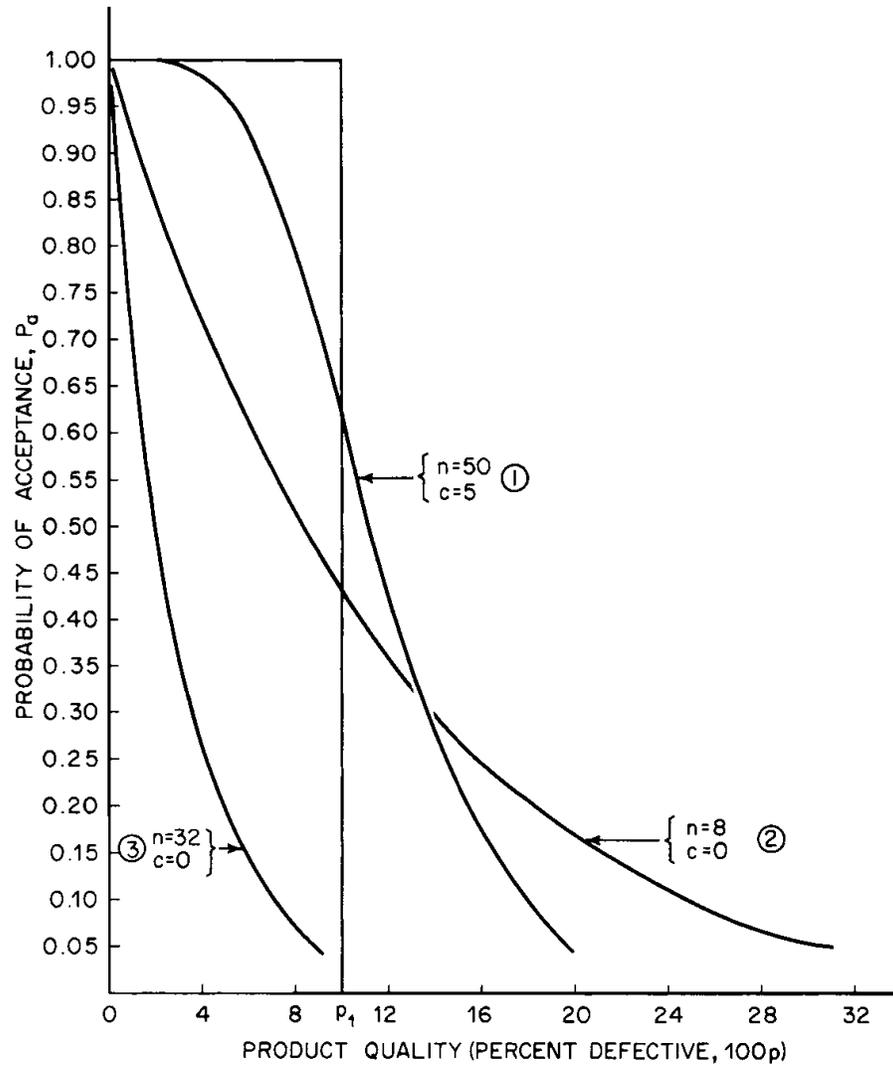
where P_{a1} is the probability of acceptance on the first sample. The ASN for multiple sampling is more complicated to calculate; see Schilling (1982).


FIGURE 46.4   Shape of the OC curve.

A comparison of ASN for some specific plans, roughly matching $n = 125$, $c = 3$, is shown in Figure 46.5. (The calculations assume that all samples selected are completely inspected.) As indicated, double and multiple sampling generally lead to economies over single sampling when quality is either very good or very poor.

Average Outgoing Quality Limit.   The acceptable quality level (AQL) and lot tolerance percent defective (LTPD) have been cited as two common quality indices for sampling plans. A third commonly used index is the average outgoing quality limit (AOQL). The AOQL is the upper limit of average quality of outgoing product from accepted lots and from rejected lots which have been screened.

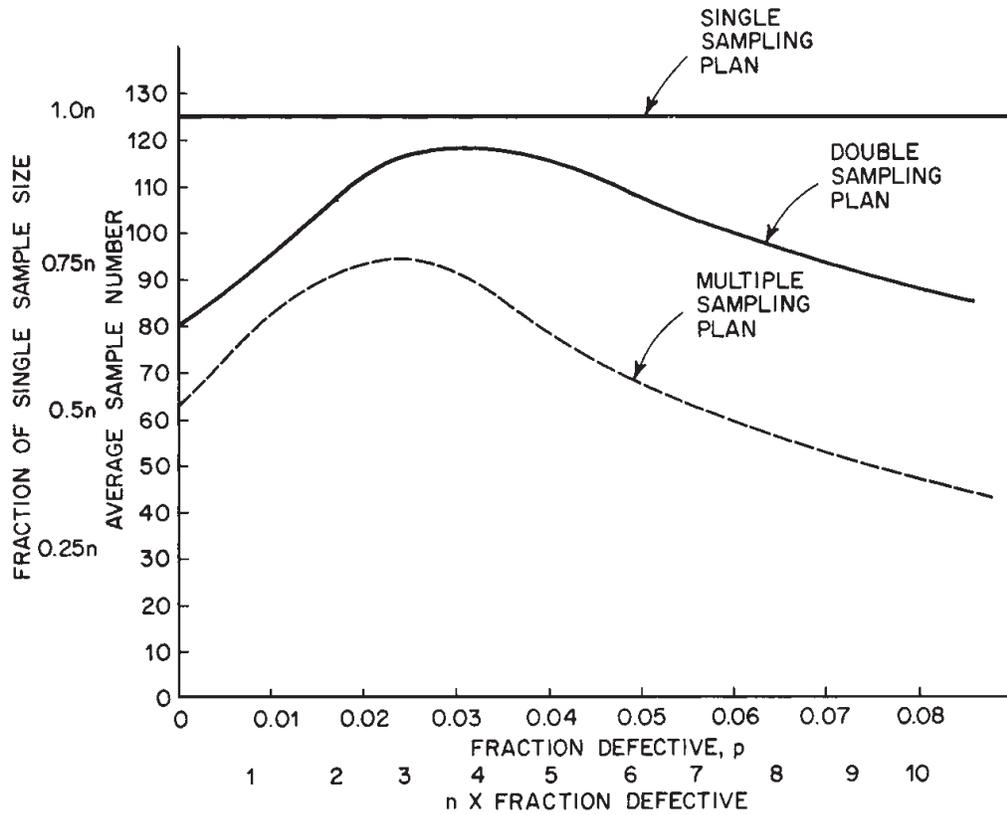
The AOQL concept stems from the relationship between the fraction defective before inspection (incoming quality) and the fraction defective after inspection (outgoing quality) when inspection is nondestructive and rejected lots are screened. When incoming quality is perfect, outgoing quality must likewise be perfect. However, when incoming quality is very bad, outgoing quality will also be near perfect, because the sampling plan will cause most lots to be rejected and 100 percent inspected. Thus, at either extreme—incoming quality very good or very bad—the outgoing quality will tend to be very good. It follows that between these extremes is the point at which the percent defective in the outgoing material will reach its maximum. This point is known as the AOQL.


FIGURE 46.5   Average sample number versus fraction defective.

If p is incoming quality, P_r is the probability of lot rejection, and all rejected lots are screened and made free of defects (i.e., 0 percent), then

$$\text{AOQ} = (p)P_a + (0)P_r = (p)P_a$$

This calculation is approximate in that it does not account for the small effect of 100 percent inspection of the units in the samples from accepted lots. Taking this into account:

$$\text{AOQ} = pP_a \left(1 - \frac{n}{N} \right)$$

for sample size n and lot size N.

Average Outgoing Quality Curve.   An example of the calculation for the AOQL and a plot of the average outgoing quality (AOQ) curve is shown in Table 46.3 and Figure 46.6. Schilling (1982) has indicated that for acceptance numbers of five or less

$$\text{AOQL} \simeq \frac{0.4}{n} (1.25c + 1)$$

Average Total Inspection.   The average total inspection (ATI) takes into account the likelihood of 100 percent inspection of rejected lots when this is possible; i.e., inspection is nondestructive. The lot size N must now be taken into account. Again with single-sampling plans with sample size n, lot size N, probability of acceptance P_a, and probability of rejection P_r,

$$\text{ATI} = P_a n + P_r N$$

TABLE 46.3 Computations for Average Outgoing Quality Limit (AOQL); for This Example, $n = 78$, $c = 1$

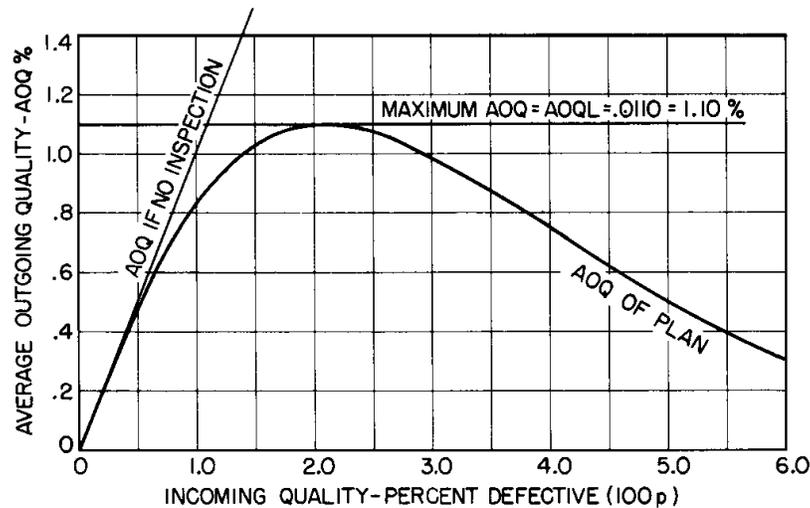
*AOQL $\cong$ maximum AOQ $\cong$ 0.01100 = 1.1%.


FIGURE 46.6 AOQ curve and AOQL for a typical sampling plan.

An extension to double sampling is simply

$$\text{ATI} = n_1 + (1 - P_{a1})n_2 + (N - n_1 - n_2)(1 - P_a)$$

where P_{a1}, is the probability of acceptance on the first sample. Extension to multiple-sampling plans of k levels is straightforward and will not be derived here. See Schilling (1982).

Minimum Total Inspection. Minimum inspection per lot, for a given type of protection, can be illustrated by the following example:

Assume that a consumer establishes acceptance criteria as an LTPD of 5 percent. A great many sampling plans meet this criterion. Some of these plans are

Take from each lot a sample n of	Accept the lot if the number of defectives does not exceed the maximum acceptance number c
46	0
78	1
106	2
134	3
160	4

Figure 46.7 shows the corresponding operating characteristic curves. Each plan has an LTPD of 5 percent; i.e., the probability of acceptance of a submitted inspection lot with fraction defective of 0.05 is 0.10. Which plan should be used? One logical basis for choosing among these plans is to use that one which gives the least inspection per lot.

The total number of units inspected consists of (1) the sample which is inspected for each lot and (2) the remaining units which must be inspected in those lots which are rejected by the sampling inspection. The number of lots rejected in turn depends on the normal level of defectives in the product so that minimum inspection is a function of incoming quality.

A sample computation of minimum inspection per lot is shown in Table 46.4. It is assumed that rejected lots are detail (100 percent) inspected. For small acceptance numbers the total inspection is high because many lots need to be detailed. For large acceptance numbers the total is again high, this time because of the large size of samples. The minimum sum occurs at a point between these extremes.

From the foregoing it is seen that for any specified conditions of

Lot tolerance percent defective

Consumer's risk

Lot size

Process average

it becomes possible to derive the values of

$$n = \text{sample size}$$

$$c = \text{allowable number of defectives in the sample}$$

to obtain

$$I_m = \text{minimum inspection per lot}$$

Similar reasoning may be applied in making a selection from a group of sampling plans designed to give the same average outgoing quality limit (AOQL).

Complete tables for sampling have been derived for minimum inspection per lot for a variety of $\bar{p}$, LTPD, and AOQL values (e.g., Dodge and Romig 1959). These will be described later.

Selection of a Numerical Value of the Quality Index.   There are three alternatives for evaluating lots: no inspection, inspect a sample, 100 percent inspection (or more). An economic evaluation of these alternatives requires a comparison of *total* costs under each of the alternatives.

Enell (1954) has suggested that a break-even point be used in the selection of quality index:

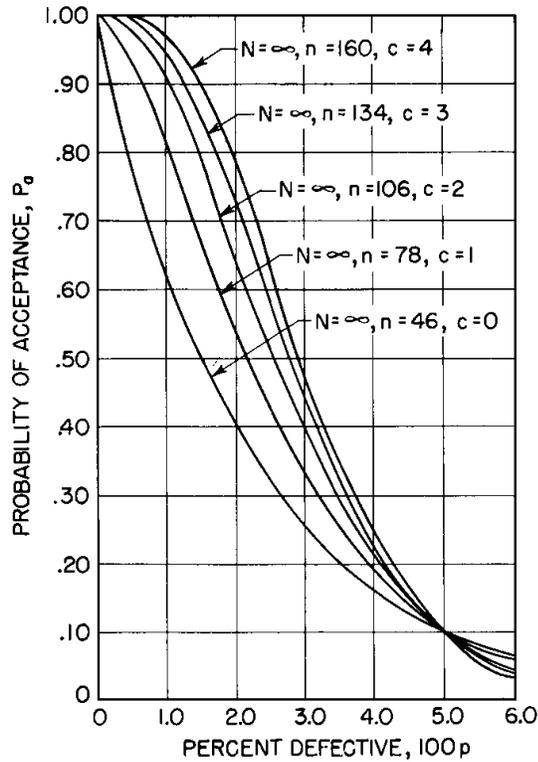
$$P_b = \frac{I}{A}$$


FIGURE 46.7 Family of sampling plans each having LTPD = 0.05.

TABLE 46.4 Computation of Minimum Inspection per Lot for 5 Alternative $n-c$ Combinations Appropriate to Lots of $N=1000$ Articles

All plans have the same lot tolerance percent defective. Incoming material has a process average percent defective, $\overline{p} = 0.5\%$.

				Average no. pieces inspected		
Sample size n	Allowable number of defects c	Probability of acceptance by sampling P_a	Probability of inspecting residue of lot $1-P_a$	In sample* n	In rest of lot† (N $-n$) × (1 $-P_a$)	Total inspected per lot
46	0	0.795	0.205	46	196	242

160	4	0.998	0.002	160	2	162

*The sample size indicates the number inspected from each lot.

†The size of the uninspected residue of the lot, multiplied by the probability that it will have to be inspected because of rejection of the sample.

‡This is the minimum sought.

where I = inspection cost per item and A = damage cost incurred if a defective slips through inspection. If it is thought that the lot quality p is less than p_b, the total cost will be lowest with sampling inspection or no inspection. If p is greater than p_b, 100 percent inspection is best. If p is unknown, it may be best to sample using an appropriate sampling plan such as an AOQL scheme.

For example, a microcomputer device costs \$0.50 per unit to inspect. A damage cost of \$10.00 is incurred if a defective device is installed in the larger system. Therefore,

$$p_b = \frac{0.50}{10.00} = 0.05 = 5.0\%$$

If it is expected that the percent defective will be greater than 5 percent, then 100 percent inspection should be used. Otherwise, use sampling or no inspection.

The formula assumes that the sample size is small compared to the lot size, the cost to replace a defective found in inspection is borne by the producer or is small compared to the damage or inconvenience caused by a defective, and no inspection errors occur.

As a 5 percent defective quality level is the break-even point between sorting and sampling, the appropriate sampling plan should provide for a lot to have a 50 percent probability of being sorted or sampled; i.e., the probability of acceptance for the plan should be 0.50 at a 5 percent defective quality level. The operating characteristic curves in a set of sampling tables such as ANSI/ASQC Z1.4 can now be examined to determine an AQL. For example, suppose that the device is inspected in lots of 3000 pieces. The operating characteristic curves for this case (code letter K) are shown in ANSI/ASQC Z1.4. The plan closest to having a P_a of 0.50 for a 5 percent level is the plan for an AQL of 1.5 percent. Therefore, this is the plan to adopt. Other economic models have been developed. For example, see Tagaras (1994) for the case of variables sampling.

In practice, the quantification of the quality index is a matter of judgment based on the following factors:

1. Past performance on quality
2. Effect of nonconforming product on later production steps
3. Effect of nonconforming product on fitness for use
4. Urgency of delivery requirements
5. Cost to achieve the specified quality level

IMPLEMENTATION OF AN ACCEPTANCE SAMPLING PROCEDURE

Assumptions Made in Sampling Plans

Inspection Error.   In implementing acceptance sampling plans, it is commonly assumed that:

1. The inspectors follow the prescribed sampling plan.
2. The inspection is made without error; i.e., no human or equipment mistakes are made in measurement or in judging conformance.

In practice, these assumptions are not fully valid. See Section 23, under Inspection Errors.

The effect of inspection error has received considerable attention in the literature of quality. For example, see Johnson, Kotz, and Rodriguez (1985, 1986, 1988, 1990) and Suich (1990).

Units of Product.   These may consist of (1) discrete pieces or (2) specimens from bulk material. The criteria used for judging the conformance of a single unit of product to standard are somewhat different for these two categories. The criteria used for judging lot conformance differ even more widely.

Seriousness Classification of Defects.   Many sampling plans set up their criteria for judging lot conformance in terms of an allowable number of defects in the sample. Since defects differ greatly in seriousness, the sampling plans must somehow take these differences into account.

Where there exists a formal plan for seriousness classification of defects, the sampling plans may be structured so that:

1. A separate sampling plan is used for each seriousness class, e.g., large sample sizes for critical defects, small sample sizes for minor defects.

2. A common sampling plan is used, but the allowable number of defects varies for each class; e.g., no critical defects are allowed, but some minor defects are allowed.

3. The criteria may be established in terms of defects per hundred units, the allowable number being different for each class.

4. The criteria may be based on demerits per unit; i.e., all defects found are converted to a scale of demerits based on the classification system.

In the absence of a formal system of seriousness classification, all defects are considered equally important during the sampling inspection. However, when nonconforming lots are subsequently reviewed to judge fitness for use, the review board gives consideration to the seriousness of the defects.

Lot Formation.   The general approach to lot formation is discussed in Section 23, under Degree of Inspection and Test Needed. While most acceptance sampling plans can be validly applied regardless of how lots are formed (skip-lot plans are an exception), the economics of inspection and the quality of the accepted product are greatly influenced by the manner of lot formation.

The interrelation of lot formation to economics of inspection is discussed in Section 23 and will not be elaborated here. The interrelation of lot formation to quality of accepted product can be seen from a single example.

Ten machines are producing the same product. Nine of these produce perfect product. The tenth machine produces 100 percent defectives. If lots consist of product from single machines, the defective product from the tenth machine will always be detected by sampling. If, however, the lots are formed by mixing up the work from all machines, then it is inevitable that some defects will get through the sampling plan.

The fact that lot formation so strongly influences outgoing quality and inspection economics has led to some guidelines for lot formation:

1. Do not mix product from different sources (processes, production shifts, input materials, etc.) unless there is evidence that the lot-to-lot variation is small enough to be ignored.

2. Do not accumulate product over extensive periods of time (for lot formation).

3. Do make use of extraneous information (process capability, prior inspections, etc.) in lot formation. Such extraneous information is especially useful when product is submitted in isolated lots, or in very small lots. In such cases the extraneous information may provide better knowledge on which to base an acceptance decision than the sampling data.

4. Do make lots as large as possible consistent with the above to take advantage of low proportionate sampling costs. (Sample sizes do not increase greatly despite large increases in lot sizes.)

When production is continuous (e.g., the assembly line) so that the "lot" is necessarily arbitrary, the sampling plans used are themselves designed to be of a "continuous" nature. These continuous sampling plans are discussed later in this section.

Selecting the Sample.   The results of sampling are greatly influenced by the method of selecting the sample. In acceptance sampling, the sample should be representative of the lot. In those cases where the inspector has knowledge of how the lot was formed, this knowledge can be used in

selecting the sample by stratification (see below). Lacking this knowledge, the correct approach is to use random sampling.

Random Sampling.   All published sampling tables are prepared on the assumption that samples are drawn at random; i.e., at any one time each of the remaining uninspected units of product has an equal chance of being the next unit selected for the sample. To conduct random sampling requires that (1) random numbers be generated and (2) these random numbers be applied to the product at hand.

Random numbers are available in prefabricated form in tables of random numbers (Appendix II, Table CC). One uses such a table by entering it at random (without "looking") and then proceeding in some chosen direction (up, down, right, left, etc.) to obtain random numbers for use. Numbers which cannot be applied to the product arrangement are discarded.

Random numbers may also be generated by various devices. These include:

1. *Calculators or computers:*   Many calculators are available with random-number routines built in. Computers are, of course, an excellent source of random numbers. Statistical software often has random numbers built in.

2. *A bowl of numbered chips or marbles:*   After mixing, one is withdrawn and its number recorded. It is then replaced and the bowl is again mixed before the next number is withdrawn.

3. *Random number dice:*   One form is icosahedron (20-sided) dice. There are three of these, each of a different color, one for units, one for tens, and one for hundreds. (Each die has the numbers from 0 to 9 appearing twice.) Hence one throw of the three dice displays a random number within the interval 000 to 999.

Once the random numbers are available, they must be adapted to the form in which the product is submitted. For systematically packed material, the container system can be numbered to correspond to the system of random numbers. For example, a lot might be submitted in 8 trays, each of which has 10 rows and 7 columns. In such a case, the trays might be numbered from 0 to 7, the rows from 0 to 9, and the columns from 0 to 6. Then, using three-digit random numbers, the digits are assigned to trays, rows, and columns, respectively.

For bulk packed materials, other practical procedures may be used. In the case of small parts, they may be strewn onto a flat surface which is marked with grid lines in a 10 × 10 arrangement. Based on two-digit random numbers, the cell at the intersection of these digits is identified. Within the cell, further positional identity can be determined with a third digit.

For fluid or well-mixed bulk products, the fluidity obviates the need for random numbers, and the samples may be taken from "here and there."

Stratified Sampling.   When the "lots" are known to come from different machines, production shifts, operators, etc., the product is actually multiple lots which have been arbitrarily combined. In such cases, the sampling is deliberately stratified; i.e., an attempt is made to draw the sample proportionately from each true lot. However, within each lot, randomness is still the appropriate basis for sampling.

A further departure from randomness may be due to the economics of opening containers, i.e., whether to open few containers and examine a few pieces from each.

Sampling Bias.   Unless rigorous procedures are set up for sampling at random and/or by stratification, the sampling can deteriorate into a variety of biases which are detrimental to good decision making. The more usual biases consist of:

1. Sampling from the same location in all containers, racks, or bins

2. Previewing the product and selecting only those units which appear to be defective (or nondefective)

3. Ignoring those portions of the lot which are inconvenient to sample

4. Deciding on a pattern of stratification in the absence of knowledge of how the lot was made up

The classic example is the legendary inspector who always took samples from the four corners and center of each tray and the legendary production worker who very carefully filled these same spots with perfect product.

Because the structured sampling plans do assume randomness, and because some forms of sampling bias can significantly distort the product acceptance decisions, all concerned should be alert to plan the sampling to minimize these biases. Thereafter, supervision and auditing should be alert to assure that the actual sampling conforms to these plans.

ATTRIBUTES SAMPLING

Overview of Single, Double, Multiple, and Sequential Plans.   In general, single, double, multiple, and sequential sampling plans can be planned to give lots of specified qualities nearly the same chance of being accepted; i.e., the operating-characteristic curves can be made quite similar (matched) if desired. However, the best type of plan for one producer or product is not necessarily best for another. The suitability of a plan can be judged by considering the following factors:

1. Average number of parts inspected
2. Cost of administration
3. Information obtained as to lot quality
4. Acceptability of plan to producers

The advantages and disadvantages of the four forms of sampling plans are tabulated in Table 46.5. The average number of parts that need to be inspected to arrive at a decision varies according to the plan and the quality of the material submitted. In cases where the cost of inspection of each piece is substantial, the reduction in number of pieces inspected may justify use of sequential sampling despite its greater complexity and higher administrative costs. On the other hand, where it is not practicable to hold the entire lot of parts while sampling and inspection are going on, it becomes necessary to set aside the full number of items that may need to be inspected before inspection even begins. In these circumstances single sampling may be preferable if the cost of selecting, unpacking, and handling parts is appreciable. It is of course simplest to train personnel, set up records, and administer a single-sampling plan. A crew of inspectors hastily thrown together cannot easily be taught all the intricacies of the more elaborate plans. However, double-sampling plans have been demonstrated to be simple to use in a wide variety of conditions, economical in total cost, and acceptable psychologically to both producer and consumer.

Lot-by-Lot Inspection.   When product is submitted in a series of lots (termed "lot-by-lot"), the acceptance sampling plans are defined in terms of

N = lot size
n = sample size
c = acceptance number, i.e., the allowable number of defects in the sample
r = rejection number

When more than one sample per lot is specified, the successive sample sizes are designated as n_1, n_2, n_3, etc. The successive acceptance numbers are c_1, c_2, c_3, etc. The successive rejection numbers are r_1, r_2, r_3, etc.

Selecting Sampling Plans.   Sampling plans are often specified by choosing two points on the OC curve: the AQL denoted by p_1 and the LTPD symbolized by p_2. Tables have been developed to facilitate the selection process by using unity (np) values from the Poisson distribution. See Cameron (1952), Duncan (1974), and Schilling and Johnson (1980). Such tables use the operating

TABLE 46.5 Comparative Advantages and Disadvantages of Single, Double, and Multiple Sampling

Feature	Single sampling	Double sampling	Multiple sampling	Sequential
Acceptability to producer	Psychologically poor to give only one chance of passing the lot	Psychologically adequate	Psychologically open to criticism as being indecisive	Psychologically open to criticism as being more indecisive than multiple
Number of pieces inspected per lot*	Generally greatest	Usually (but not always) 10 to 50% less than single sampling	Generally (but not always) less than double sampling by amounts of the order of 30%	Minimum over all attributes plans
Administration cost in training, personnel, records, drawing and identifying samples, etc.	Lowest	Greater than single sample	Greater	Greatest
Information about prevailing level of quality in each lot	Most	Less than single sample	Less than double	Least

*This is not to be confused with total cost of inspection, which includes administration cost of the plan.

46.18

ratio, $R = p_2/p_1$, in conjunction with the unity value of (np_1) or (np_2) to obtain the sample size and acceptance number(s) for the plan whose OC curve passes through the points specified. Often other unity values are provided which assess other properties of the plan. Such tables are illustrated below by the Schilling-Johnson (1980) table, reproduced in part as Table 46.6, which uses producer risk $\alpha = 0.05$ and consumer risk $\beta = 0.10$ with equal sample sizes at each stage of a double or multiple sampling plan. The table provides matched sets of single, double, and multiple sampling plans, such that their OC curves are essentially equivalent. For example, if $p_1 = 0.012$ and $p_2 = 0.053$ then $R = 4.4$. The closest value given under the column for R is 4.058, corresponding to an acceptance number of 4. The sample size is then found to be $n = 7.994 \div 0.053 = 150.8$, which would usually be taken to be 150. The operating characteristic curve for the plan can be seen in Figure 46.3.

Single Sampling.   In single sampling by attributes, the decision to accept or reject the lot is based on the results of inspection of a single sample selected from the lot. The operation of a single-sampling plan by attributes is given in Figure 46.8. The characteristics of an attributes sampling plan are given in Table 46.7.

Double Sampling.   In double sampling by attributes, an initial sample is taken, and a decision to accept or reject the lot is reached on the basis of this first sample if the number of nonconforming units is either quite small or quite large. A second sample is taken if the results of the first sample are not decisive. The operation of an attributes double-sampling plan is given in Figure 46.9. The characteristics of an attributes double-sampling plan are given in Table 46.8.

Multiple Sampling.   In multiple sampling by attributes, more than two samples can be taken in order to reach a decision to accept or reject the lot. The chief advantage of multiple sampling plans is a reduction in sample size for the same protection. The operation of multiple sampling by attributes is given in Figure 46.10. The characteristics of a multiple sampling plan are given in Table 46.9.

Sequential Sampling.   In sequential sampling, each item is treated as a sample of size 1, and a determination to accept, reject, or continue sampling is made after inspection of each item. The major advantage of sequential sampling plans is that they offer the opportunity for achieving the minimum sample size for a given protection. The operation of sequential sampling by attributes is given in Figure 46.11. The characteristics of a sequential sampling plan are given in Table 46.10. Attributes sequential plans will be found tabulated by producer's and consumer's risk in the international standard ISO 8422 (1991).

Rectification Schemes.   Rectification schemes are used when it is desired to ensure that the average outgoing quality level of a series of lots will not exceed specified levels. Such schemes employ 100 percent inspection (screening), with nonconforming items replaced by conforming items.

There are two basic types of rectification schemes: LTPD schemes and AOQL schemes. LTPD schemes ensure consumer quality level protection for each lot, while AOQL schemes ensure AOQL protection for a series of lots. Both types of schemes minimize ATI at the projected process average percent nonconforming. See Dodge and Romig (1959).

Continuous Sampling.   Some production processes deliver product in a continuous stream rather than on a lot-by-lot basis. Separate plans have been developed for such continuous production based on the AOQL concept. These plans generally start with 100 percent inspection until some consecutive number of units free of defects is found and then provide for inspection on a sampling basis until a specified number of defective units is found. One hundred percent inspection is then instituted again until a specified number of consecutive good pieces is found, at which time sampling is reinstituted. Continuous sampling plans have been proposed by Harold F. Dodge and modifications

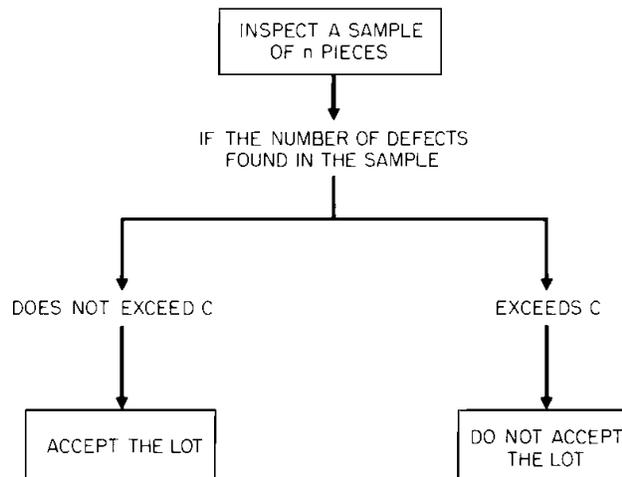
SCHEMATIC OPERATION OF SINGLE SAMPLING


FIGURE 46.8 Schematic of single sampling. In practice, the lot not to be accepted may be repaired, junked, etc. Sampling tables usually assume that the lot is detail-inspected and the defective pieces are all repaired or replaced by good pieces.

TABLE 46.7   Single Sampling by Attributes

Example: Determine a plan which will have AQL $= 100\ p_1 = 1.0\%$ with producer risk $\alpha = 0.05$ and LTPD $= 100p_2 = 5.0\%$ with consumer risk $\beta = 0.10$. Suppose a sample is taken from a lot of $N = 500$ and four nonconforming units are found.

Summary of plan	Calculations
I. Restrictions: Random sample of dichotomous data	

II. Necessary information·
   A. Producer quality level, p_1
   B. Producer risk, α
   C. Consumer quality level, p_2
   D. Consumer risk, β
	II.
	   A. $p_1 = 0.01$
	   B. $\alpha\ = 0.05$
	   C. $p_2 = 0.05$
	   D. $\beta = 0.10$

III. Selection of plan (using Table 46.6)
   A. Calculate operating ratio
 	
$\qquad R = p_2\ /\ p_1$
 	
   B. Choose single sampling plan (S) from Table 46.6 which shows $R \leq$ the value calculated
   C. Acceptance and rejection numbers are given
   D. Determine sample size from value of (np_2) shown for the plan as $n = (np_2)/p_2$; round up
	III.
	   A. $R = 0.05/0.01$
	$\qquad = 5$
	
	   B. Choose Plan 3S since R shown is 4.891
	
	   C. Ac $= 3$
	$\qquad$ Re $= 4$
	   D.
	$\quad n = \dfrac{6.681}{0.05}$

TABLE 46.7   Single Sampling by Attributes *(Continued)*

Summary of plan	Calculations
IV. Elements	IV.
A. Sample size: See III above	*A.* $n = 134$
B. Statistic: d = number nonconforming in sample	*B.* $d = 4$
C. Decision criteria:	
1. Accept if $d \le c$	*C.* $4 > 3$, reject
2. Reject if $d > c$	
V. Action: Dispose of lot as indicated by decision rules.	V. Reject
VI. Measures (using Table 46.6)	VI.
A. Probability of acceptance (OC curve)	*A.*
1. Under each value of probability of acceptance listed across top of table, there corresponds a value of np shown for the plan	1. $P_a = 0.50$ corresponds to $np = 3.672$
2. Divide the values of np by sample size n to get p	2. $p = \dfrac{3.672}{134} = 0.027$
3. Draw OC curve from corresponding values of p and P_a	3. $p = 0.027$ $P_a = 0.50$
B. Average sample number (ASN curve)	*B.*
1. Calculate p from P_a as above	1. $P_a = 0.50$ $p = 0.027$
2. Under the value np from which p was calculated is listed a value of ASN/n_1	2. $ASN/n_1 = 1$
3. Multiply ASN/n_1 by n to obtain ASN corresponding to p	3. $(1)(134) = 134$
4. Draw ASN curve from corresponding values of p and P_a	4. $p = 0.027$ $ASN = 134$
C. Average outgoing quality	*C.*
1. Use formula $$AOQ \simeq p\,P_a$$	1. at $p = 0.027$, $$AOQ = 0.027\,(0.50) = 0.014$$
D. Average outgoing quality limit $$AOQL \simeq \frac{0.4}{n}(1.25c + 1) \text{ for } c \le 5$$	*D.* 1. $AOQL \simeq$ $$\frac{0.4}{134}[1.25(3)+1] \simeq 0.019$$
E. Average total inspection $$ATI = n\,P_a + N(1 - P_a)$$	*E.* at $p = 0.027$ $$ATI = 134(0.5) + 500(0.5) = 317$$

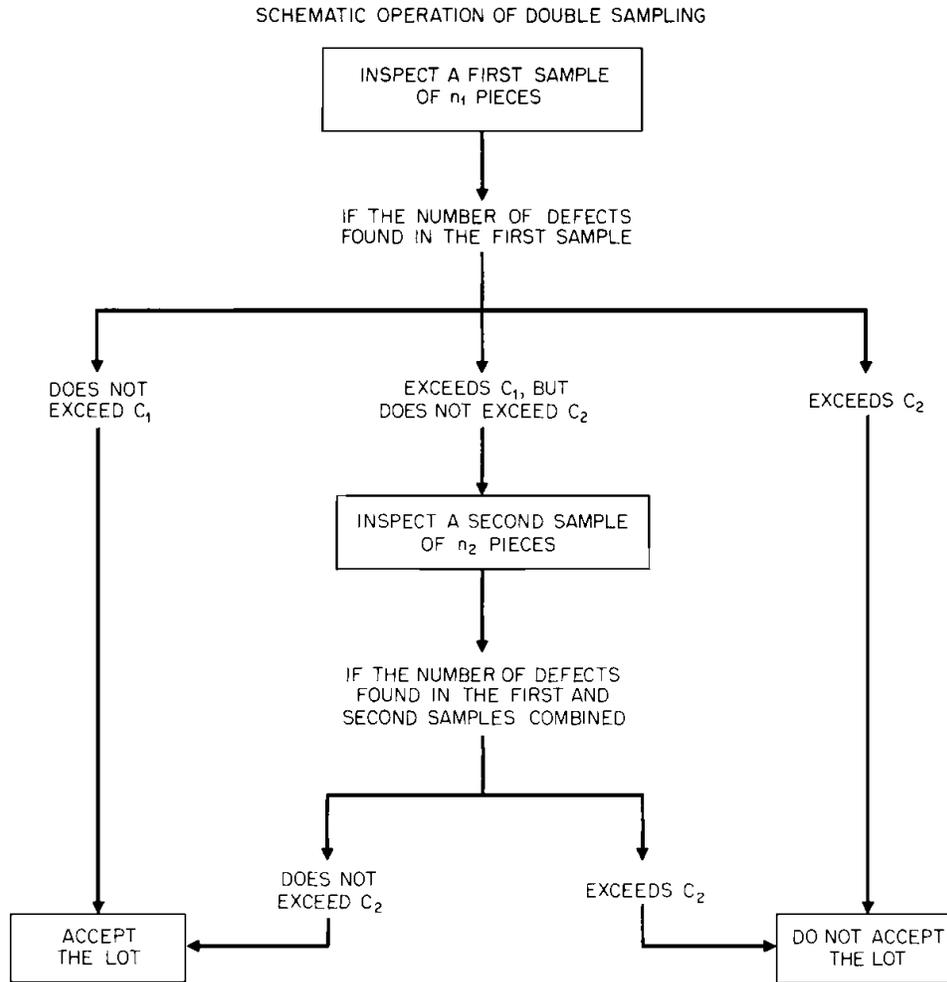
SCHEMATIC OPERATION OF DOUBLE SAMPLING


FIGURE 46.9   Schematic of double sampling. In regard to the lot not to be accepted, inspect the remainder of the pieces, replacing or repairing those defective.

TABLE 46.8   Double Sampling by Attributes

Example: Determine a double sampling plan which will have AQL $= 100p_1 = 1.0\%$ with producer risk $\alpha = 0.05$ and LTPD $= 100p_2 = 5.0\%$ with consumer risk $\beta = 0.10$. Suppose a sample is taken from a lot of $N = 500$ and four non-conforming units are found.

Summary of plan	Calculations
I. Restrictions: Random sample of dichotomous data	

II.   Necessary information
    A. Producer quality level, p_1
    B. Producter risk, α
    C. Consumer quality level, p_2
    D. Consumer risk, β
	II.
	
	A. $p_1 = 0.01$
	B. $\alpha = 0.05$
	C. $p_2 = 0.05$
	D. $\beta = 0.10$

III.   Selection of plan (using Table 46.6)
    A. Calculate operating ratio
 	
        $R = p_2 / p_1$
	III.
	
	A. $R = 0.05/0.01$
	
	    $= 5$

TABLE 46.8 Double Sampling by Attributes (*Continued*)

Summary of plan	Calculations
B. Choose double sampling plan (*D*) from Table 46.6 which shows $R \leq$ the value calculated	*B.* Choose plan 3D since R shown is 4.398
C. Acceptance (*a*) and rejection (*r*) numbers are given as Ac and Re	*C.* First sample $a_1 = 1, r_1 = 4$ Second sample $a_2 = 4, r_2 = 5$
D. Determine first sample size from value of (np_2) shown for the plan as $n = (np_2)/p_2$ This is sample size of each of the double samples	*D.* $n = 4.398/0.05$ $= 88$

IV. Elements   IV.

A. Sample size: See III above	*A.* $n_1 = 88$ $n_2 = 88$
B. Statistic: d_1 = number nonconforming in first sample; d_2 = number nonconforming in second sample	*B.* $d_1 = 4$
C. Decision criteria	*C.*
1. Accept on first sample if $d_1 \leq a_1$	1. 4 not $\leq$ 1
2. Reject on first sample if $d_1 \geq r_1$	2. 4 $\geq$ 4, reject
3. Take a second sample if $a_1 < d_1 < r_1$	
4. Accept on second sample if $d_1 + d_2 \leq a_2$	
5. Reject on second sample if $d_1 + d_2 \geq r_2$	

V. Action: V.
Dispose of lot as indicated by decision rules.   Reject

VI. Measures (using Table 46.6)   VI.

A. Probability of acceptance (OC curve)	*A.*
1. Under each value of probability of acceptance listed across the top of table, there corresponds a value of np shown for the plan	1. $P_a = 0.50$ corresponds to $np = 2.465$
2. Divide the values of np by sample size n to get p	2. $p = \dfrac{2.465}{88}$ $= 0.028$
3. Draw OC curve from corresponding values of p and P_a	3. $p = 0.028$ $P_a = 0.50$
B. Average sample number (ASN curve)	*B.*
1. Calculate p from P_a as above	1. $P_a = 0.50$ $p = 0.028$
2. Under the value np from which p was calculated is listed a value of ASN/n_1	2. ASN/$n_1 = 1.470$
3. Multiply ASN/n_1 by n_1 to obtain ASN corresponding to p	3. 1.470(88) $= 129.4$
4. Draw ASN curve from corresponding values of p and P_a	4. $p = 0.028$ ASN $= 129.4$
C. Average outgoing quality	*C.*

1. Use formula
        $AOQ \simeq p\,P_a$
	1. at $p = 0.028$
	    $AOQ = 0.028(.5)$
	        $= 0.014$

Summary of plan	Calculations

D. Average outgoing quality limit
  1. AOQL = maximum of AOQ curve
 	
E. Average total inspection ATI = $n_1 + n_2(1 - P_{a_1}) + (N - n_1 - n_2)(1 - P_a)$ where
  P_{a_1} is probability of acceptance on first
  sample
	D.
	  1. AOQL = 0.0151 at
	    p = 0.022
	
	E. P_{a_1} = probability no more
	    than one defective
	    in 88
	  P_{a_1} = 0.29
	  ATI = 88 + 88 (0.71) +
	    324(0.50)
	    = 312.5

Inspect a first sample of n_1 pieces

If the number of defectives
in the first sample

Does not   Exceeds c_1, but does   Equals or
exceed c_1 not equal or exceed r_1 exceeds r_1

Inspect a second sample
of n_2 pieces

If the total number of
defectives in the first and
second samples combined

Does not   Exceeds c_2, but does   Equals or
exceed c_2 not equal or exceed r_2 exceeds r_2

Inspect a third sample
of n_3 pieces

If the total number of
defectives in the first
three samples combined

Does not   Exceeds c_3, but does   Equals or
exceed c_3 not equal or exceed r_3 exceeds r_3

Accept   Etc.   Do not
the   accept
lot   the lot *

FIGURE 46.10   Schematic operation of multiple sampling. The asterisk means some of these plans continue to the "bitter end"; i.e., the taking of samples continues if necessary until the lot is fully inspected, unless the plan has meanwhile "made up its mind." Other plans, described as "truncated," are designed to force a decision after a certain number of inconclusive samples have been examined.

TABLE 46.9   Multiple Sampling by Attributes

Example: Determine a multiple sampling plan which will have AQL = $100p_1$ = 1.0% with producer risk α = 0.05 and LTPD = $100p_2$ = 5.0% with consumer risk β = 0.10. Suppose a sample is taken from a lot of N = 500 and four non-conforming units are found.

Summary of plan	Calculations
I. Restrictions: Random sample from dichotomous population	

II. Necessary information
  A. Producer quality level, p_1
  B. Producer risk, α
  C. Consumer quality level, p_2
  D. Consumer risk, β
	II.
	
	  A. p_1 = 0.01
	  B. α = 0.05
	  C. p_2 = 0.05
	  D. β = 0.10

III. Selection of plan (Table 46.6)	III.
A. Calculate operating ratio $R = p_2/p_1$	A. R = 0.05/0.01 = 5
B. Choose multiple sampling plan (M) from Table 46.6 which shows $R \le$ the value calculated	B. Choose plan 3M since R shows 4.672

C. Acceptance (a) and rejection (r) numbers are given as Ac and Re; note # indicates acceptance is not possible at that sample	C.
	    Ac = #, 0, 1, 2, 3, 4, 6
	    Re = 3, 3, 4, 5, 6, 6, 7

D. Determine first sample size from value of (np_2) shown for the plan as
    $n = (np_2)/p_2$
  This is sample size of each of the multiple samples
	D. n = 1.626/0.05
	      = 33

IV. Elements
  A. Sample size: See III above
  B. Statistic: $\sum\limits_{i=1}^{k} d_i$ = total number nonconforming up to kth sample
  C. Decision Criteria
    1. Accept on kth sample if
        $\sum\limits_{i=1}^{k} d_i \le a_k$
    2. Reject on kth sample if
        $\sum\limits_{i=1}^{k} d_i \ge r_k$
    3. Continue sampling if
        $a_k < \sum\limits_{i=1}^{k} d_i < r_k$
	IV.
	
	  A. n = 33
	  B. $\sum\limits_{i=1}^{1} d_i$ = 4
	
	  C.
	    1. # indicates cannot accept
	
	    2. 4 $\ge$ 3, reject on first sample

V. Action Dispose of lot as indicated by decision rules	V. Reject

VI. Measures (using Table 46.6)
  A. Probability of acceptance (OC curve)
    1. Under each value of probability of acceptance listed across the top of the table, there corresponds a value of np shown for the plan
	VI.
	  A.
	    1. P_a = 0.50 corresponds to np = 0.910

TABLE 46.9 Multiple Sampling by Attributes (*Continued*)

Summary of plan	Calculations
2. Divide the values of np by sample size n to get p	2. $p = \dfrac{0.910}{33} = 0.028$
3. Draw OC curve from corresponding values of p and P_a	3. $p = 0.028$ $P_a = 0.50$
B. Average sample number (ASN curve)	B.
1. Calculate p from P_a as above	1. $P_a = 0.50$ $p = 0.028$
2. Under the value np from which p was calculated is listed a value of ASN/n_1	2. ASN/$n_1 = 3.288$
3. Multiply ASN/n_1 by n to obtain ASN corresponding to p	3. ASN $= 3.288(33)$ $= 108.5$
4. Draw ASN curve from corresponding values of p and P_a	4. $p = 0.028$ ASN $= 108.5$
C. Average outgoing quality	C.
1. Use formula AOQ $\simeq p\,P_a$	1. at $p = 0.028$ AOQ $\simeq 0.028(.5)$ $= 0.014$
D. Average outgoing quality limit AOQL $=$ maximum of AOQ curve	D. AOQL $= 0.0148$ at $p = 0.022$
E. Average total inspection (approximate) ATI $\approx$ ASN $(P_a) + N(1 - P_a)$	E. ATI $\simeq 108.5(0.5) + 500(0.5)$ $\simeq 304$

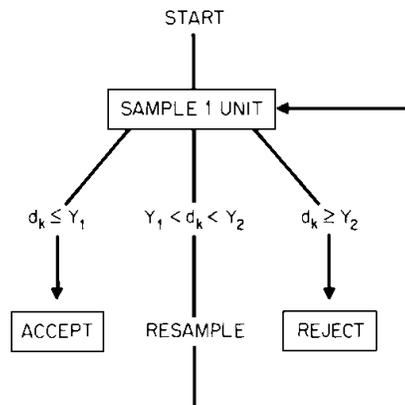

FIGURE 46.11 Schematic operation of sequential sampling. (*From Schilling, 1982, p. 156.*)

TABLE 46.10 Sequential Sampling by Attributes

Example: Determine a sequential sampling plan which will have AQL = $100p_1$ = 1% with producer risk α = 0.05 and LTPD = $100p_2$ = 5% with consumer risk β = 0.10. Suppose all the samples taken from a lot of 500 are defective.

Summary of plan	Calculations

I. Restrictions
   Random sample of dichotomous data

II. Necessary information
   A. Producer quality level, p_1
   B. Producer risk, α
   C. Consumer quality level, p_2
   D. Consumer risk, β

II.
   A. p_1 = 0.01
   B. α = 0.05
   C. p_2 = 0.05
   D. β = 0.10

III. Selection of plan
   A. Parameters
   1. $h_1 = \log[(1 - \alpha)/\beta] / \{\log(p_2/p_1) + \log[(1 - p_1)/(1 - p_2)]\}$
   2. $h_2 = \log[(1 - \beta)/\alpha] / \{\log(p_2/p_1) + \log[(1 - p_1)/(1 - p_2)]\}$
   3. $s = \log[(1 - p_1)/(1 - p_2)] / \{\log(p_2/p_1) + \log[(1 - p_1)/(1 - p_2)]\}$
   B. Acceptance criteria
   1. Acceptance line
   $$y_1 = sk - h_1$$
   2. Rejection line
   $$y_2 = sk + h_2$$

   3. k = number of samples taken

III.
   A.
   1. h_1 = 1.3639

   2. h_2 = 1.7510

   3. s = 0.02499

   B.
   1. y_1 = 0.02499k − 1.3639
   2. y_2 = 0.02499k + 1.7510

   3. Take k = 2

IV. Elements
   A. Sample size
   Not definite since samples are taken one at a time
   B. Statistic
   d_k = cumulative number nonconforming by the kth sample
   C. Decision criteria
   1. Accept if $d_k \leq y_1 = sk - h_1$

   2. Reject if $d_k \geq y_2 = sk + h_2$
   3. Continue sampling if $y_1 < d_k < y_2$

IV.
   A.

   B. At k = 2
   d_2 = 2

   C.
   1. 2 not $\leq$ − 1.31, cannot accept
   2. 2 $\geq$ 1.8, reject
   3. Discontinue sampling

V. Action: Dispose of lot as indicated by the decision rule

V. Reject

VI. Measures
   A. Probability of acceptance (OC curve)
   1. Pick arbitrary value of h
   2. Then
   $$p = \frac{1 - [(1 - p_2)/(1 - p_1)]^h}{(p_2/p_1)^h - [(1 - p_2)/(1 - p_1)]^h}$$
   and
   $$P_a = \frac{[(1 - \beta)/\alpha]^h - 1}{[(1 - \beta)/\alpha]^h - [\beta/(1 - \alpha)]^h}$$

VI.
   A.
   1. h = 1
   2. p = 0.01
   P_a = 0.95

TABLE 46.10 Sequential Sampling by Attributes (*Continued*)

Summary of plan	Calculations
B. Average sample number (ASN curve)	*B.*
1. Calculate p and P_a as above	1. $p = 0.01$
	$P_a = 0.95$
2. Then	2. ASN = 81

$$\text{ASN} = \frac{\left\{ \begin{array}{l} P_a \log \left[(\beta/(1 - \alpha)\right] + \\ (1 - P_a) \log \left[(1 - \beta)/\alpha\right] \end{array} \right\}}{\left\{ \begin{array}{l} p \log (p_2/p_1) + (1 - p) \\ \log \left[(1 - p_2)/(1 - p_1)\right] \end{array} \right\}}$$

Summary of plan	Calculations
C. Average outgoing quality (AOQ curve)	*C.*
1. Use approximate formula	1. At $p = 0.01$
$\text{AOQ} \simeq p\,P_a$	$\text{AOQ} \simeq 0.01(0.95)$
	$= 0.0095$
D. Average outgoing quality limit	*D.* AOQL $= 0.0145$ at
AOQL = maximum of AOQ curve	$p = 0.021$
E. Average total inspection (approximate)	*E.* At $p = 0.01$
$\text{ATI} \approx \text{ASN}\,(P_a) + N(1 - P_a)$	$\text{ATI} \approx 81(.95) + 500$
	(0.05)
	$\simeq 102$

developed by Dodge and Torrey (1951). Dodge (1970) recounts these and other developments in the evolution of continuous sampling plans. MIL-STD-1235B (1981) provides a tabulation of continuous sampling plans.

The following are prerequisites for application of the single-level continuous sampling plans:

1. The inspection must involve "moving product," i.e., product which is flowing past the inspection station, e.g., on a conveyer belt.

2. Rapid 100 percent inspection must be feasible.

3. The inspection must be relatively easy.

4. The product must be homogeneous.

CSP-1 Plans. CSP-1 plans use 100 percent inspection at the start. When i successive units are found to be acceptable and when there is assurance that the process is producing homogeneous product, 100 percent inspection is discontinued and sampling is instituted to the extent of a fraction f of the units. The sampling is continued until a defective unit is found. One hundred percent inspection is then reinstated and the procedure is repeated. Dodge (1943) has provided graphs which can be used to select such plans based on the AOQL desired. See also Schilling (1982).

For example, consider the plan $i = 35, f = \frac{1}{10}$. One hundred percent inspection is used until 35 successive units are found nondefective. Sampling, at the rate of 1 unit in 10, is then instituted. If a defective is found, 100 percent inspection is reinstituted and continued until 35 successive units are found nondefective, at which time sampling is reinstituted.

CSP-2 Plans. CSP-2 plans were developed to permit sampling to continue even if a single defective is found. Again, 100 percent inspection is used at the start until i successive units are found free of defects. When sampling is in effect and a defective is found, 100 percent inspection is instituted only if a second defective occurs in the next i or fewer sample units inspected. Details on the selection of such plans will be found in Dodge and Torrey (1951) or in Schilling (1982).

Stopping Rules.   Murphy (1959) has investigated four different "stopping rules" for use with CSP-1 plans. He concludes that a useful rule is to stop when a specified number of defectives is found during any one sequence of 100 percent inspection.

Multilevel Continuous Sampling.   Continuous sampling plans have been developed by Lieberman and Solomon (1955) and others which reduce the sampling rate beyond that of other continuous plans when the quality level is better than a defined AOQL. In addition, sudden changes in the amount of inspection are avoided by providing for several "levels" of inspection. Figure 46.12 outlines the procedure for using the plan. The procedure provides for reducing the sampling rate each time i successive units are found to be free of defects. The first sampling rate after leaving 100 percent inspection is $f,$ and each succeeding sampling rate is f raised to one larger power. The number of sampling levels is k. Thus, if $f = 1/2$ and $k = 3$, the successive sampling rates are $1/2$, $1/4$, and $1/8$.

Notice that all the continuous plans discussed so far are based on the AOQL concept, i.e., requiring periods of 100 percent inspection during which only nondefective product is accepted. This action controls the average defectiveness of accepted product at some predetermined level. In all these cases, inspection must be nondestructive to employ the AOQL principle.

Additional detail on continuous sampling plans will be found in Stephens (1979). A sequential approach to continuous sampling is given in Connolly (1991).

Skip-Lot Schemes.   Skip-lot sampling plans are used when there is a strong desire to reduce the total amount of inspection. The approach is to require some initial criterion be satisfied, such as 10 or so consecutively accepted lots, and then determine what fraction of lots will be inspected. Given this fraction, the lots to be inspected are chosen using some random selection procedure. The assumptions on which the use of skip-lot plans are based are much like those for chain-sampling plans (see below). OC curves for the entire skip-lot sampling scheme can be derived, and an AOQL concept does apply. Strong dependence is made on the constancy of production and consistency of process quality as well as faith in the producer and inspector. The skip-lot sampling scheme was devised by Dodge (1955*a*) and is, in essence, an extension of continuous sampling acceptance plans with parameters i and f. He designated the initial scheme as SkSP-1. Here, a single determination of acceptability was made from a sample of size $n = 1$ from each lot. Lots found defective under sampling were 100 percent inspected or replaced with good lots. The AOQL then was in terms of the long-term average proportion of defective *lots* that would reach the customer. This is called AOQL-2. Later, Dodge and Perry (1971) incorporated the use of a "reference" sampling plan to determine whether a lot is acceptable or rejectable. Such skip-lot plans are designated SkSP-2 and require 100 percent inspection of rejected lots. The resulting AOQL is in terms of the long-term average proportion of individual product *units* that would reach the customer. This is called AOQL-1.

The application of skip-lot sampling should be confined to those instances where a continuous supply of product is obtained from a reasonably stable and continuous process.

The parameters of the SkSP-2 plan (in terms of continuous sampling) are:

i = number of successive lots to be found conforming to qualify for skipping lots either at the start or after detecting a nonconforming lot

f = fraction of lots to be inspected after the initial criteria have been satisfied

n = sample size per inspected lot

c = acceptance number for each inspected lot

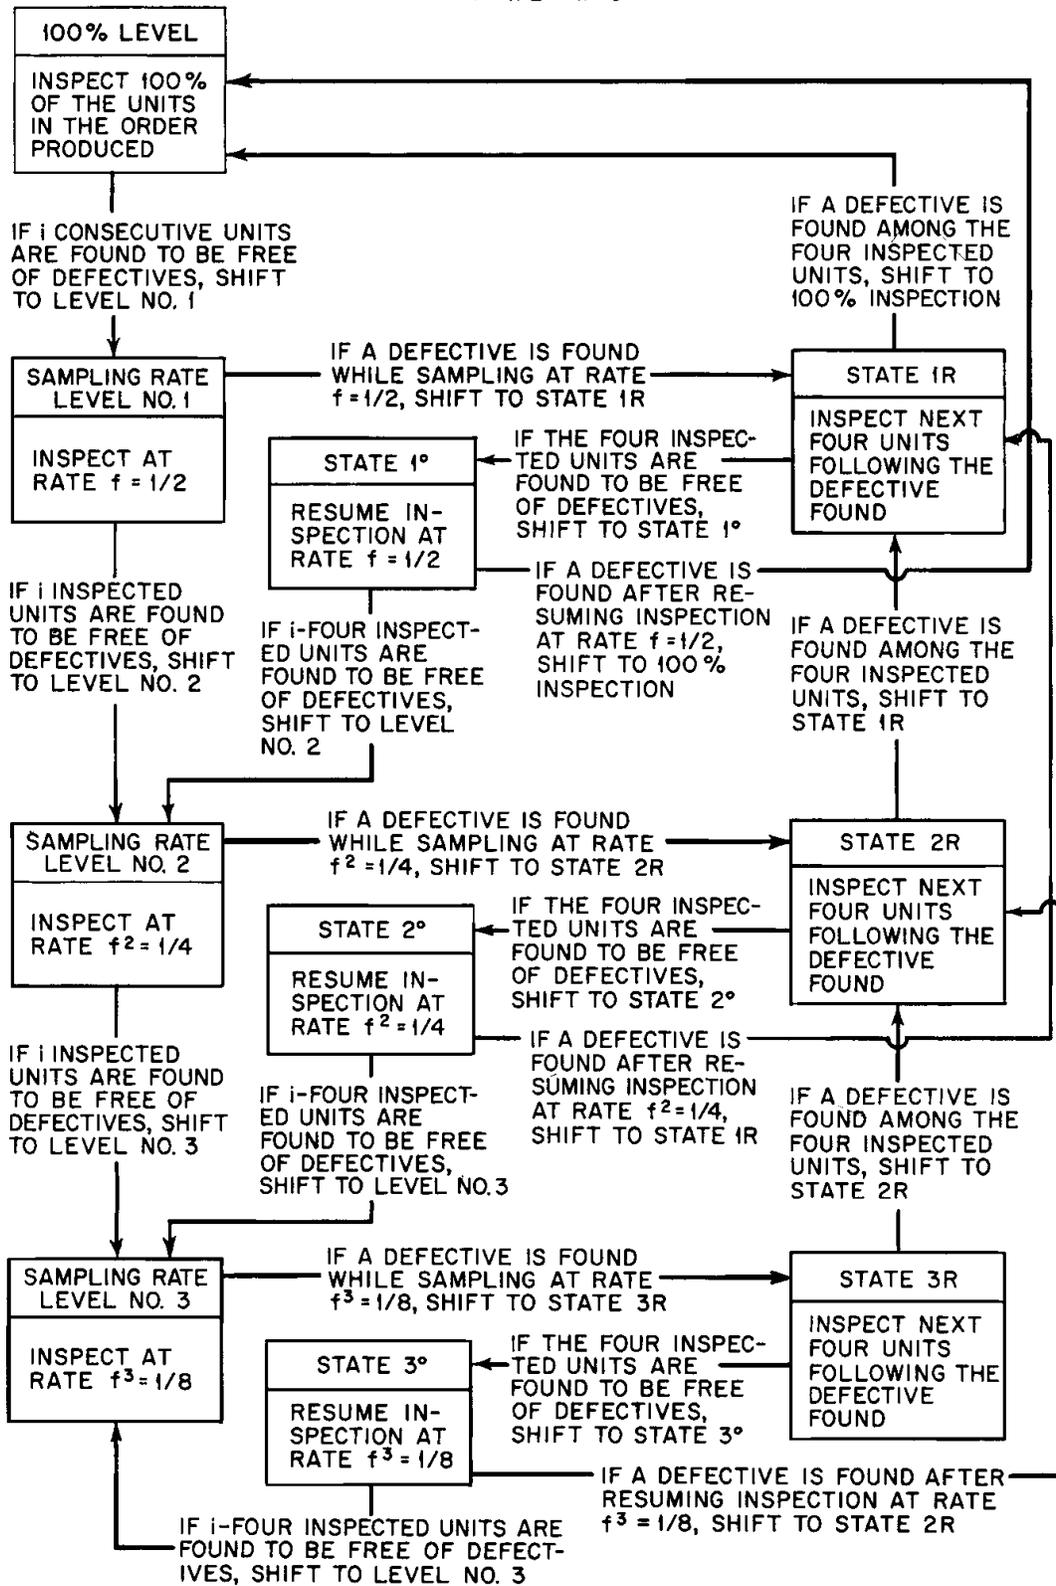
For example, if $i = 15, f = 1/3, n = 10, c = 0$, the plan is to inspect 10 units from each lot submitted until 15 consecutive lots are found conforming, i.e., have no defective in the sample. Then one-third of the submitted lots are chosen at random for inspection and inspected to the same n and c. As long as all lots are found to be conforming, the f-rate applies. When a nonconforming lot is identified, reversion to inspection of all lots occurs until again 15 consecutive lots are found to be conforming, and then skipping is permissible again.


FIGURE 46.12   Procedure for multilevel continuous sampling.

Many values of f and i are possible. For SkSP-1 these may be obtained from the Basic Curves for Plan CSP-1. See Dodge (1955*a*). In using SkSP-2, unity values for selection of a plan having a designated operating ratio will be found in Dodge and Perry (1971). See also Schilling (1982).

One further consideration is whether to apply the skip-lot procedure to only one characteristic of a product, to all characteristics simultaneously, or just to some. The plan is obvious and straightforward when applied only to one product characteristic, perhaps a particularly expensive one in time or dollars. If applied to several characteristics, it might be best to inspect the f fraction for these characteristics on each lot. For example, if 6 characteristics are candidates for skip-lot sampling and $f = {}^1\!/_3$, perhaps 2 of these would be examined on one lot, two on another, and two on the third, again in some random fashion, so that all lots receive some inspection. Of course, if the most expensive part of the sampling scheme were forming the lot, sampling from it, and keeping records, the choice might be to inspect all characteristics on the same sample units. This argument may be extended to the case where all inspection characteristics are on a skip-lot basis; but if inspection is very complex, this is difficult to visualize.

Perry (1973) has extended skip-lot plans in many ways including the incorporation of multi-level plans. See Perry (1973*a*). Skip-lot plans are described in detail by Stephens (1982).

Chain Sampling.

Chain-sampling plans utilize information over a series of lots. The original plans by Dodge (1955), called ChSP-1, utilized single sampling on an attributes basis with n small and $c = 0$. The distinguishing feature is that the current lot under inspection can also be accepted if one defective unit is observed in the sample provided that no other defective units were found in the samples from the immediately preceding i lots, i.e., the chain. Dodge and Stephens (1965, 1966) derived some two-stage chain-sampling plans which make use of cumulative inspection results from several samples and are generalizations and extensions of ChSP-1. Conversely, ChSP-1 is a subset of the new plans, and the discussion here will be in terms of the original plan.

Before discussing the details of the plans, the general characteristics of chain sampling are described. Chain-sampling plans, in comparison with single-sampling plans, have the characteristic of "bowing up" the OC curve for small fractions defective while having little effect on the end of the curve associated with higher fractions defective. The effectiveness of chain-sampling plans strongly depends upon the assumptions on which the plans are based, namely:

1. Production is steady, as a continuing process.
2. Lot submittal is in the order of production.
3. Attributes sampling is done where the fraction defective p is binomially distributed.
4. A fixed sample size from each lot is assumed.
5. There is confidence in the supplier to the extent that lots are expected to be of essentially the same quality.

Chain-sampling plans are particularly useful where inspection is costly and sample sizes are relatively small. However, they may also be found useful with large sample sizes. The advantage over double-sampling plans is the fixed sample size. The disadvantage is that moderate changes in quality are not easily detected. However, major changes in quality are detected as easily with chain-sampling plans having much smaller sample sizes as with single-sampling with the same AQL.

The original ChSP-1 plan is to inspect a sample of n units from a lot, accept the lot if zero defectives were found in the n units, or accept the lot if one defective were found in the sample and no defectives were found in the samples from the immediately preceding i lots. See Figure 46.13.

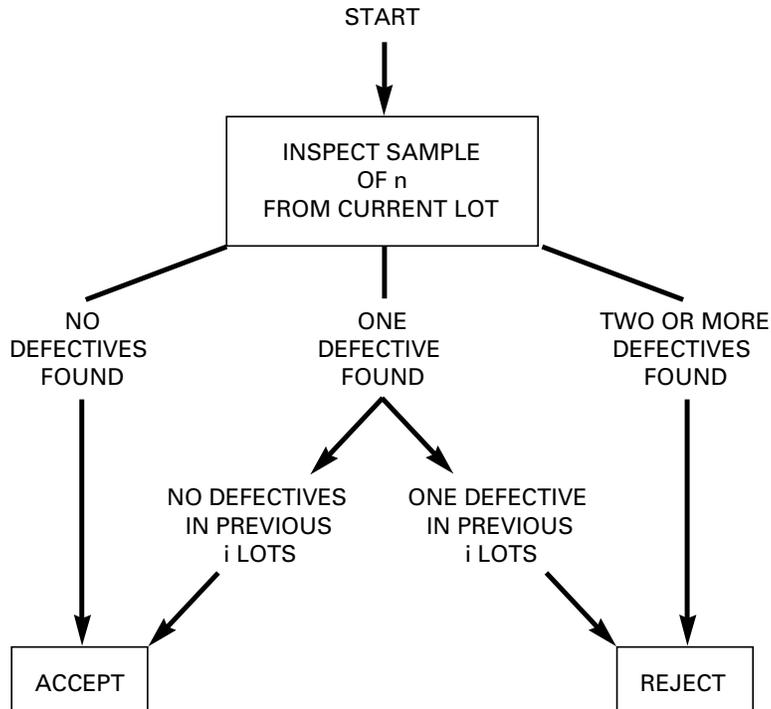
Formulas for the OC curves for ChSP-1 are given by Dodge (1955) and for the two-stage procedure will be found in Dodge and Stephens (1965, 1966) while Raju (1991) has developed three-stage chain plans. All are based on the type B sampling situation. Soundararajan (1978) has prepared tables of unity values for selection of chain-sampling plans from various criteria. Stephens (1982) provides additional detail on implementing chain plans. Govindaraju (1990) gives tables for determining ChSP-1 plans given acceptable quality level and limiting quality level.


FIGURE 46.13   Flowchart of ChSP-1 chain sampling scheme. (*From Schilling, 1982, p. 452.*)

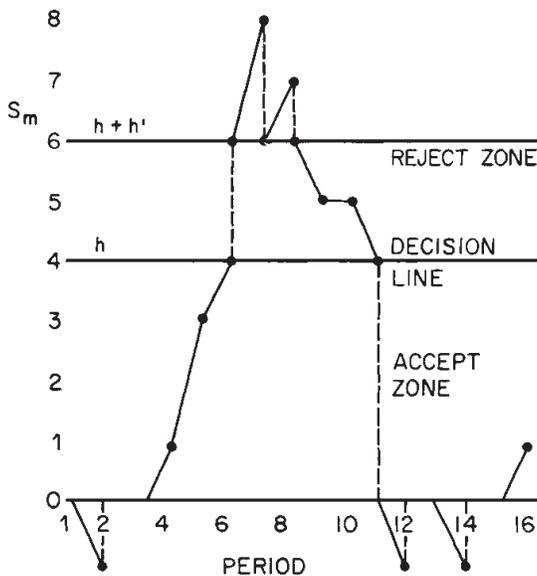
Cumulative Sum Sampling Plans.   A scheme has been devised by Beattie (1962) whereby the continuous inspection approach may be employed when inspection is destructive. Acceptance or rejection of the continuously produced product is based on the cumulation of the observed number of defectives. In addition, it is possible to discriminate between two levels of quality, an acceptable quality level (AQL) and rejectable quality level (RQL).


FIGURE 46.14   Form of chart for acceptance under cumulative sum sampling plans.

Prior to the development of continuous and cumulative sum plans, the following situation frequently occurred when inspection was destructive. Since production was continuous, usually there was no technically rational procedure for defining lots. A common procedure was to accumulate product until a lot was formed, but then the time delay in making a decision on the product was often too long, and a few short periods of bad production could cause a large quantity of good product to be rejected. Various approaches to lessening this jeopardy were used, all with some logical or practical drawback.

The procedure of Beattie (1962) establishes two zones, an accept zone and a reject zone, and product is accepted or rejected according to the cumulative sum of defectives observed. Figure 46.14 illustrates the plan. To implement the procedure, a sample of size n is chosen at regular intervals from production. The units are inspected and the number of defective units d_i in the ith sample recorded. Then,

$$S_m = \sum_{i=1}^{m} (d_i - k)$$

is accumulated, where k is a parameter of the scheme and S_m is computed and plotted according to the following rules:

1. Start the cumulation, S_m, at zero.

2. Accept product as long as $S_m < h$, where h is a second parameter of the scheme. When $S_m < 0$, return the cumulation to zero.

3. When h is crossed or reached from below, reject product and restart the cumulation at $h + h'$ (h' is a third parameter of the plan).

4. Continue rejecting product as long as $S_m > h$. When $S_m > h + h'$, return calculation to $h + h'$ and continue rejecting product until $S_m < h$.

5. When h is crossed or reached from above, accept product and restart cumulation at zero.

The discriminatory capability of the plans is controlled through the choice of $k, h,$ and h' and their combinations. In familiar terms, k is akin to an acceptance number and h defines how far one is willing to deviate from this number over a long run and still accept product. The quantity h' is essentially how much evidence is required to be assured the process has been corrected.

The protection offered by this type of plan, which is similar to a type B acceptance situation, is defined by an OC curve which is determined by the ratio of the average run length (ARL) in the accept zone to the sum of the ARL in the accept and reject zones.

Published Tables and Procedures.   The published plans cover primarily three quality indices: AQL, LTPD, and AOQL.

AQL Plans.   Sampling schemes indexed by AQL are designed to give high assurance for type B situations (that is, sampling from a process) of lot acceptance when the process fraction defective is less than or equal to that AQL. These plans are devised for producer's protection or to keep the producer's risk small. Consideration is given to what might be called the other end of the plan, the consumer's risk, through the switching rules. If there is interest in controlling both producer's risk and consumer's risk with the use of schemes indexed by AQL values, the best approach is to study the scheme OC curves and choose the plan which provides adequate protection against both types of risks. See Schilling and Sheesley (1978); also Schilling and Johnson (1980).

MIL-STD-105 is the best-known sampling scheme indexed by AQL. The AQLs presented in this standard form a sequence which is evident in the standard. The sequence chosen, while arbitrary, does provide a sensible grouping and indexing of plans for use. The steps to be applied in AQL sampling acceptance procedures are summarized in Table 46.11.

LTPD Plans.   Sampling schemes indexed by LTPD or other values of limiting quality (LQ) are designed for type A situations that are essentially the mirror image of plans indexed by AQL. That is, the plans are chosen such that the consumer's risk of accepting a submitted lot of product with quality equal to or worse than the LQ is equal to or less than some specified value. Specifically, LTPD plans provide a 10 percent probability of accepting lots of the listed LTPD quality. The Dodge-Romig sampling scheme is the best-known set of plans indexed by LTPD. The derivative standards of MIL-STD-105 also provide some LQ plans. Schilling (1978) has developed a set of type A lot sensitive plans with $c = 0$ which are selected directly from the lot size and the LTPD using a simple table. Properties of these plans under curtailment have been developed by Govindaraju (1990).

AOQL Plans.   Sampling schemes indexed by AOQL are derived to provide assurance that the long-run average of accepted quality, given screening of rejected lots, will be no worse than the indexed AOQL value. The Dodge-Romig (1959) plans provide the best available tables of sampling plans indexed by AOQL.

TABLE 46.11   Summary of Lot-by-Lot Sampling Procedure

Establishment of standards (by inspection executive):
    Decide what shall be a unit of product.
    Classify the quality characteristics for seriousness.
    Fix an acceptable quality level for each class.
    Fix an inspection level for the product.
Installation of procedure (by inspection supervisor):
    Arrange for formation of inspection lots.
    Decide what type of sampling shall be used (single, double, multiple).
    Choose sampling plan from tables.
Operation of procedure (by line inspector):
    Draw sample units from each inspection lot.
    Inspect each sample unit.
    Determine whether to accept or reject the inspection lot (if sampling for acceptance) or
        whether to urge action on the process (if sampling for control).
Review of past results (by inspection supervisor):
    Maintain a record of lot acceptance experience and cumulative defects by successive lots.
    Determine whether to tighten or reduce inspection on future lots.
Feedback
    Insure that the results of inspection are fed back to all components and especially the
        producer to motivate action for quality improvement.

AQL Attributes Sampling System.   Most attributes AQL sampling systems are derivatives of the 105 series of acceptance sampling procedures, issued by the United States Department of Defense. This series was initiated with MIL-STD-105A in 1950 and concluded with MIL-STD-105E issued 10 May 1989. This series was canceled 27 February 1995. The best known 105 derivatives are the U.S. commercial version ANSI/ASQC Z1.4 (1993) and the international standard ISO-2859-1 (1989). With the cancellation of MIL-STD-105E, ANSI/ASQC Z1.4 was adopted by the U.S. military for future acquisitions.

ISO 2859-1 (1989) is part of the international ISO 2859 series of integrated standards to be used with the ISO 2859-1 AQL system. ISO 2859-0 (1995) provides an introduction to acceptance sampling as well as a guide to the use of ISO 2859-1, which is the central AQL sampling system in the series. ISO 2859-2 (1985) gives Limiting Quality (LQ) sampling plans for isolated lots to be used individually or in cases where the assumptions implicit in AQL schemes do not apply. ISO 2859-3 (1991) presents skip-lot sampling procedures which may be used as a substitute for Reduced Sampling in ISO 2859-1. Related U.S. national standards are ANSI/ASQC S2 (1995) which is an introduction to the ANSI/ASQC Z1.4 (1993) AQL scheme; ANSI/ASQC Q3 (1988) for Limiting Quality; and ANSI/ASQC S1 (1996) for skip-lot inspection. The international standard ISO 8422 (1991) also provides attribute sequential plans which may be used with ISO 2859-1.

The quality index in ANSI/ASQC Z1.4 (1993) and its international counterpart ISO 2859-1 (1989) is the acceptable quality level (AQL):

- A choice of 26 AQL values is available ranging from 0.010 to 1000.0. (Values of 10.0 or less may be interpreted as percent defective or defects per hundred units. Values above 10.0 must be interpreted as defects per hundred units.)

- The probability of accepting at AQL quality varies from 89 to 99.5 percent.

- Nonconformances are classified as A, B, C according to degree of seriousness.

- The purchaser may, at its option, specify separate AQLs for each class or specify an AQL for each kind of defect which a product may show.

The user also specifies the relative amount of inspection or inspection level to be used. For general applications there are three levels, involving inspection in amounts roughly in the ratio of 1 to 2.5 to 4. Level II is generally used unless factors such as the simplicity and cost of the item, inspection cost, destructiveness of inspection, quality, consistency between lots, or other factors make it appropriate to use another level. The standard also contains special procedures for "small-sample

inspection" where small sample sizes are either desirable or necessitated by some aspects of inspection. Four additional inspection levels (S1 through S4) are provided in these special procedures.
The procedure for choice of plan from the tables is outlined below.

1. The following information must be known:
   a. Acceptable quality level.
   b. Lot size.
   c. Type of sampling (single, double, or multiple).
   d. Inspection level (usually level II).
2. Knowing the lot size and inspection level, obtain a code letter from Table 46.12.
3. Knowing the code letter, AQL, and type of sampling, read the sampling plan from one of the nine master tables (Table 46.13 is for single-sampling normal inspection; the standard also provides tables for double and multiple sampling).

For example, suppose that a purchasing agency has need for a 1 percent AQL for a certain characteristic. Suppose also that the parts are bought in lots of 1500 pieces. From the table of sample size code letters (Table 46.12), it is found that letter K plans are required for inspection level II, the one generally used. Then the plan to be used initially with normal inspection would be found in Table 46.13 in row K. The sample size is 125. For AQL = 1.0, the acceptance number is given as 3 and the rejection number is given as 4. This means that the entire lot of 1500 units may be accepted if 3 or fewer defective units are found in the sample of 125, but must be rejected if 4 or more are found. Where an AQL is expressed in terms of "nonconformities per hundred units," this term may be substituted for "nonconforming units" throughout. Corresponding tables are provided in the standard for tightened and reduced inspections.

Inspection Severity—Definitions and General Rules for Changing Levels. The commonly used AQL attributes acceptance sampling plans make provisions for shifting the amount of inspection

TABLE 46.12 Sample Size Code Letters*

Lot or batch size		General inspection levels		
		I	II	III
2 to	8	A	A	B
9 to	15	A	B	C
16 to	25	B	C	D
26 to	50	C	D	E
51 to	90	C	E	F
91 to	150	D	F	G
151 to	280	E	G	H
281 to	500	F	H	J
501 to	1,200	G	J	K
1,201 to	3,200	H	K	L
3,201 to	10,000	J	L	M
10,001 to	35,000	K	M	N
35,001 to	150,000	L	N	P
150,001 to	500,000	M	P	Q
500,001 and over		N	Q	R

*Sample size code letters given in body of table are applicable when the indicated inspection levels are to be used. The Standard includes an added table of code letters for small-sample inspection.

TABLE 46.13 Master Table for Normal Inspection (Single Sampling)

Acceptable Quality Levels (normal inspection)

Each cell under an AQL column shows "Ac Re" (acceptance number, rejection number). ↓ = use first sampling plan below arrow; ↑ = use first sampling plan above arrow.

Ac = Acceptance number.

Re = Rejection number.

46.38

and/or the acceptance number as experience indicates. If many consecutive lots of submitted product are accepted by an existing sampling plan, the quality of submitted product must exceed that specified as necessary for acceptance. This makes it desirable to reduce the amount and cost of inspection (with a subsequent higher risk of accepting an occasional lot of lesser quality) simply because the quality level is good. On the other hand, if more than an occasional lot is rejected by the existing sampling plan, the quality level is either consistently lower than desired or the quality level fluctuates excessively among submitted lots. In either case it is desirable to increase the sampling rate and/or reduce the acceptance number to provide greater discrimination between lots of adequate and inadequate quality.

Three severities of inspection are provided: normal, tightened, and reduced. All changes between severities are governed by rules associated with the sampling scheme. Normal inspection is adopted at the beginning of a sampling procedure and continued until evidence of either lower or higher quality than that specified exists. Schematically, the rules for switching severities specified in MIL-STD-105D and E, ANSI/ASQC Z1.4 (1993) and ISO 2859-1 (1989) are given in Figure 46.15.

From the schematic it can be seen that the criteria for change from normal to tightened and back to normal are simple and straightforward. (This is a vast improvement over early issues of MIL-STD-105.) Again, the change from reduced to normal is straightforward and occurs with the first indication that quality has slipped. Considerably more evidence is required to change from normal to reduced.

In using schemes like MIL-STD-105E, ANSI/ASQC Z1.4 (1993), or ISO 2859-1 (1989), the customer assumes that the changes from the normal to tightened and reduced to normal are a necessary part of the scheme. (Recall that such AQL plans provide primarily producer's assurance that quality at the AQL level will be accepted.) The change from normal to tightened or reduced to normal occurs when evidence exists that the quality level has deteriorated. In this way, the consumer's protection is maintained.

On the other hand, the supplier is interested in keeping inspection costs as low as possible consistent with the demands placed upon it. Certainly it is desirable to change from tightened to normal inspection when conditions warrant. Generally, it would be economic to change from normal to reduced except in those cases where record-keeping costs or bother exceed the saving in reduced sampling effort. The initiative for these types of change generally rests with the supplier; only in those instances where an economic advantage exists would a customer insist on reduced inspection. This might occur, e.g., when the customer is using these sampling plans, where inspection is destructive or degrading, or when the psychological impact on the supplier makes reduced inspection a motivational force.

The case could arise where a complex item is being inspected for many characteristics, some of which are classified as critical (A), some major (B), and some minor (C). A different sampling plan could be in effect for each class. It is also possible on this same product to have reached the situation where, for example, reduced inspection could be in effect for A defects, tightened inspection for B defects, and normal inspection for C defects. The bookkeeping involved with complete flexibility of sampling plan choice by classification of characteristics and inspection severity can be enormous. On the other hand, the savings involved with lower inspection rates, especially with destructive inspection, could be sizable. Inspection cost and convenience, along with the consequences of the error of applying an improper sampling plan, are the main determinants in any decision to use anything but the highest sampling rate associated with all defect classifications and whether to take advantage of reduced inspection for one or more defect classes when allowed. Of course, when tightened inspection is dictated by sampling experience, there is no recourse but to adopt it for at least that classification or characteristic, other than to discontinue acceptance inspection of submitted product.

The standard also provides limiting quality (LQ) single-sampling plans with a consumer's risk of 10 percent (LTPD) and 5 percent for use in isolated lot acceptance inspection. If other levels of LQ are desired, the individual OC curves can be examined to adopt an appropriate plan.

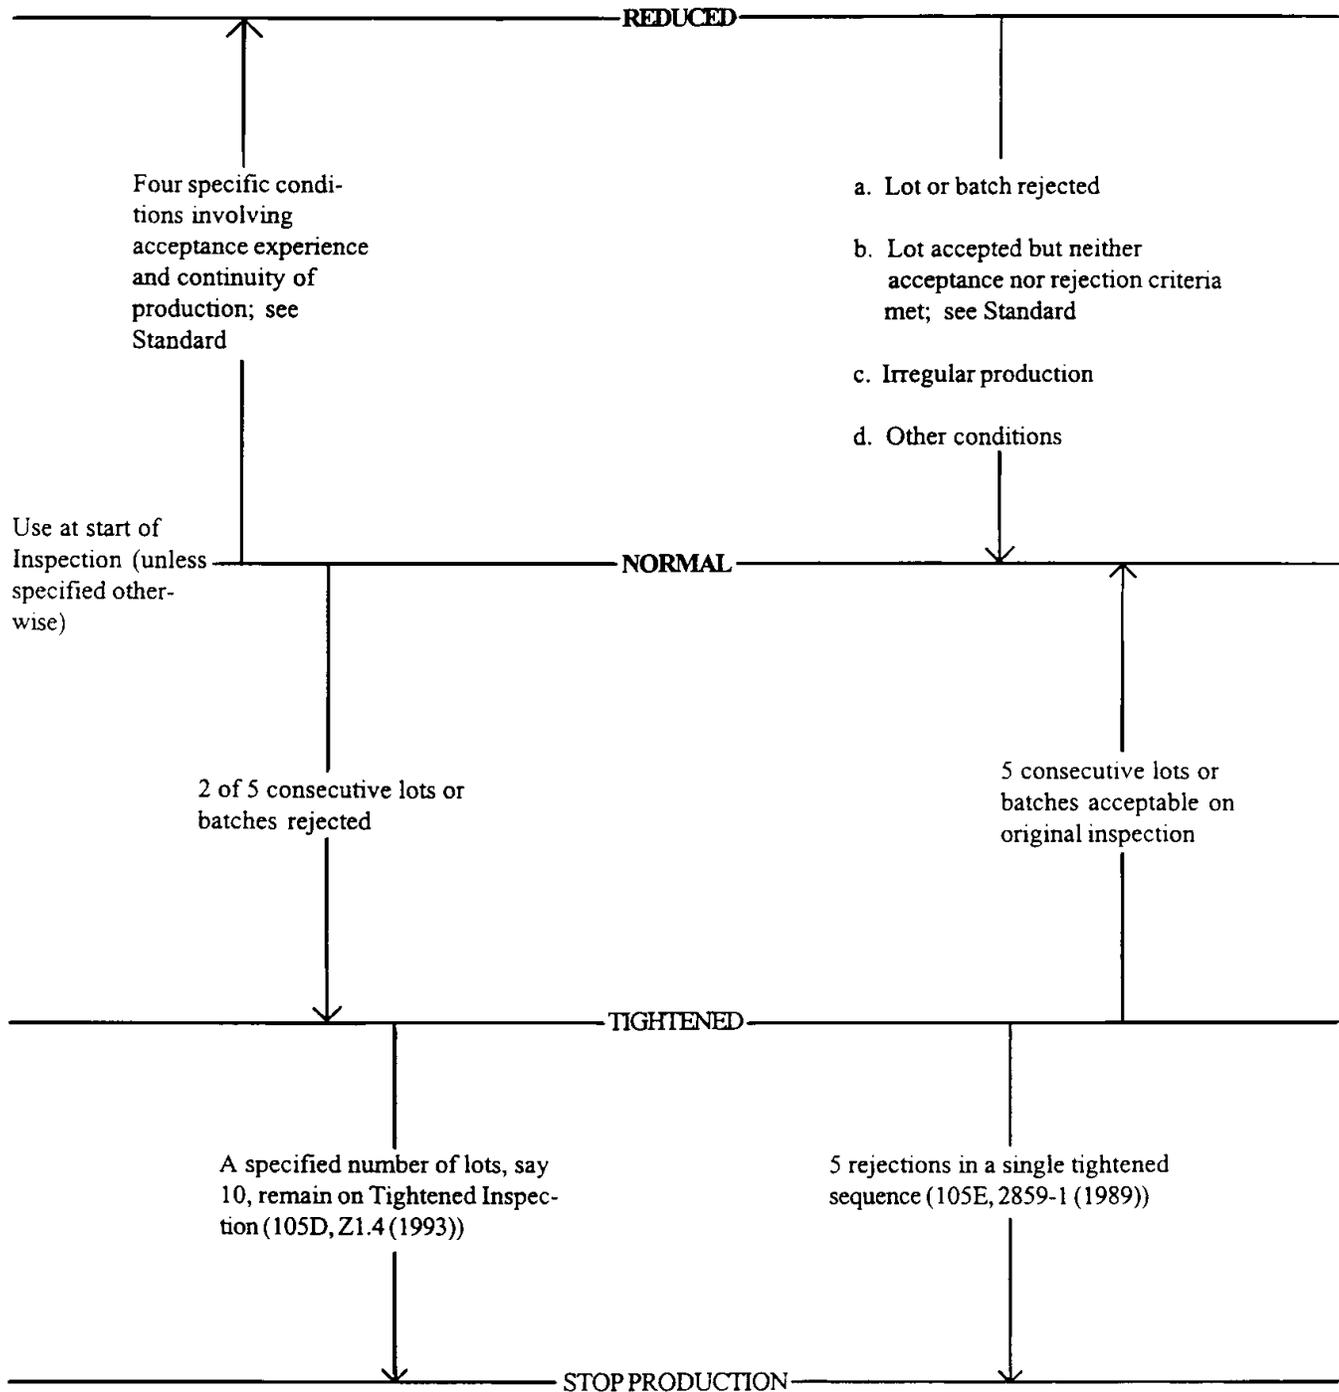
Finally, a table of AOQL values is included for each of the single-sampling plans for normal and tightened inspection. These may also be used as rough guides for corresponding double- and multiple-sampling plans.


FIGURE 46.15   Rules for switching inspection severity, MIL-STD-105D and E, ANSI/ASQC Z1.4 (1993) and ISO 2859-1 (1989).

The sampling plans in MIL-STD-105E, ANSI/ASQC Z1.4, and ISO 2859-1 are sufficiently varied in type (single, double, multiple), amount of inspection, etc., to be useful in a great number of situations. The inclusion of operating characteristic curves and average sample size curves for most of the plans is a noteworthy advantage of the standards.

Dodge-Romig Sampling Tables.   Dodge and Romig (1959) provide four different sets of tables:

1. Single-sampling lot tolerance tables (SL)
2. Double-sampling lot tolerance tables (DL)

3. Single-sampling AOQL tables (SA)

4. Double-sampling AOQL tables (DA)

All four types of plans were constructed to give minimum total inspection for product of a given process average. All lots rejected are assumed to be screened, and both the sampling and the expected amount of 100 percent inspection were considered in deriving the plan which would give minimum inspection per lot. This is a particularly appropriate approach for a manufacturer's inspection of its own product as when the product of one department is examined prior to use in another, especially when processes are out of control. Practically, it may be reasonable to use the same theory even when the sampling is done by the purchasing company and the detailing of rejected material is done by the supplying company, since in the long run all the supplier's costs to provide material of a specified quality are reflected in the price.

The first and second sets of tables are classified according to lot tolerance percent defective at a constant consumer's risk of 0.10. Available lot tolerance plans range from 0.5 to 10.0 percent defective. In contrast, the third and fourth sets of tables are classified according to the average outgoing quality limit (AOQL) which they assure. Available AOQL values range from 0.1 to 10.0 percent. Lot tolerance plans emphasize a constant low consumer's risk (with varying AOQLs). In other words, they are intended to give considerable assurance that individual lots of poor material will seldom be accepted. The AOQL plans emphasize the limit on poor quality in the long run, but do not attempt to offer uniform assurance that individual lots of low quality will not get through. The relative importance of these two objectives will guide the choice of types of plan.

Table 46.14 shows a representative Dodge-Romig table for single sampling on the lot tolerance basis. All the plans listed in this table have the same risk (0.10) of accepting submitted lots that contain exactly 5 percent of defective units. The table has six columns. Each of these lists a set of plans appropriate to a specified average value of incoming quality. For example, if the estimated process average percent defective is between 2.01 and 2.50 percent, the last column at the right gives the plans that will provide the minimum inspection per lot. However, the assurance that a lot of quality 5 percent defective will be rejected is the same for all columns, so an initial incorrect estimate of the process average would have little effect except to increase somewhat the total number of pieces inspected per lot. The selection of a plan from this table thus requires only two items of information: the size of the lot to be sampled and the prevailing average quality of the supplier for the product in question. If the process average is unknown, the table is entered at the highest value of process average shown.

Zero Acceptance Number Plans.   In an increasingly litigious society, zero acceptance number plans have enjoyed increasing popularity. This is due, in part, from the notion that no defectives in the sample implies there are no defectives in the rest of the lot; and that defectives found in the sample indicate that the rest of the lot is equally contaminated. This is in line with a zero defects approach to quality. Continual improvement, however, implies lack of perfection and a constant effort to reveal and appropriately deal with quality levels that are not zero. If the state-of-the-art quality levels are indeed not zero, plans with nonzero acceptance numbers and correspondingly larger sample sizes will better discriminate between quality levels, thus facilitating corrective action when needed. Sample size is important as well as the acceptance number! A lot 13 percent defective has 50:50 odds of rejection by the plan $n = 5$, $c = 0$ or by the plan $n = 13$, $c = 1$. Thus, $c = 0$ and $c = 1$ can give equal protection at this point. However, the $c = 1$ plan can discriminate between AQL and LTPD levels that are closer together.

The zero acceptance number plans are useful for emphasizing zero defects and in product liability prevention. The $c = 0$ requirement, however, forces the consumer quality level to be 41 times higher than the producer quality level, since this is a mathematically unavoidable characteristic of $c = 0$ plans. If the consumer quality level is to be closer to the producer quality level, other acceptance numbers must be used. This is why lawyers like and statisticians dislike exclusive use of $c = 0$ plans. A simple estimator of the number of nonconformances outgoing from a $c = 0$ plan with rectification has been given by Greenberg and Stokes (1992).

TABLE 46.14 Dodge-Romig Table* for Lot Tolerance Single Sampling

Lot tolerance percent defective = 5.0%

Process average % Lot size	0–0.5 n*	c*	AOQL* %	0.06–0.50 n	c	AOQL %	0.51–1.00 n	c	AOQL %	1.01–1.50 n	c	AOQL %	1.51–2.00 n	c	AOQL %	2.01–2.50 n	c	AOQL %

Note: n = size of sample; entry of "All" indicates that each piece in lot is to be inspected.

c = allowable defect number for sample.

AOQL = average outgoing quality limit.

Source: Reproduced from Dodge and Romig (1959) by permission of the publisher and of Bell Telephone Laboratories, Inc.

Several plans have been developed to incorporate the $c = 0$ requirement. These are

- *Lot sensitive plan:*   Presents a simple table for Type A sampling that can be used to determine the sample size given the lot size for a desired LTPD. See Schilling (1978).
- *Parts per million AOQL sampling plans:*   Give Type B plans to achieve stated AOQL in parts per million given lot size. Also shows LTPD of plans presented. See Cross (1984).
- *AQL sampling plans:*   Codified Type B plans indexed by AQL and lot size compatible with MIL-STD-105E Normal Inspection (only). See Squeglia (1994).
- *AQL sampling scheme:*   Switches sample sizes between two $c = 0$ plans to increase discrimination over single sampling plans. Called TNT plans, they utilize switching rules in the manner of MIL-STD-105E. See Calvin (1977).

The tightened-normal-tightened (TNT) plan is of special interest in that it improves upon the operating characteristics of a single sample $c = 0$ plan. The switching rules of 105 or its derivatives may be used to switch between normal and tightened inspection. Two plans are used, each with $c = 0$: a normal plan with a given sample size n_N and a tightened plan with a larger sample size n_T. Switching between them will build a shoulder on the OC curve of the normal plan, thus increasing discrimination.

The normal and tightened plan sample sizes n_N and n_T can be found using a method developed by Schilling (1982) as follows:

$$n_T = \frac{230.3}{\text{LTPD}(\%)} \qquad n_N = \frac{5.13}{\text{AQL}(\%)}$$

Thus, if it is desired to achieve AQL = 1 percent and LTPD = 5 percent, $n_T = 230.3/5 = 46.1 \simeq 46$ and $n_N = 5.1/1 \simeq 5$. Then, using Z1.4 switching rules to switch between the plans $n = 46$, $c = 0$ for tightened inspection and $n = 5$, $c = 0$ for normal inspection, the desired values of AQL and LTPD can be obtained. Procedures and tables for the selection of TNT plans are given in Soundararajan and Vijayaraghavan (1990).

VARIABLES SAMPLING

Overview.   In using variables plans, a sample is taken and a measurement of a specified quality characteristic is made on each unit. These measurements are then summarized into a simple statistic (e.g., sample mean) and the observed value is compared with an allowable value defined in the plan. A decision is then made to accept or reject the lot. When applicable, variables plans provide the same degree of consumer protection as attributes plans while using considerably smaller samples.

Table 46.15 summarizes various types of variables plans showing, for each, the assumed distribution, the criteria specified, and special features.

Sampling for Percent Nonconforming.   When interest is centered on the proportion of product outside measurement specifications, and when the underlying distribution of individual measurements is known, variables plans for percent nonconforming may be used. These plans relate the proportion of individual units outside specification limits to the population mean through appropriate probability theory. The sample mean, usually converted to a test statistic, is then used to test for the position of the population mean.

Assume the distribution of individual measurements is known to be normal and a plan is desired such that the OC curve will pass through the two points $(p_1, 1 - \alpha)$ and (p_2, β) where

p_1 = acceptable quality level

$1 - \alpha$ = probability of acceptance at p_1

TABLE 46.15 Summary of Variables Sampling Plans

Type of plan	Plan	Assumed distribution	Criteria specified	Features
	Single-sampling variables plan	Normal	Acceptable and rejectable percent nonconforming	Formulas for determining sample size and acceptance criteria to meet defined risks.
	Double-sampling variables plan	Normal	Acceptable and rejectable percent nonconforming	Tables for determining sample size and acceptance criteria to meet defined risks.
Percent nonconforming	Narrow-limit gauging	Normal	Acceptable and rejectable percent nonconforming	Tables for determining sample size and acceptance criteria to meet defined risks.
	Lot plot	None	Allowable percent nonconforming	Requires 50 measurements. Simple calculations and graphical procedure used to evaluate lot.

TABLE 46.15 Summary of Variables Sampling Plans *Continued*

Type of plan	Plan	Assumed distribution	Criteria specified	Features
Lot or process parameter— general	Test of hypothesis	Appropriate for test	Mean or standard deviation	Formulas for determining sample size and acceptance criteria to meet defined risks.
	Acceptance control chart	Appropriate for determining acceptable and rejectable values of mean	Mean	Graphical procedure to determine if mean falls within defined limits.
	Sequential sampling	Normal	Mean or standard deviation	Procedures for evaluating one measurement at a time to determine if mean falls within defined limits. Complex but total sample size lower than with other plans.
Published plans for percent nonconforming	MIL-STD-414 ANSI/ASQC Z1.9 ISO 3951	Normal	Acceptable quality level (percent defective)	Tables and procedures for lot evaluation to a specified AQL. Requires tightened and reduced inspection. OC curves given. Includes mixed plans for use when lots have been screened before submission to sampling inspection.
Lot or process parameter—bulk sampling	Specific bulk sampling models	Appropriate for test	Mean	Formulas for determining sample size to estimate mean with specified confidence interval. Applicable for gaseous, liquid, or solid products which occur in nondiscrete units.

p_2 = rejectable quality level

β = probability of acceptance at p_2

The OC curve should appear as indicated in Figure 46.16. Some important plans of this type are described below.

Single Sampling.   The rationale for variables sampling plans for percent non-conforming is illustrated in Figure 46.17, which assumes the underlying distribution of measurements to be normal with standard deviation σ known.

Suppose the following sampling plan is used to test against an upper specification limit U:

1. Sample n items from the lot and determine the sample mean $\overline{X}$.

2. Test against an acceptance limit $(U - k\sigma)$, k standard deviation units inside the specification.

3. If $\overline{X} \leq (U - k\sigma)$, accept the product; otherwise reject the product.

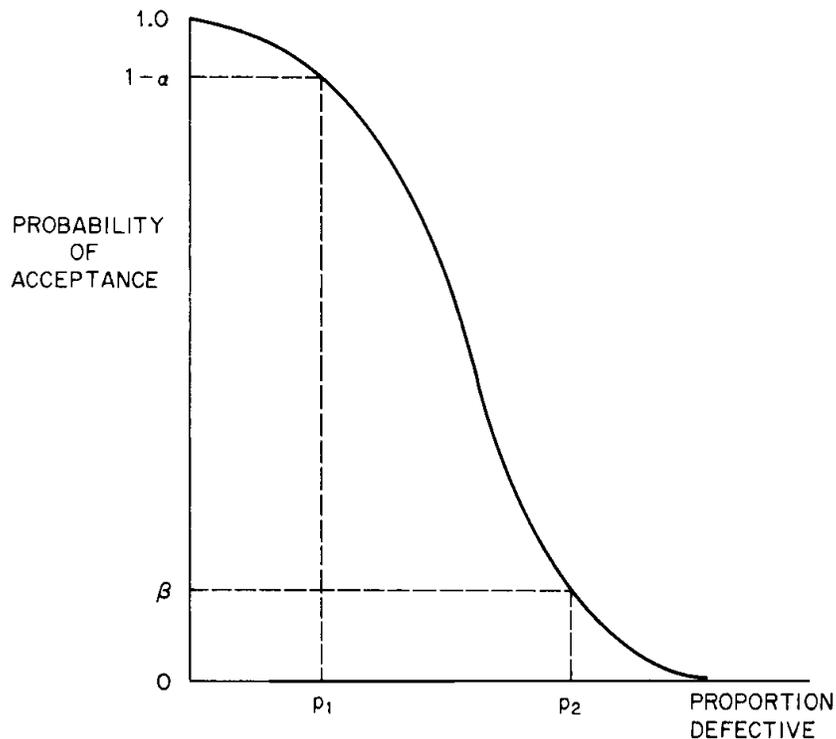
The situation is analogous, but reversed, for a lower specification limit. If the distribution of individual measurements is normal, as shown, a proportion p of the product above the specification limit U implies the mean of the distribution must be fixed at the position indicated by μ. Means of samples of size n are, then, distributed about μ, as shown; so the probability of obtaining an $\overline{X}$ not greater than $(U - k\sigma)$ is indicated by the shaded area of the distribution of sample means. This shaded area is the probability of acceptance when the fraction nonconforming in the process is p. Note that the normal shape supplies the necessary connection between the distribution of the sample means and the proportion of product nonconforming. While, for reasonable sample sizes, the distribution of sample means will be normal, regardless of the shape of the underlying distribution of individual measurements, it is the underlying distribution of measurements itself that determines the relationship of μ and p. Hence, the plan will be quite sensitive to departures from normality.


FIGURE 46.16   Operating characteristic curve.
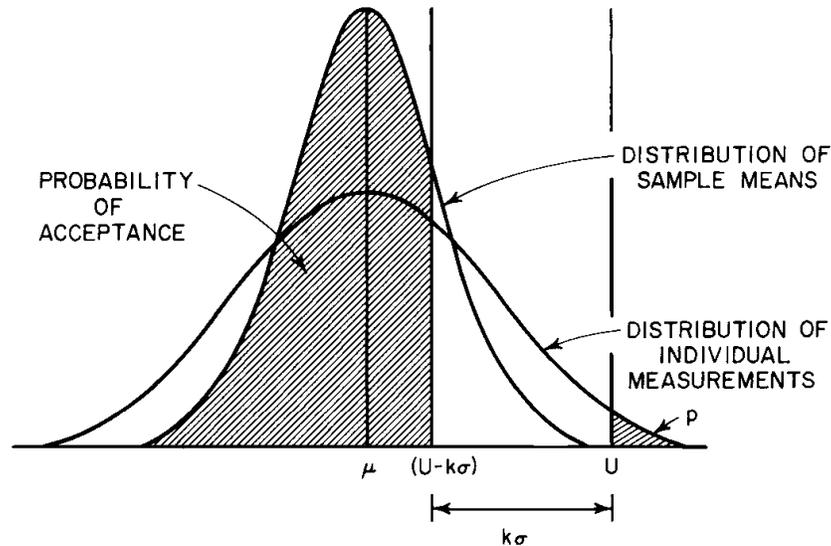

FIGURE 46.17 $(U-k\sigma)$ method.

Since $\overline{X} \le U - k\sigma$ is equivalent to $(U - \overline{X})/\sigma \ge k$, the above sampling plan may be expressed as follows:

1. Sample n items from the lot and determine the sample mean $\overline{X}$.

2. If $(U - \overline{X})/\sigma \ge k$, accept the product; otherwise reject the product. Note that for a lower specification limit L, the inequality becomes $(\overline{X} - L)/\sigma \ge k$.

This is the method used to specify variables sampling plans in MIL-STD-414 (1957) and its civilian versions, ANSI/ASQC Z1.9 (1993) and ISO 3951 (1989).

Using Figure 46.17 and normal probability theory, it is possible to calculate the probability of acceptance P_a for various possible values of p, the proportion defective. For example, from Figure 46.17 we see that using an upper tail z value, $z_{1 - P_a} = (z_p - k) \sqrt{n}$. So the probability of exceeding $z_{1 - P_a}$ is $1 - P_a$ from which we obtain P_a. By symmetry, this relationship can be used with a lower specification limit as well.

A graph of P_a versus p traces the operating characteristic curve of the acceptance sampling plan. Figure 46.18 shows the operating characteristic curve of the variables plan $n = 19$, $k = 1.908$, testing against a single-sided specification limit with known standard deviation. For comparative purposes, the OC curve of the attributes plan $n = 125$, $c = 3$ is also given. Note that the OC curves intersect at about $p = 0.01$ and $p = 0.05$, indicating roughly equivalent protection at these fractions defective.

Probability theory appropriate to other methods of specifying variables plans (e.g., standard deviation unknown, double specification limits) can be used to give the OC curves and other properties of these procedures. Formulas for determining plans to meet specific prescribed conditions can also be derived. Note that the OC curves of variables plans are generally considered to be type B. That is, they are regarded as sampling from the process producing the items inspected, rather than the immediate lot of material involved.

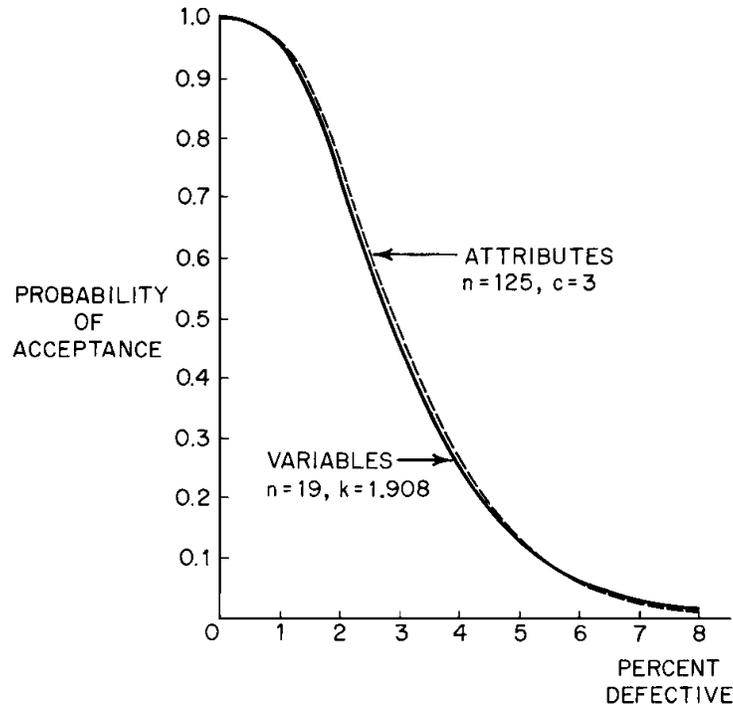
Two-Point Variables Plans for Percent Nonconforming.   Two-point single-sampling plans for variables inspection can be readily obtained using an approximation derived by Wallis. For example, a two-point plan testing against a single specification limit, incorporating producer's quality level p_1 and consumer's quality level p_2 with producer's and consumer's risks fixed at $\alpha = 0.05$ and $\beta = 0.10$ may be found using


FIGURE 46.18   Operating characteristic curve.

$$k = 0.438Z_1 + 0.562Z_2$$

$$n_\sigma = \frac{8.567}{(Z_1 - Z_2)^2}$$

or

$$n_s = \left(\frac{1 + k^2}{2}\right) n_\sigma$$

Here Z_1 is the standard normal deviate corresponding to an upper tail area of p_1, and Z_2 is the standard of normal deviate corresponding to an upper tail area of p_2. Use n_σ or n_s depending on whether the standard deviation is known or unknown. For other risks or double specification limits more detailed procedures are necessary. See Duncan (1974).

As an example of the use of the procedure, consider $p_1 = 0.01$, $p_2 = 0.05$, $\alpha = 0.05$, $\beta = 0.10$. Application of the formulas with $Z_1 = 2.326$ and $Z_2 = 1.645$ gives $k = 1.94$, $n_\sigma = 18.5 \simeq 19$ and $n_s = 53.3 \simeq 54$. This plan closely matches the attributes plan $n = 125$, $c = 3$. Using the formula given above we see that for $p = p_1 = 0.01$, $Z_{1-P_a} = (2.326 - 2.94)\sqrt{19} = 1.68$ so $1 - P_a = 0.046$ and $P_a = 0.954$.

A procedure for applying double-sampling variables plans was first presented by Bowker and Goode (1952). Tables to expedite the selection and application of these plans are given by Sommers (1981). Double sampling by variables can account for about a 20 percent reduction in average sample number from single sampling. For example, the plan matching the single-sampling plan derived above would have average sample size of 14.9 for the known standard deviation plan and 41.4 when the standard deviation is unknown. The application of double-sampling by variables is analogous to double sampling by attributes.

The relative efficiency of two-point variables plans over the matched attributes plans varies with k. Hamaker (1979) has shown that

$$\frac{n_a}{n_\sigma} = 2\pi p_k(1 - p_k)e^{k^2}$$

where p_k is the upper tail normal area corresponding to the standard normal deviate $Z = k$, and n_a is the attributes sample size. For the example above, $k = 1.94$ so $p_k = .0262$ and $n_a/n_\sigma = 6.9$ and we observe that $131/19 = 6.9$.

Narrow-Limit Gaging for Percent Nonconforming.

Narrow- (or compressed-) limit gaging plans bridge the gap between variables and attributes inspection by combining the ease of attributes with the power of variables inspection to reduce sample size. An artificial specification limit is set inside the specification limit. Samples are selected and gaged against this artificial "narrow limit." The narrow limit is set using the properties of the normal distribution, to which the product is assumed to conform. A standard attributes sampling plan is applied to the results of gaging to the narrow limit and the lot is sentenced accordingly.

The criteria for the narrow-limit gaging plan are, then, as follows:

n = sample size

c = acceptance number

t = number of standard deviation units the narrow-limit gage is set inside the specification limit.

The standard deviation σ is assumed to be known.

A set of two-point plans having a minimum sample size for selected values of producer's and consumer's quality levels with $\alpha = 0.05$ and $\beta = 0.10$ has been given by Schilling and Sommers (1981). They have also compiled a complete set of narrow-limit plans matching MIL-STD-105E, ANSI/ASQC Z1.4, and ISO 2859-1.

Consider the plan having producer's and consumer's quality levels $p_1 = 0.01$ and $p_2 = 0.05$ with $\alpha = 0.05$ and $\beta = 0.10$. The appropriate plan given in the Schilling-Sommers tables is $n = 28$, $c = 14$, $t = 1.99$. A narrow-limit gage is set 1.99σ inside the specification limit. A sample of 28 is taken and gaged against each unit. If 15 or more units fail the narrow limit, the lot is rejected. Otherwise, it is accepted.

A good approximation to the optimum narrow limit plan can be constructed from the corresponding known standard deviation variables plan (n_σ, k) as follows:

$$n = \frac{3n_\sigma}{2} \qquad t = k \qquad c = \frac{3n_\sigma}{4} - \frac{2}{3}$$

For the example of the two-point variables plan given above, we have seen that $n_\sigma = 18.5$ and $k = 1.94$

$$n = 27.8 \simeq 28 \qquad t = 1.94 \qquad c = 13.2 \simeq 14$$

Narrow-limit plans have had many successful applications and are readily accepted by inspectors because of the ease with which they can be applied.

Lot Plot.

Probably no variables acceptance sampling plan matches the natural inclination of the inspector better than the lot plot method developed by Dorian Shainin (1950) at the Hamilton Standard Division of United Aircraft Co. The procedure employs a histogram and rough estimates of the extremes of the distribution of product to determine lot acceptance or rejection. A standard sample size of 50 observations is maintained.

The method is useful as a tool for acceptance sampling in situations where more sophisticated methods may be inappropriate or not well received by the parties involved. The lot plot plan is especially useful in introducing statistical methods. The subjective aspects of the plan (classification of frequency distributions, their construction, etc.) and its fixed sample size suggest the use of more objective procedures in critical applications. The wide initial acceptance of Shainin's (1952) work attests to its appeal to inspection personnel. The lot plot method is outlined in Table 46.16. See Grant and Leavenworth (1979) for details. For a critical review, see Moses (1956).

TABLE 46.16   Variables Plans for Percent Defective Lot Plot

Example: A lot plot is to be used in inspecting the width of caps. A sample of 50 is taken in 10 subgroups of 5 with the following results:

1	2	3	4	5	6	7	8	9	10
0.2538	0.2581	0.2556	0.2531	0.2501	0.2521	0.2541	0.2555	0.2489	0.2529
0.2519	0.2571	0.2542	0.2566	0.2506	0.2557	0.2499	0.2569	0.2557	0.2579
0.2508	0.2521	0.2521	0.2534	0.2534	0.2569	0.2514	0.2553	0.2542	0.2565
0.2537	0.2545	0.2521	0.2557	0.2516	0.2541	0.2536	0.2496	0.2529	0.2577
0.2529	0.2563	0.2518	0.2519	0.2559	0.2524	0.2492	0.2512	0.2546	0.2541

These data are shown analyzed in Fig. 46.19. Should the lot be accepted?

Summary of plan	Calculations

I. Restrictions: None.

II. Necessary information: Specification limits.

III. Selection of plan.
    A. Plan is constant lot to lot.
    B. A special form (Fig. 46.19) is used to apply plan.

IV. Elements
    A. Sample size: A random sample of 50 pieces is taken from the lot in 10 subsamples of 5 each. Subsample identification is maintained.

    B. Statistic (for symmetric distribution).

        1. Statistic is $\overline{\overline{X}} \pm 3\hat{\sigma}$ calculated as follows:

          a. Construct cells for frequency distribution on chart.

            (1) Determine mean $\overline{X}_1$ and range R_1 for the first subgroup

            (2) Position $\overline{X}_1$ at line number 0 on lot plot form

            (3) Set cell width w so that $w \simeq R_1/4$

            (4) Fill in lot plot form with cell midpoints

          b. Tally measurements for frequency distribution using subsample number as tally mark. Tally marks form a histogram.

          c. Record range of each subsample on form in terms of number of cells between lowest and highest tally mark for each subgroup.

          d. Calculate grand mean $\overline{\overline{X}}$ from frequency distribution in terms of line numbers above (+) and below (−) arbitrary origin taken as the zero cell.

B.

1*a.* $\overline{X}_1 = 0.2526, R_1 = 0.003$

     $\overline{X}_1 \sim 0.253$ at 0

     $w \simeq \dfrac{0.003}{4} = 0.00075$

     take $w = 0.001$

1*b.* See Fig. 46.19

1*c.* See Fig. 46.19 under "range" on right side

1*d.* Zero cell shown as arrow in Fig. 46.19 $\overline{\overline{X}} = +0.14$

TABLE 46.16 Variables Plans for Percent Defective Lot Plot (*Continued*)

Summary of plan	Calculations
e. Draw $\overline{\overline{X}}$ on chart in terms of line numbers.	1*e.* $\overline{\overline{X}}$ drawn 0.14 cell widths above middle of zero cell
f. Estimate 3σ of line numbers from average of subsample ranges $3\hat{\sigma} = 3\overline{R}/d_2 = 1.29\,\overline{R}$	1*f.* $3\hat{\sigma} = 1.29\left(\dfrac{51}{10}\right) = 6.6$
g. Label $\overline{\overline{X}} \pm 3\sigma$ in terms of line numbers as (1) ULL = Upper Lot Limit ($\overline{\overline{X}}$ + $3\hat{\sigma}$) (2) LLL = Lower Lot Limit ($\overline{\overline{X}}$ − $3\hat{\sigma}$)	1*g.* See Fig. 46.19 marked ULL and LLL
h. Draw specification limits on chart.	1*h.* See Fig. 46.19 marked SPEC

    C. Decision criteria.
       1. Acceptance criterion.
         a. Symmetric distribution well within specification limits—accept automatically.
         b. Symmetric distribution other than above:
            (1) Lot limits within specification—accept.
            (2) Lot limits outside specification—estimate proportion of product outside specification with special technique using code strip. If less than allowable value—accept. See reference below.
         c. Nonsymmetric, bimodal distributions, etc. Special technique provided for estimating proportion out of specification using code strip. See reference below. If less than allowable value—accept.
       2. Rejection criterion: Reject otherwise.

V. Action: Dispose of lot as indicated. The Lot plot form provides a useful communication device with vendor.	V. Reject the lot

  VI. Characteristics: See source reference below.

  VII. Reference: Shainin, 1950.

A special lot plot card is helpful in simplifying some of the calculations. Figure 46.19 shows the form filled out for the example given in Table 46.16.

Grand Lot Schemes.

Acceptance inspection and compliance testing often require levels of protection for both the consumer and the producer that make for large sample size relative to lot size. A given sample size can, however, be made to apply to several lots jointly if the lots can be shown to be homogeneous. This reduces the economic impact of a necessarily large sample size. Grand lot schemes, as introduced by L. E. Simon (1941), can be used to effect such a reduction. Application of the grand lot scheme has been greatly simplified by incorporating graphical analysis of means procedures in verifying the homogeneity of a grand lot. In this way individual sublots are subjected to control chart analysis for uniformity in level and variation before they are combined into a grand lot. The resulting approach can be applied to attributes or variables data, is easy to use, provides high levels of protection economically, and can reduce sample size by as much as 80 percent. It may be applied to unique "one-off" lots, isolated lots from a continuing series, an isolated sequence of lots, or to a continuing series of lots. The procedure has been described in depth by Schilling (1979).

Sampling for Process Parameter.

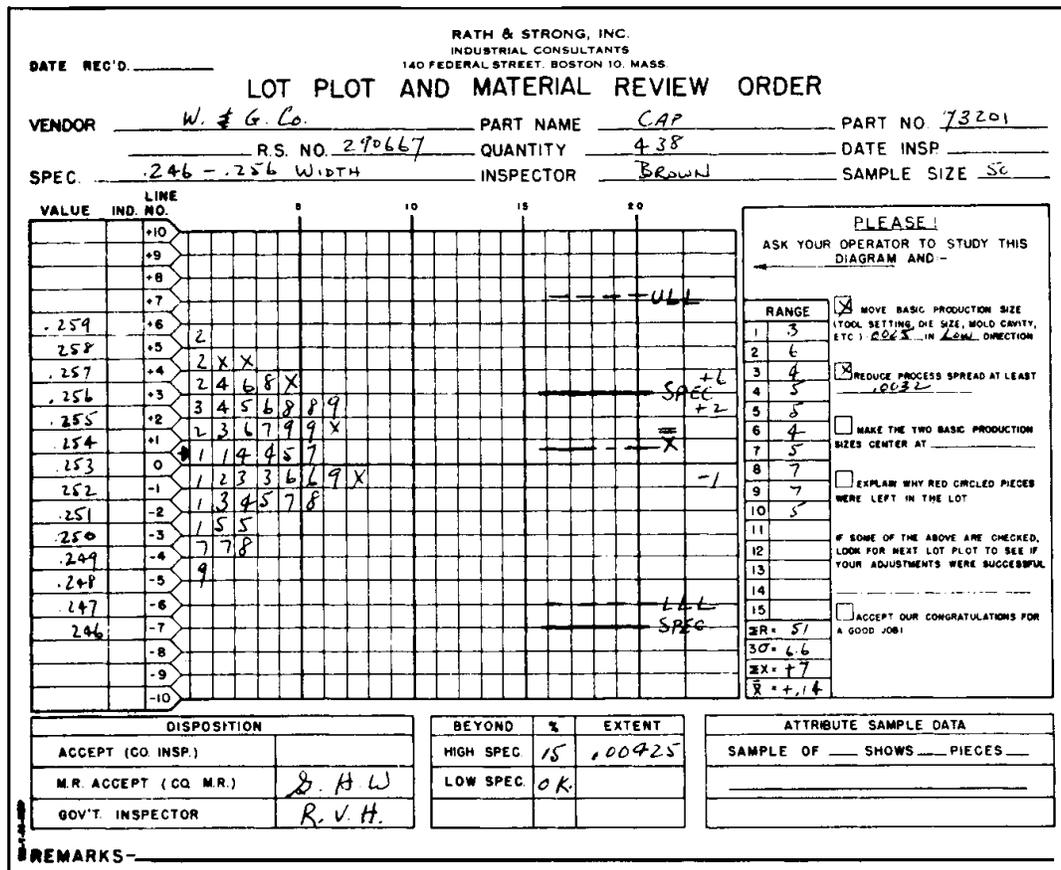
When process parameters are specified, sampling plans can be developed from analogous tests of significance with corresponding OC curves. These plans do not require percent nonconforming to be related to the process mean, since the specifications to which they are applied are not in terms of percent nonconforming. This means that assumptions of process distribution may not need to be as rigorously held as in variables plans for percent nonconforming.


FIGURE 46.19   Illustration of lot plot method.

With specifications stated in terms of process location or variability, as measured by specific values of the mean μ or the process standard deviation σ, interest is centered not on fraction defective, but rather on controlling the parameters of the distribution of product to specified levels. From specifications of this type, it is usually possible to distinguish two process levels which may be used as bench marks as conceived by Freund (1957):

1. APL = acceptable process level—a process level which is acceptable and should be accepted most of the time by the plan.

2. RPL = rejectable process level—a process level which is rejectable and should be rejected most of the time by the plan.

The probability of acceptance for each of these process levels is usually specified as:

$$1-\alpha \;=\; \text{probability of acceptance at the APL}$$
$$\beta \;=\; \text{probability of acceptance at the RPL}$$

where α = producer's risk, β = consumer's risk.

Variables plans appropriate for this type of specification can be derived from the operating characteristic curves of appropriate tests of hypotheses. This is the case for single-sampling plans for process parameter which are, simply, appropriately constructed tests of hypotheses, e.g., testing the hypothesis that μ equals a specific value, against a one- or two-sided alternative. Thus, the statistical tests presented in Section 44 under Statistical Tests of Hypotheses can be used for this type of acceptance sampling plan.

Sequential sampling procedures have been developed which are particularly useful when levels of process parameter are specified. They usually offer a substantial decrease in sample size over competing procedures, although they may be difficult to administer. To use sequential sampling:

1. Take a sample of one measurement at a time.

2. Plot the cumulative sum T of an appropriate statistic against the sample number n.

3. Draw two lines

$$T_2 = h_2 + sn$$
$$T_1 = -h_1 + sn$$

where the intercepts h_1 and h_2 are values associated with the plan used and the symbol s is not a standard deviation but is a constant computed from the values of the acceptable process level (APL) and the rejectable process level (RPL). The use of s here corresponds to its use in the literature of sequential sampling plans.

4. Continue to sample if the cumulative sum lies between these lines, and take the appropriate action indicated if the plot moves outside the lines.

Procedures for constructing such plans and determining appropriate values of h_1, h_2, and s are given in detail in Duncan (1974) and Schilling (1982).

Acceptance control charts offer a unique answer to the problem of sampling for process parameter and can be used to implement such plans when an acceptable process level and rejectable process level are defined in terms of the mean value. They satisfy the natural desire of inspection personnel to observe quality trends and to look upon sampling as a continuing process.

These charts incorporate predetermined values of consumer and producer risk in the limits and so provide the balanced protection for the interested parties that is often lacking in the use of a conventional control chart for product acceptance.

It is not necessary that the population of individual measurements be normally distributed. The distribution must be known so that acceptable and rejectable values of the mean can be calculated. The procedure then uses the normal distribution in the analysis of the sample mean because the

distribution of sample means of samples of reasonable size may be regarded as normal for any distribution of individual measurements.

The procedure for implementing this technique is shown in Table 46.17. The acceptance control chart concept is shown in Figure 46.20, and an acceptance control chart example is shown in Figure 46.21. See Freund (1957) for additional details.

TABLE 46.17 Variables Plans for Process Parameter—Acceptance Control Charts

Example: The specification limits for electrical resistance are 620 and 680, the AQL 2.5%, and the standard deviation 13. Assuming a normal distribution of individual measurements, the mean may be as low as 620 + 1.96 (13), or 646, or as high as 680 − 1.96 (13), or 654. This pair of values represents the range of the acceptable process level (APL). It was decided that the rejectable process level would occur when 14% was beyond a specification limit. Thus, the range of RPL was 620 + 1.08 (13) and 680 − 1.08 (13), or 634 and 666. Should the lot be accepted if $\overline{X}$ = 647?

Summary of plan	Calculations
I. Restrictions: None	
II. Necessary information (single-sided specification)	II.
A. σ = known standard deviation	*A.* σ = 13
B. μ_1 = APL (acceptable process level) with $P_a = 1 - a$	*B.* μ_1 = 654, P_a = 0.95
C. μ_2 = RPL (rejectable process level) with $P_a = \beta$	*C.* μ_2 = 666, P_a = 0.10
III. Selection of plan: See below	
IV. Elements	IV.
A. Sample size $$n = \left[\frac{(z_\alpha + z_\beta)\,\sigma}{\mu_2 - \mu_1} \right]^2$$ where z_p cuts off upper tail area of p in standard normal curve	*A.* $$n = \left[\frac{(1.645 + 1.282)\,(13)}{12} \right]^2$$ n = 10.06 ~ 10
B. Statistic: $\overline{X}$ = mean of sample of n	*B.* $\overline{X}$ = 647
C. Decision criteria	*C.* $d =$
1. Compute: $$d = \frac{z_\alpha}{z_\alpha + z_\beta}\lvert \mu_2 - \mu_1 \rvert$$	$$\left(\frac{1.645}{1.645 + 1.282} \right)(12)$$ = 6.74 Upper ACL = 654 + 6.74 = 660.74
and set the acceptance control limit, ACL, a distance d from APL in the direction of the RPL. Sign of $\lvert \mu_2 - \mu_1 \rvert$ ignored.	By symmetry Lower ACL = 646 − 6.74 = 639.26
2. Construct an acceptance control chart (Fig. 46.20) and accept if $\overline{X}$ falls within acceptance control limits; reject otherwise. Double-sided specification chart shown (see remarks below). Use appropriate half of chart for single-sided specification.	Plot as in Fig. 46.21

Published Tables and Procedures.   There is often much more involved in acceptance sampling than simple tests of hypotheses. Sampling plans applied individually to guard against an occasional discrepant lot can be reduced to hypothesis tests. Sampling plans, however, may be combined into sampling schemes, intended to achieve a predetermined objective. Sampling schemes, as overall strategies using one or more sampling plans, have their own measures such as AOQ (average outgoing quality) or ATI (average total inspection), not to be found in hypothesis testing. Thus, MIL-STD-105E (1989) and its civilian versions ANSI/ASQC Z1.4 (1993) and ISO 2859-1 (1989) together with their variables counterpart MIL- STD-414 (1957) and its modified civilian versions ANSI/ASQC Z1.9 (1993) and ISO 3951 (1989) are sampling schemes which specify the use of various sampling plans under well-defined rules. The latter assume the individual measurements to which they are applied to be normally distributed.

The variables standards allow for the use of three alternative measures of variability: known standard deviation σ, estimated standard deviation s, or average range $\bar{R}$. If the variability of the process producing the product is known and stable as verified by a control chart, it is profitable to use σ. The choice between s and $\bar{R}$, when σ is unknown, is an economic one. The range requires larger sample sizes but is easier to understand and compute. The operating characteristic curves given in the standards are based on the use of s, the σ and $\bar{R}$ plans having been matched, as closely as possible, to those using s.

MIL-STD-414 and ANSI/ASQC Z1.9 (1993) offer two alternative procedures. In addition to the method using an acceptance constant k, each standard also presents a procedure for estimating the proportion of defective in the lot from the variables evidence. The former method is called Form 1; the latter is called Form 2. Form 2 is the preferred procedure in MIL-STD-414 since the switching rules for reduced and tightened inspection cannot be applied unless the fraction defective of each lot is estimated from the sample. The switching rules of ANSI/ASQC Z1.9 were patterned after MIL-STD-105D (1964) and can be used with Form 1 or Form 2. ISO 3951 presents a graphical alternative to the Form 2 procedure to be used with switching rules also patterned after MIL-STD-105D.

Application of these variables schemes follows the pattern of MIL-STD-105E, which was also an AQL sampling scheme. Sample sizes are determined from lot size, and after choosing the measure of variability to be used and the Form of the acceptance procedure, appropriate acceptance limits are obtained from the standard. As in MIL-STD-105E, operating characteristic curves are included in the variables standards. These should be consulted before a specific plan is instituted. Note that the plans contained in MIL-STD-414 and MIL-STD-105E did not match; however the plans in ANSI Z1.9 are matched to MIL-STD-105E, ANSI/ASQC Z1.4 and ISO 2859-1 as are those in ISO 3951.

Since they are AQL schemes, these standards are based on an overall strategy which incorporates switching rules to move from normal to tightened or reduced inspection and return depending on the quality observed. These switching rules are indicated in Figure 46.22 for ANSI/ASQC Z1.9 (1993) and should be used if the standard is to be properly applied. The switching rules for ANSI/ASQC Z1.9 (1993) are the same as those of ANSI/ASQC Z1.4 (1993) except that the limit numbers for reduced inspection have been eliminated. This allows these standards to be readily interchanged. ISO 3951 switching rules differ slightly but are analogous to 105, while MIL-STD-414 rules are unique.

REDUCED

- Preceding 10 Lots Accepted on Normal
- Production Steady
- Considered Desirable by Responsible Authority

- Lot Rejected
- Production Irregular
- Other Conditions Warrant

NORMAL

- 2 of 5 Consecutive Lots or Batches Rejected

- 5 Consecutive Lots or Batches Accepted on Original Inspection

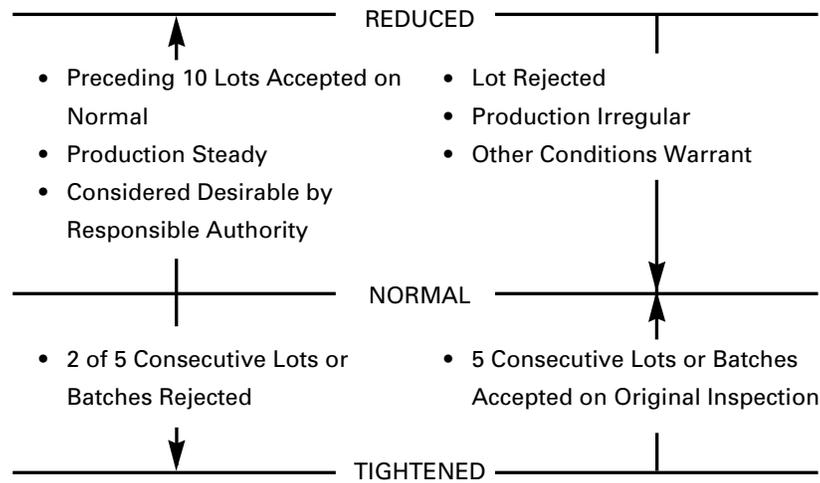
TIGHTENED


FIGURE 46.22   Switching rules for ANSI/ASQC Z1.9 (1993).

A check sequence for application of MIL-STD-414, ANSI/ASQC Z1.9 and ISO 3951 is given in Figure 46.23. Table 46.18 and Table 46.21 show the specific steps involved in application of the two forms using the sample standard deviation as a measure of variability. The graphical method of ISO 3951 is shown in Table 46.24 and Figure 46.24. Although the basic procedures of ANSI/ASQC Z1.9 (1993) and the graphical methods of ISO 3951 are analogous to MIL-STD-414, it should be noted that ranges, inspection levels, and tables of plans are different in these standards, since Z1.9 and ISO 3951 were revised to match MIL-STD-105D while 414 remained matched to MIL-STD-105A (1950). Procedures for upper, lower, and double specification limits are indicated in these tables together with appropriate references to the standard and an illustrative example. Modifications to the procedure, necessary when variability is measured by average range or a known standard deviation, are described. Table 46.25 shows the relationship of the statistics and procedures used under the various measures of variability allowed, for each of the forms.

These standards have a liberal supply of excellent examples. The reader is referred to the standards for more detailed examples of their applications.

Variables sequential plans for use with ISO 3951 (1989), ISO 2859-1 (1989), and their counterparts are provided in ISO 8423 (1991).

Mixed Plans.   One disadvantage of variables is the fact that screened lots may at times be rejected by a sample $\bar{X}$ or s indicating percent defective to be high when, actually, the discrepant material has been eliminated. To prevent rejection of screened lots, double-sampling plans have been developed which use a variables criterion on the first sample and attributes on the second sample. Lots are accepted if they pass variables inspection; however, if they do not pass, a second sample is taken and the results are judged by an attributes criterion. In this way screened lots will not be rejected, since rejections are made only under the attributes part of the plan. These plans provide a more discriminating alternative when it is necessary to use $c = 0$. This type of plan was proposed by Dodge (1932). The plan has been discussed in some detail by Bowker and Goode (1952), Gregory and Resnikoff (1955), and Schilling and Dodge (1969). MIL-STD-414 and ANSI/ASQC Z1.9 (1993) allow for the use of such procedures, although only ANSI/ASQC Z1.9 (1993) is properly matched to MIL-STD-105E or ANSI/ASQC Z1.4 (1993) to allow for proper use of mixed plans. The steps involved are shown in Table 46.26.

RELIABILITY SAMPLING

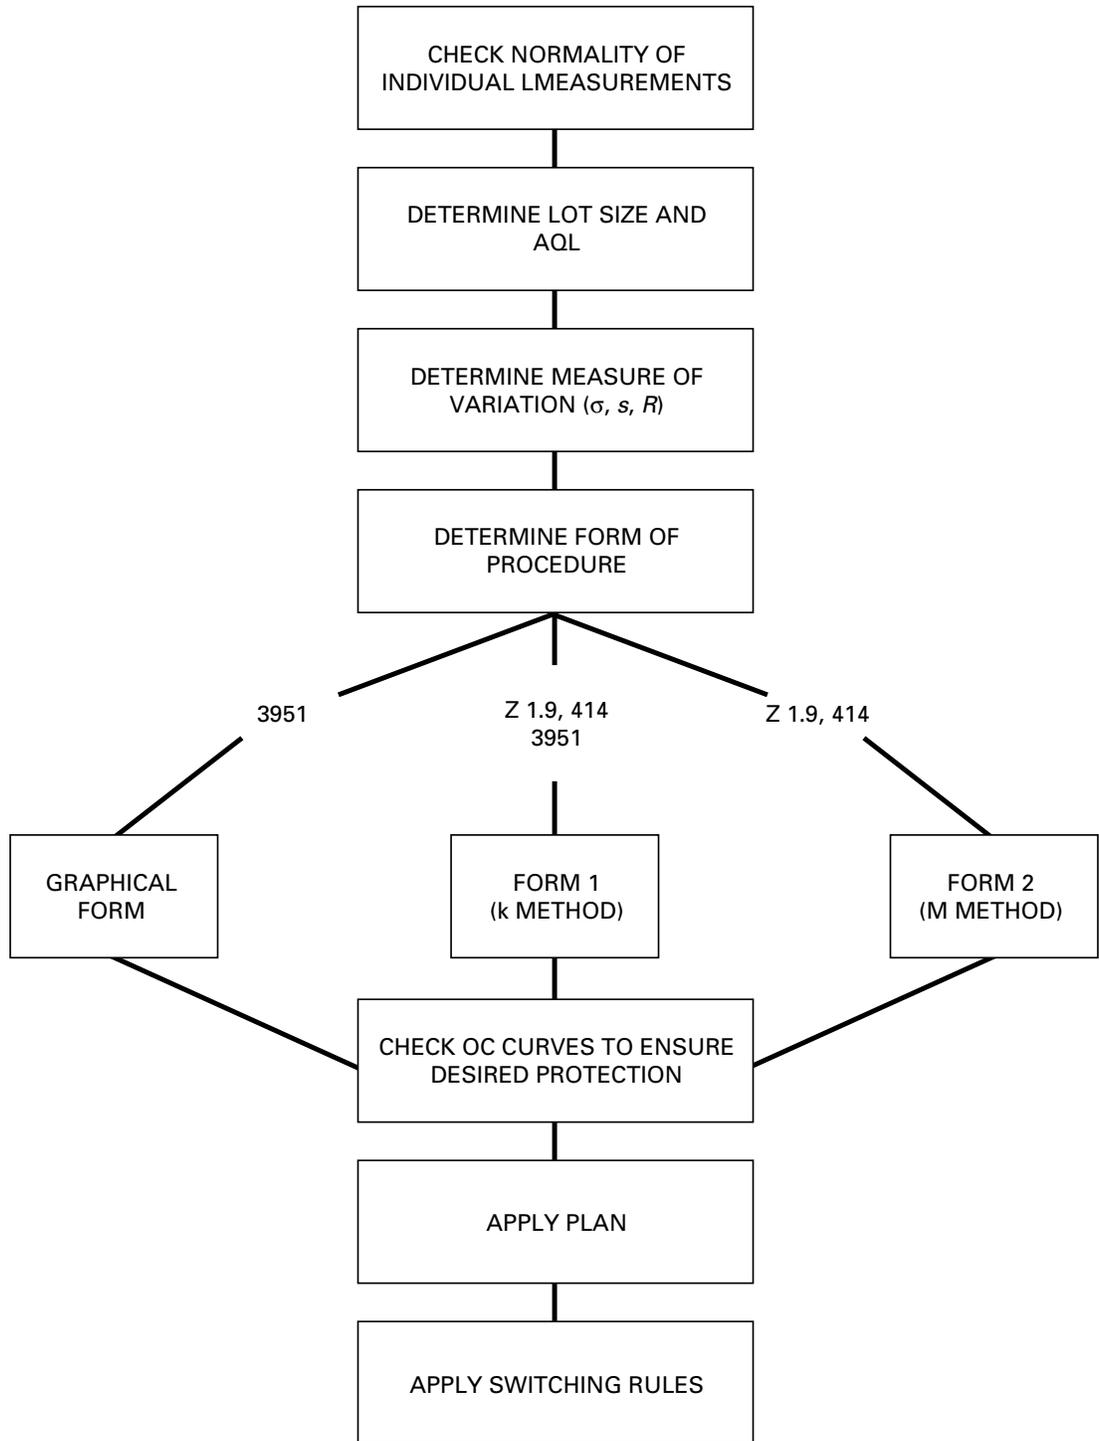
Overview.   Sampling plans for life and reliability testing are similar in concept and operation to the variables plans previously described. They differ to the extent that, when units are not all


FIGURE 46.23   Check sequence for MIL-STD-414, ANSI/ASQC Z1.9, and ISO 3951.

TABLE 46.18 MIL-STD-414 (1957), ANSI/ASQC Z1.9 (1993) and ISO 3951 (1989), Variability Unknown, Standard Deviation Method, Form 1

Example: The specification for electrical resistance of a certain component is 620 to 680 ohms. A lot of 100 is submitted for inspection, normal inspection, with AQL = 2.5 percent. Should the lot be accepted if $\bar{X}$ = 647 and s = 17.22?

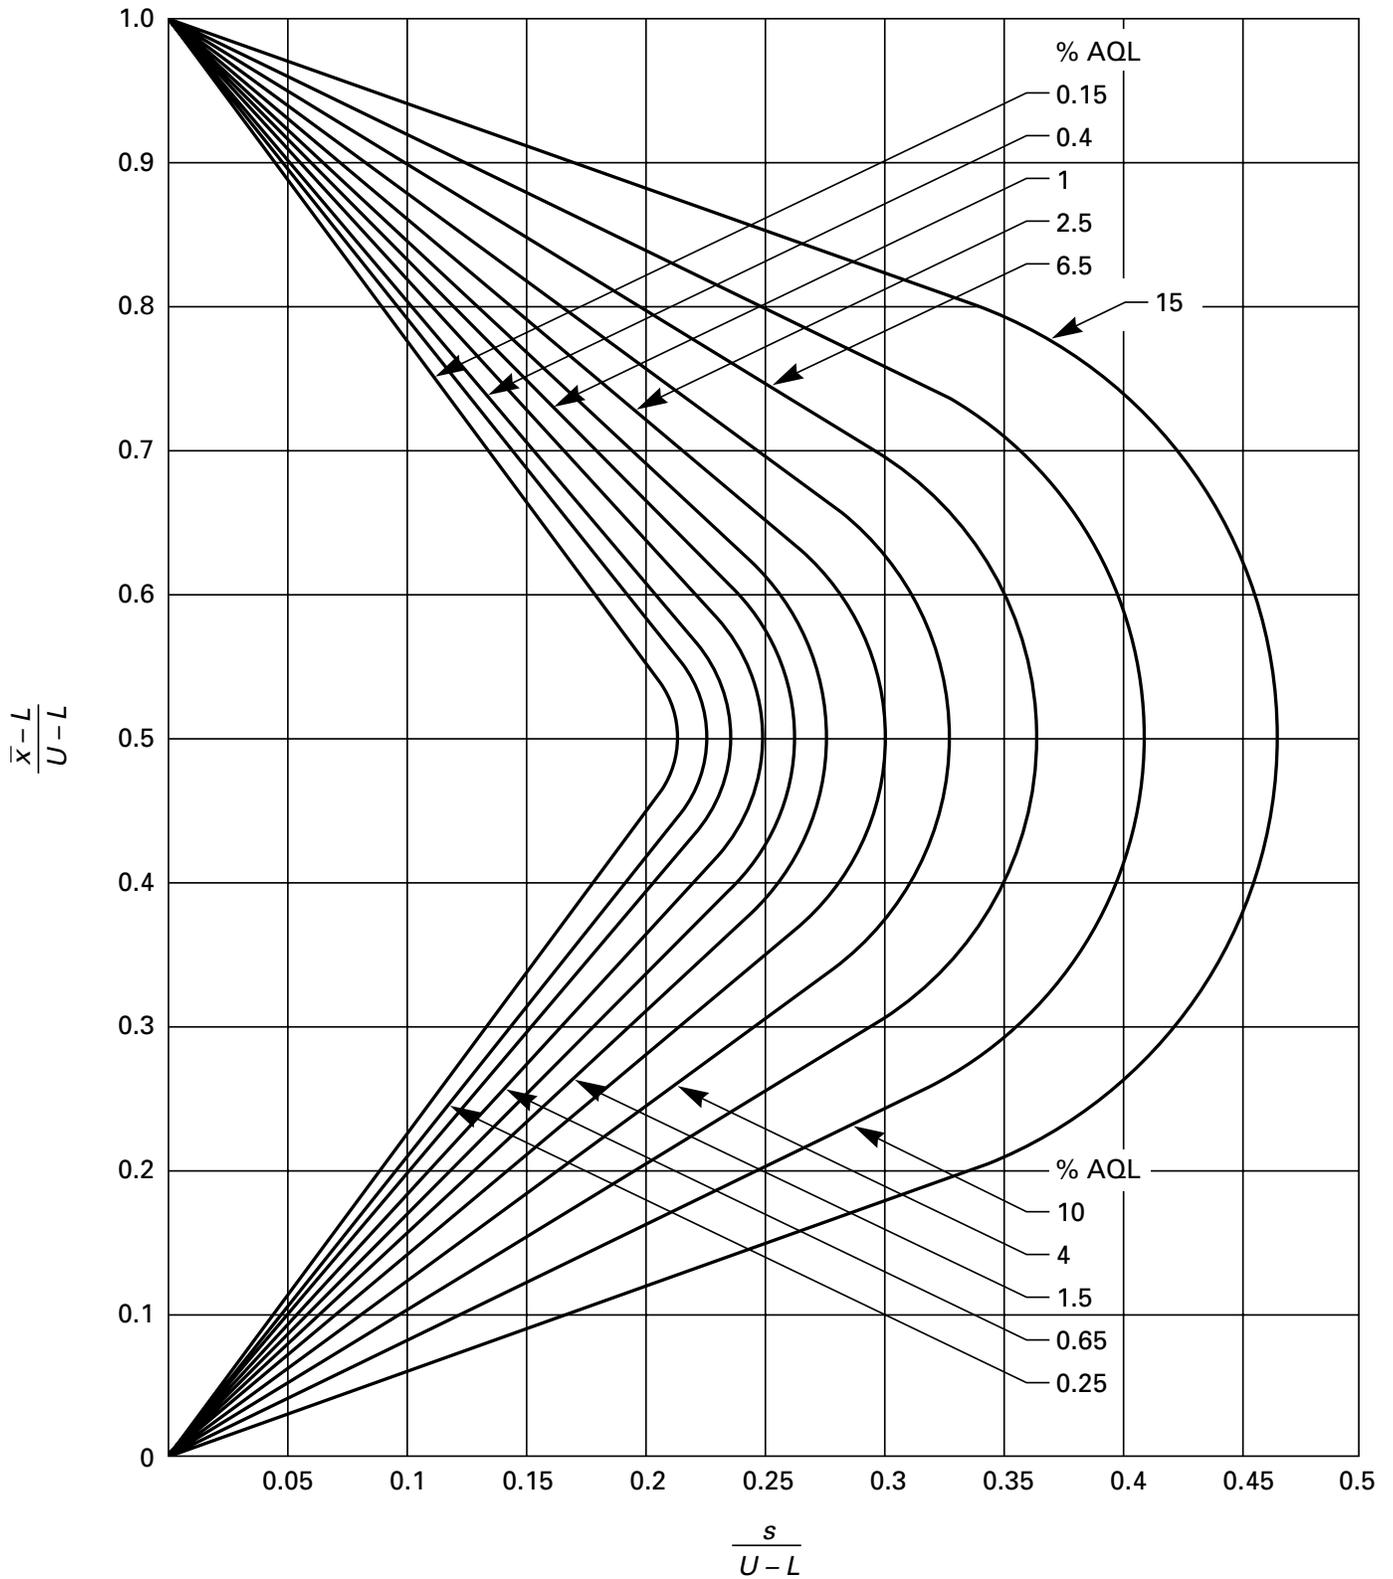
Summary of plan	Calculations
I. Restrictions: Individual measurements normally distributed	MIL-STD-414 Example
II. Necessary information	II.
A. Lot size	*A.* Lot size=100
B. AQL	*B.* AQL=2.5%
C. Severity of inspection: normal, tightened, reduced	*C.* Normal inspection
III. Selection of plan	III.
A. Determine code letter (Table 46.19 for MIL-STD-414 only) from lot size and inspection level [normally, inspection level IV is used in MIL-STD-414 and inspection level II in ANSI/ASQC Z1.9 (1993) and ISO 3951 unless otherwise specified]	*A.* Code F
B. From code letter and AQL, determine (Table 46.20 for MIL-STD-414 only)	*B.*
1. Sample size = n	n=10
2. Acceptance constant = k	k=1.41
C. Double specification limits: obtain MSD = $F(U-L)$, where F is obtained from appropriate table in the Standard	*C.* MSD = 0.298(680 − 620) = 17.88
IV. Elements	IV.
A. Sample size: See above	*A.* n = 10
B. Statistic	*B.* T_U = (680 − 647)/17.22 = 1.92
1. Upper specification: $T_U = (U - \bar{X})/s$	T_L = (647 − 620)/17.22 = 1.57
2. Lower specification: $T_L = (\bar{X} - L)/s$	
3. Double specification: T_U and T_L	
C. Decision Criteria	*C.*
1. Acceptance criterion	
a. Upper specification: $T_U \geq k$	1.92 > 1.41
b. Lower specification: $T_L \geq k$	1.57 > 1.41
c. Double specification: $T_U \geq k$, $T_L \geq k$, and $s \leq$ MSD	17.22 < 17.88
2. Rejection criterion: Reject otherwise	
V. Action: Dispose of lot as indicated and refer to switching rules for next lot	V. Accept the lot
VI. Characteristics: OC curves given.	
VII. Reference: 1957 version of MIL-STD-414, ANSI/ASQC Z1.9 (1992) and ISO 3951 (1989)	
VIII. Remarks (use appropriate tables from Standard)	
A. Range method	
1. Use $\bar{R}$ of subsamples of 5 if $n \geq 10$; use R if $n < 10$	
2. Substitute $\bar{R}$ for s in statistics	
3. Double specifications—use values of f (for MAR) in place of F (for MSD), where MAR is the maximum allowable range	
B. Variability known: Substitute σ for s in statistics	
C. ISO 3951 uses a special procedure for separate AQLs	


FIGURE 46.24 Acceptance curves for combined double specification limits: standard deviation method—sample size code letter F (sample size 10).

*Sample size code letters given in body of table are applicable when the indicated inspection levels are to be used.

run to failure, the length of the test becomes an important parameter determining the characteristics of the procedure. Further, time to failure tends to conform naturally to skewed distributions such as the exponential or as approximated by the Weibull. Accordingly, many life test plans are based on these distributions. When time to failure is normally distributed and all units tested are run to failure, the variables plans assuming normality, discussed above, apply; attributes plans such as ANSI/ASQC Z1.4 or ISO 2859 may also be used. Life tests, terminated before all units have failed, may be

1. Failure terminated—a given sample size n is tested until the rth failure occurs. The test is then terminated.
2. Time terminated—a given sample size n is tested until a preassigned termination time T is reached. The test is then terminated.

Furthermore, these tests may be based upon specifications written in terms of one of the following characteristics:

1. *Mean life:*   The mean life of the product
2. *Hazard rate:*   Instantaneous failure rate at some specified time t
3. *Reliable life:*   The life beyond which some specified proportion of items in the lot or population will survive
4. *Failure rate* (FR or λ):   The percentage of failures per unit time (say 1000 hours of test)

Relation of Life Characteristics.   Specification and test of various life characteristics are intimately related. Tables 46.27 and 46.28 will be found useful in converting life test characteristics. Formulas for various characteristics are shown in terms of mean life μ. Thus, using the tables, it will be found that a specification of mean life $\mu = 1000$ hours for a Weibull distribution with $\beta = 2$ is

   C. Severity of inspection: normal, tightened, reduced
	II.
	   A. Lot size = 100
	   B. AQL = 2.5%
	   C. Normal inspection

III. Selection of plan
   A. Determine (Table 46.19 for MIL-STD-414 only) code letter from lot size and inspection level (usually, inspection level IV is used in MIL-STD-414 and inspection level II in ANSI/ASQC Z1.9)
   B. From code letter and AQL, determine (Table 46.22 for MIL-STD-414 only)
     1. Sample size = n
     2. Value of M
	III.
	   A. Code F
	
	   B.
	
	     n = 10
	     M = 7.29

IV. Elements
   A. Sample size: See above
   B. Statistic
     1. Upper specification: $Q_U = (U - \overline{X})/s$
     2. Lower specification: $Q_L = (\overline{X} - L)/s$
     3. Double specification: Q_U and Q_L
   C. Estimate Percent Defective from Table 46.23
     1. Upper specification: estimate p_U (%) from Q_U and n
     2. Lower specification: estimate p_L (%) from Q_L and n
     3. Double specification: estimate p (%) = p_U (%) + p_L(%)
   D. Decision criteria
     1. Acceptance criterion
       a. Upper specification: p_U (%) < M
       b. Lower specification: p_L(%) < M
       c. Double specification: p(%) < M
     Note: if AQLs not equal on upper and lower specifications, obtain M for each and apply a, b, c, above, using larger of two M values in c
	IV.
	   A. n = 10
	   B.
	     Q_U = (680 − 647)/17.22
	       = 1.92
	     Q_L = (647 − 620)/17.22
	       = 1.57
	
	   C.
	
	     p_U (%) = 1.68
	
	     p_L(%) = 4.92
	
	     p(%) = 6.60
	   D.
	
	     6.60 < 7.29

TABLE 46.21 MIL-STD-414 and ANSI/ASQC Z1.9 (1993), Variability Unknown, Standard Deviation Method, Form 2 (*Continued*)

Summary of plan	Calculations
2. Rejection criterion: Reject otherwise	
V. Action: Dispose of lot as indicated and refer to switching rules for next lot.	V. Accept the lot
VI. Characteristics: OC curves given	
VII. Reference: 1957 version of MIL-STD-414 and ANSI/ASQC Z1.9 (1993).	

VII. Remarks (use appropriate tables from Standard)
  A. Range method—similar except:
    1. Use $\overline{R}$ of subsamples of 5 if $n \geq 10$; use R if $n < 10$
    2. Substitute $\overline{R}/c$ for s in statistics, where c is a scale factor given with n and M in the Standard
  B. Variability known—similar except:
    1. Substitute σ/v for s in statistics, where v factor is given with n and M in the Standard	

equivalent to a hazard rate of 0.000157 at 100 hours or to a reliable life of 99.22 percent surviving at 100 hours.

Exponential Distribution: H108.   *Quality Control and Reliability Handbook* MIL-HDBK-108 (1960) is widely used and presents a set of life test and reliability plans based on the exponential model for time to failure. The plans contained therein are intended for use when mean time to failure β is specified[2] in terms of acceptable mean life β_0 and unacceptable mean life β_1. Testing may be conducted:

With replacement: Units replaced when failure occurs. Test time continues to be accumulated on replacement unit.

Without replacement: Units not replaced upon failure.

The handbook contains three types of plans:

1. *Life tests terminated upon occurrence of a preassigned number of failures:*   Here, *n* units are tested until *r* failures occur. The average life is calculated and compared with an acceptable value defined by the plan, and a decision is made.

2. *Life tests terminated at a preassigned time:*   Here, *n* units are tested for a specified length of time *T.* If *T* is reached before *r* failures occur, the test is stopped and the lot accepted. If *r* failures occur before *T* is reached, the test is stopped and the lot rejected.

3. *Sequential life testing plans:*   Here *n* units are placed on test, and time and failures are recorded until sufficient data are accumulated to reach a decision at specified risk levels. Periodically

---

[2]Note that elsewhere in this handbook the mean value is described by the symbol μ.

TABLE 46.24 ISO 3951 (1989) Variability Unknown, Standard Deviation Method, Double Specifications with Combined AQL, Graphical Procedures

Example: The specification for electrical resistance of a certain component is 620 to 680 ohms. A lot of 100 is submitted for inspection, inspection level II, normal inspection, with AQL = 2.5 percent. Should the lot be accepted if $\bar{X} = 647$ and $s = 17.227$?

Summary of plan	Calculations
I. Restrictions: Individual measurements, normally distributed	
II. Necessary information	II.
A. Lot size	A. Lot size = 100
B. AQL (combined for both specification limits)	B. AQL = 2.5 percent
C. Severity of inspection	C. Normal inspection
III. Selection of plan	III.
A. Determine code letter from lot size and inspection level; usually inspection level II is used	A. Code F
B. From code letter and AQL, determine sample size	B. $n = 10$
IV. Elements	IV.
A. Sample size: See above	A. $n = 10$
B. Statistic: $\dfrac{s}{U - L}$ and $\dfrac{\bar{X} - L}{U - L}$	B. 0.287 and 0.450
C. Decision criteria	C.
1. If $s > \text{MSSD} = f_s(U - L)$ reject outright	1. $17.22 < .298(60) = 17.88$
2. Select acceptance chart corresponding to code letter and AQL and plot above statistics on chart	2. See Figure 46.24
3. Acceptance criterion: Point plots inside accept zone	3. Point plots inside accept zone. Accept the lot
4. Rejection criterion: Point plots outside accept zone	
V. Action: Dispose of lot as indicated and refer to switching rules for next lot; see above	
VI. Characteristics: OC curves given	
VII. Reference: ISO 3951 (1989)	
VIII. Remarks: Analogous methods are available for average range $\bar{R}$ or known standard deviation σ, by substituting $\bar{R}$ or σ in the above.	

throughout the test, the time accumulated on all units is calculated and compared with the acceptable amount of time for the total number of failures accumulated up to the time of observation. If the total time exceeds the limit for acceptance, the lot is accepted; if the total time is less than the limit for rejection, the lot is rejected. If the total time falls between the two limits, the test is continued.

Plans are given for various values of the consumer and producer risks, and operating characteristic curves are provided for life tests terminated at a preassigned number of failures or preassigned time. Special tables are also included showing the expected saving in test time by increasing the sample size or by testing with replacement of failed units.

TABLE 46.25   Application of MIL-STD-414, ANSI/ASQC Z1.9 (1993), and ISO 3951

Step	Section	Form 1	Form 2	Graphical
Preparatory		Obtain k and n from appropriate tables	Obtain M and n from appropriate tables	Select appropriate acceptance chart
Determine criteria	Section B (s)	$T_U = \dfrac{U - \overline{X}}{s}$ $T_L = \dfrac{\overline{X} - L}{s}$	$Q_U = \dfrac{U - \overline{X}}{s}$ $Q_L = \dfrac{\overline{X} - L}{s}$	$A = \dfrac{\overline{X} - L}{U - L}$ $V = \dfrac{s}{U - L}$
	Section C $(\overline{R})$	$T_U = \dfrac{U - \overline{X}}{\overline{R}}$ $T_L = \dfrac{\overline{X} - L}{\overline{R}}$	$Q_U = \dfrac{(U - \overline{X})c}{\overline{R}}$ $Q_L = \dfrac{(\overline{X} - L)c}{\overline{R}}$	$A = \dfrac{\overline{X} - L}{U - L}$ $V = \dfrac{\overline{R}}{U - L}$
	Section D (σ)	$T_U = \dfrac{U - \overline{X}}{\sigma}$ $T_L = \dfrac{\overline{X} - L}{\sigma}$	$Q_U = \dfrac{(U - \overline{X})v}{\sigma}$ $Q_L = \dfrac{(\overline{X} - L)v}{\sigma}$	$A = \dfrac{\overline{X} - L}{U - L}$ $V = \dfrac{\sigma}{U - L}$
Estimation			Enter table with n and Q_U or Q_L to get p_U or p_L	
Action	Single specification	Accept if $T_U \geq k$ or $T_L \geq k$	Accept if $p_U \leq M$ or $p_L \leq M$	
	Double specification	Accept if* $T_U \geq k$, $T_L \geq k$ and s < MSD or $\overline{R}$ < MAR	Accept if $p_U + p_L \leq M$	Accept if (A, V) plots inside acceptance curve
Standard/ Specification		414, 1.9/single, double* 3951/single, double with separate AQL's	414, 1.9/single, double	3951 double with combined AQL

Note: c = scale factor; $v = \sqrt{\dfrac{n}{n - 1}}$

* Not official procedure.
Source: ANSI/ASQC Z1.9 (1993), ISO 3951 (1989).

Weibull Distribution: TR-3, TR-4, TR-6, TR-7.

United States Defense Department quality control and reliability technical reports TR-3 (1961), TR-4 (1962), TR-6 (1963), and TR-7 (1965) have presented sampling plans based on an underlying Weibull distribution of individual measurement t.

Plots on probability paper or goodness-of-fit tests must be used to assure that individual measurements are distributed according to the Weibull model. See Wadsworth, Stephens, and Godfrey (1982). When this distribution is found to be an appropriate approximation to the failure distribution, methods are available to characterize a product or a process in terms of the three parameters of the Weibull distribution (see Sections 44 and 48 under the Weibull Distribution). These include probability plots and also point and interval estimates. Sampling plans are available for use with the Weibull approximation, which assumes shape and location parameters to be known. The plans are given in the technical reports mentioned above and are based in the following criteria:

TABLE 46.26   Variables Plans for Percent Defective, Mixed Variables—Attributes, ANSI/ASQC Z1.9 (1993)

Example: The specification for electrical resistance of a certain component is 620 to 680 ohms. A lot of 100 is submitted for inspection, inspection level II, normal inspection, with AQL = 2.5 percent. Should the lot be accepted if $\bar{X}$ = 647 and s = 17.22?

Summary of plan	Calculations
I. Restrictions: Measurements normally distributed	

II. Necessary information
  A. Lot size
  B. AQL
	II.
	  A. Lot size = 100
	  B. AQL = 2.5%

III. Selection of plan
  A. Using AQL and Lot Size, select appropriate variables plan from ANSI/ASQC Z1.9 (1993), Normal Inspection
  B. Using AQL and Lot Size, select single-sampling attributes plan from ANSI/ASQC Z1.4 (1993), using Tightened Inspection
	III.
	  A. n =10
	    M=7.26
	
	  B. ANSI/ASQC Z1.4 gives Code F
	    n=32
	    c=1

IV. Elements
  A. Sample size: See above; use items drawn in first sample as part of second sample
  B. Statistic: Use appropriate statistics from ANSI/ASQC Z1.9 (1993) and ANSI/ASQC Z1.4 (1993), as indicated in each standard
  C. Decision criteria
    1. Apply ANSI/ASQC Z1.9 (1993) plan
      a. Accept lot if plan accepts
      b. Otherwise, apply ANSI/ASQC Z1.4 (1993) plan, taking additional samples to satisfy sample size requirements
    2. Apply ANSI/ASQC Z1.4 (1993) plan if necessary
      a. Accept lot if plan accepts
      b. Otherwise reject lot
	IV.
	  A. First sample: n=10
	    Second sample:
	    n=(32−10)
	    n=22
	
	  C. Table 46.21 indicates ANSI/ASQC Z1.9 (1993) plan accepts; if the plan rejected the lot, an additional 22 samples would be drawn and the ANSI/ASQC Z1.4 (1993) plan applied to the number of defectives in the combined sample of 32

V. Action A. Dispose of lot as indicated	V. Accept the lot

VI. Characteristics
  A. Since the procedure outlined is a "dependent" mixed plan, see the following references:
    1. σ known: Schilling and Dodge (1969)
    2. σ unknown: Gregory and Resnikoff (1955)
    3. Approximation for σ unknown: Bowker and Goode (1952)	

Source: ANSI/ASQC Z1.9 (1993).

TABLE 46.27 Life Characteristics for Two Failure Distributions

$$Exponential\ f(t) = \frac{1}{\mu}\ e^{-t/\mu}$$

$$Weibull^*f(t) = \frac{\beta t^{\beta-1}}{\eta^{\beta}}\ e^{-(t/\eta)^{\beta}}\ where\ \mu = \eta\Gamma\left(1 + \frac{1}{\beta}\right)$$

Life characteristic	Exponential	Weibull
Proportion $F(t)$ failing before time t	$F(t) = 1 - e^{-t/\mu}$	$F(t) = 1 - e^{-g(t/\mu)^{\beta}}$
Proportion $R(t)$ of population surviving to time t	$R(t) = e^{-t/\mu}$	$R(t) = e^{-g(t/\mu)^{\beta}}$
Mean life, ML or mean time between failures	μ	μ
Hazard rate, $Z(t)$, instantaneous failure rate at time t	$Z(t) = \frac{1}{\mu}$	$Z(t) = \frac{\beta g t^{\beta-1}}{\mu^{\beta}}$
Cumulative hazard rate $M(t)$ for period 0 to t	$M(t) = \frac{t}{\mu}$	$M(t) = \frac{g t^{\beta}}{\mu^{\beta}}$
Failure rate λ or average hazard rate period 0 to t, $m(t)$	$\lambda = \frac{1}{\mu}$	$m(t) = \frac{g t^{\beta-1}}{\mu^{\beta}}$

*Weibull parameters explained in Section 48. The formulas given here are those of H108 (exponential) and TR-3 (Weiball).

β	0.33	0.67	1.33	1.67	3.33	4.00	5.00
g	1.8171	1.2090	0.8936	0.8289	0.6973	0.6750	0.6525

*The columns of this table are subdivisions of the rows. Thus when $\beta = 1.2$, the value of g is 0.9292.

1. Mean life criterion (TR-3)
2. Hazard rate criterion (TR-4)
3. Reliable life criterion (TR-6)
4. All three (TR-7)

The tables cover a wide range of the family of Weibull distributions by providing plans for shape parameter β from $\frac{1}{3}$ to 5. The technical reports abound in excellent examples and detailed descriptions of the methods involved.

Technical report TR-7 (1965) provides factors and procedures for adapting MIL-STD-105D plans to life and reliability testing when a Weibull distribution of failure times can be assumed. Tables of the appropriate conversion factors are provided for the following criteria:

Table	Criterion	Conversion factor
1	Mean life	$(t/\mu) \times 100$
2	Hazard rate	$tZ(t) \times 100$
3	Reliable life ($r = 0.90$)	$(t/p) \times 100$
4	Reliable life ($r = 0.99$)	$(t/p) \times 100$

Each table is presented in three parts, each of which is indexed by 10 values of β ($\beta = {}^1/_3, {}^1/_2, {}^2/_3, 1, 1^1/_3, 1^2/_3, 2, 2^1/_2, 3^1/_2, 4$). TR-7 is used in a manner analogous to the other three technical reports.

BULK SAMPLING[3]

Bulk material may be of gaseous, liquid, or solid form. Usually it is sampled by taking increments of the material, blending these increments into a single composite sample, and then, if necessary, reducing this gross sample to a size suitable for laboratory testing.

If bulk material is packaged or comes in clearly demarked segments, if it is for all practical purposes uniform within the packages, but varying between packages, and if the quality of each package in the sample is measured, then the sampling theory developed for discrete units may be employed.

A special theoretical discussion is necessary for the sampling of bulk material:

1. If the packages are uniform but the increments from individual packages are not tested separately; instead they are physically composited, in part at least, to form one or more composite samples that are tested separately.

2. If the contents of the packages are not uniform so that the question of sampling error arises with respect to the increments taken from the packages.

3. If the bulk material is not packaged and sample increments have to be taken from a pile, a truck, a railroad car, or a conveyer belt.

In the above circumstances, the special aspects that make bulk sampling different from the sampling of discrete indivisible units are:

1. The possibility of physical compositing and the subsequent physical reduction (or subsampling) that is generally necessary.

2. The need in many cases to use a mechanical sampling device to attain the increments that are taken into the sample. In this case the increments are likely to be "created" by the use of the sampling device and cannot be viewed as preexisting.

Objectives of Bulk Sampling.   In most cases the objective of sampling bulk material is to determine its mean quality. This may be for the purpose of pricing the material or for levying custom duties or other taxes, or for controlling a manufacturing process in which the bulk material may be used. It is conceivable that interest in bulk material may also at times center on the variability of the material; or, if it is packaged, on the percent defective; or on the extreme value attained by a segment or package, as described in ASTM (1968). In view of the limited space that is available, the discussion will be restricted to estimation of the mean quality of a material.

---

[3]This section is condensed from Section 25A of the third edition of this handbook, prepared by Acheson J. Duncan.

Special Terms and Concepts.   A number of special terms and concepts are used in the sampling of bulk material. These are

1. *Lot:*   The mass of bulk material the quality of which is under study—not to be confused with a statistical population.

2. *Segment:*   Any specifically demarked portion of the lot, actual or hypothetical.

3. *Strata:*   Segments of the lot that are likely to be differentiated with respect to the quality characteristic under study.

4. *Increment:*   Any portion of the lot, generally smaller than a segment.

5. *Sample increments:*   Those portions of the lot initially taken into the sample.

6. *Gross sample:*   The totality of sample increments taken from the lot.

7. *Composite sample:*   A mixture of two or more sample increments.

8. *Laboratory sample:*   That part of a larger sample which is sent to the laboratory for test.

9. *Reduction:*   The process by which the laboratory sample is obtained from a composite sample. It is a method of sampling the composite sample. It may take the form of hand-quartering or riffling or the like.

10. *Test-unit:*   That quantity of the material which is of just sufficient size to make a measurement of the given quality characteristic.

11. *Quality of a test-unit:*   The expected value of the hypothetically infinite number of given measurements that might be made on the test-unit. Any single measurement is a random sample of one from this infinite set. The analytical variance is the variance of such measurements on the infinite set.

12. *Mean of a lot:*   If a lot is exhaustively divided into a set of M test-units, the mean of the qualities of these M test-units is designated the mean of the lot. It is postulated that this mean will be the same no matter how the M test-units are obtained. This assumes that there is no physical interaction between the quality of test-units and the method of division. See item 16 below.

13. *Mean of a segment (stratum, increment, composite sample, or laboratory sample):*   Defined in a manner similar to that used to define the mean of a lot. It is assumed that the segment is so large relative to the size of a test- unit that any excess over the integral number of test-units contained in the segment can be theoretically ignored. If this is not true, then the quality of the fraction of a test-unit remaining is arbitrarily taken to be the quality of the mean of the segment minus this fraction.

14. *Uniformity:*   A segment of bulk material will be said to be uniform if there is no variation in the segment. If, for example, every cubic centimeter of a material contains exactly the same number of "foreign particles," the density of these particles would be said to be uniform throughout the segment. See the note under item 15, however.

15. *Homogeneous:*   A segment of bulk material will be said to be homogeneous with respect to a given quality characteristic if that characteristic is randomly distributed throughout the segment.
    Note: The character of being uniform or homogeneous is not independent of the size of the units considered. The number of foreign particles may be the same for every cubic meter of a material, and with respect to this size unit the material will be said to be uniform. For units of size 1 cubic centimeter, however, there may be considerable variation in the number of foreign particles, and for this size of unit the material would not be judged to be uniform. The same considerations are involved in the definition of homogeneity. The number of foreign particles per cubic meter could vary randomly from one cubic meter to the next, but within each cubic meter there might be considerable (intraclass) correlation between the number of foreign particles in the cubic centimeters that make up the cubic meter.

16. *Systematic physical bias:*   If the property of the material is physically affected by the sampling device or method of sampling employed, the results will have a systematic bias. A boring or cutting device, for example, might generate sufficient heat to cause loss of moisture.

17. *Physical selection bias:*   If a bulk material is a mixture of particles of different size, the sampling device may tend to select more of one size particle than another. This means that if a segment was exhaustively sampled by such a device, early samples would tend to have relatively more of certain size particles than later samples.

18. *Statistical bias:*   A function of the observations that is used to estimate a characteristic of a lot, e.g., its mean, is termed a "statistic." A statistic is statistically biased if in many samples its mean value is not equal to the lot characteristic it is used to estimate.

Determination of the Amount of Sampling.

Since the variance of a sample mean $\sigma_{\bar{X}}^2$ is a function of the amount of sampling, say the number of increments taken, then once a model has been adopted and a formula obtained for $\sigma_{\bar{X}}^2$, it becomes possible to determine the amount of sampling required to attain a confidence interval of a given width or to attain a specified probability of making a correct decision.

A similar approach is involved in determining the amount of sampling to get a desired set of risks for lot acceptance and rejection.

Models and Their Use.

Sampling plans for discrete product have been cataloged in a number of tables. This has not yet been possible for bulk sampling, and instead, a "sampling model" must be created for each type of bulk material and the model used to determine the sample size and acceptance criteria for specific applications.

A bulk sampling model consists of a set of assumptions regarding the statistical properties of the material to be sampled plus a prescribed procedure for carrying out the sampling. A very simple model, for example, would be one in which it is assumed that the quality characteristics of the test-units in a lot are normally distributed and simple random sampling is used.

With the establishment of a model, a formula can generally be derived for the sampling variance of an estimate of the mean of a given lot. This must be uniquely derived based on the type of product, lot formation, and other factors. The reader is urged to consult the references for specific formulas (see especially Duncan, 1962). From an estimate of this sampling variance, confidence limits can be established for the lot mean, and/or a decision with given risk can be made about the acceptability of the lot.

Let the variance of a sample mean be denoted as $\sigma_{\bar{X}}^2$ and its estimate as $s_{\bar{X}}^2$. Then "0.95 confidence limits" for the mean of the lot will be given by

$$0.95 \text{ confidence limits for } \mu = \bar{X} \pm t_{0.025} S_{\bar{X}}$$

where μ is the mean of the lot, $\bar{X}$ is the sample mean, and $t_{0.025}$ is the 0.025 point of a *t*-distribution for the degrees of freedom involved in the determination of $s_{\bar{X}}^2$.

If a decision is to be made on the acceptability of a lot, a criterion for acceptability will take some such form as

$$\text{Accept if } t = \frac{\bar{X} - L}{s_{\bar{X}}} \text{ is positive or if it has a negative value numerically less than } t_{0.025}$$

where L is the lower specification limit on the product and $t_{0.025}$ is the 0.025 point of a *t*-distribution for the degrees of freedom involved in the determination of $s_{\bar{X}}^2$. See Grubbs and Coon (1954).

Models for Distinctly Segmented Bulk Material ("Within and Between" Models).

Much bulk material comes in distinctly segmented form. It may be packaged in bags, bales, or cans, for example, or may come in carloads or truckloads.

For distinctly segmented material it can be established that the overall variance of individual test-units is, for a large number of segments each with a large number of test-units, approximately equal to the sum of the variance between segments and the average variance within segments. In what follows, the variance within segments is assumed the same for all segments.

Model 1A. Isolated Lots, Nonstratified Segments.   For an isolated lot of distinctly segmented material, the sampling procedure will be to take an increment of *m* test-units from each of *n* segments, reduce each increment to a laboratory sample, and measure its quality *X*. The mean of the *n* test-units is taken as an estimate of the mean of the lot.

Model 1B. One of a Series of Lots.   Suppose the current lot is one of a series of lots of distinctly segmented material and that estimates of the between and within variances have been made in a pilot study, together with estimates of the reduction variance and test variance. It will be assumed that the reduction variance yielded by the pilot study is valid for larger amounts than that used in the study.

With the given prior information, an estimate of the sampling variance for the current sample estimate of mean lot quality can be based on the pilot study, and there is need only for a current check on the continued validity of this study. Consequently, composite samples can be used requiring only a few measurements, and the cost of inspection of the current lot may be considerably curtailed.

The "Within and Between" Models: Stratified Segments.   In some situations the quality characteristic of the bulk material may be stratified in that in each segment it may vary from layer to layer and is not randomly distributed throughout the segment. Difficulties in formulating a model for stratified segments of this kind can be overcome if the strata are reasonably parallel and if the increments taken from the sample segments are taken perpendicular to the strata and penetrate all strata. In taking a sample from a bale of wool, for example, a thief could cut a sample running vertically from top to bottom of the bale.

Models for Bulk Material Moving in a Stream.   In many instances the bulk material to be sampled is moving in a stream, say on a conveyer belt. In such instances it is the common practice to take increments systematically from the stream, the increment being taken across the full width of the stream.

Isolated Lots.   If increments are taken at random from the stream, we would have a simple random sample from the lot, and we could proceed much as indicated for isolated lots of distinctly segmented material.

Model 2A. A Stream of Lots: A Segregation Model.   When a stream of bulk material persists for some time, with possible interruptions, determinations of quality and/or action decisions may have to be made for a number of lots. Here, a pilot study might be profitable.

The kind of pilot study needed will depend on the assumptions about the statistical properties of the material in the stream. If the quality of the material varies randomly in the stream, then a pilot study based on a number of randomly or systematically taken increments would be sufficient to determine the variance of the material, and this could be used to set up confidence limits for the means of subsequent lots or make decisions as to their acceptability, even though in each of these lots a single composite sample was taken.

Obtaining the Test-Units.   Three factors are important in obtaining the test-units.

1. *The models discussed above assume random sampling:*   Either the increments are picked at random (using, preferably, random numbers if the units can be identified) or the increments are selected systematically from material that is itself random. Random sampling may have to be undertaken while the material is in motion or being moved. If random sampling cannot be used, special efforts should be made to get a representative picture of a lot, noting strata and the like. Some element of randomness must be present in a sampling procedure to yield a formula for sampling variance.

2. *Grinding and mixing:*   In the processing of bulk material and in the formation of composite samples, grinding and/or mixing may be employed in an attempt to attain homogeneity or at least to reduce the variability of the material.

If a material can be made homogeneous for the size increment that is to be used in subsequent sampling, then an increment of that size can be viewed as a random sample of the material. The

attainment of homogeneity of bulk material in bags, cartons, barrels, etc., is thus a worthy objective when the contents of these containers are to be sampled by a thief or other sampling instruments. However, random sampling does not guarantee minimum sampling variation, and grinding and mixing may lead to a reduction in overall sampling variation without attaining homogeneity. See Cochran (1977).

Although grinding and mixing are aimed at reducing variability, these operations may in some circumstances cause segregation and thus increase variability.

3. *Reduction of a sample to test-units:*   Measurements often may be made directly on the sample itself. However, sometimes a portion of the sample must be carefully reduced in either particle size or physical quantity to facilitate laboratory testing. The unreduced portion of the sample may be retained for subsequent reference for legal purposes or verification of results. An example of a technique is coning and quartering. The material is first crushed and placed in a conical pile, which is then flattened. The material is then separated into quarters and opposite quarters selected for further quartering or as the final test-units.

Bicking (1967) and Bicking et al. (1967) provide unique details on obtaining test-units for a large variety of specific bulk products.

Tests of Homogeneity.   The homogeneity of bulk material may be tested by $\bar{X}$-charts and c-charts. For mixtures of particles that can be identified, local homogeneity may be tested by running a χ^2 short-distance test. See Shinner and Naor (1961).

BAYESIAN PROCEDURES

The concept that experience or analytical studies can yield prior frequency distributions of the quality of submitted lots and that these "prior" distributions can in turn be used to derive lot-by-lot sampling plans has gained some popularity in recent years. This is generally termed the "Bayesian approach." Bayes' theorem and the Bayesian decision theory concept are discussed in Section 44, Basic Statistical Methods. The general concept of the use of prior information is discussed in Section 23, under Degree of Inspection and Testing Needed.

Considerable literature exists on Bayesian sampling. However, a very limited number of sampling tables based on particular prior distributions of lot quality are available. Calvin (1984) provides procedures and tables for implementing Bayesian plans. Another example is the set of tables by Oliver and Springer (1972), which are based on the assumption of a Beta prior distribution with specific posterior risk to achieve minimum sample size. This avoids the problem of estimating cost parameters. It is generally true that a Bayesian plan requires a smaller sample size than does a conventional sampling plan with the same consumer's and producer's risk. Among others, Schaefer (1967) discusses single sampling plans by attributes using three prior distributions of lot quality. Given specified risks α and β, sampling plans which satisfied these risks and which minimized sample size were determined. For example, with a particular prior distribution, $n = 6$ and $c = 0$ gave protection equivalent to a conventional sampling plan with $n = 34$, $c = 0$.

Advantages similar to those quoted above are usually cited. However, one prime factor is frequently ignored: How good is the assumption on the prior distribution? Hald (1960) gives an extensive account of sampling plans based on discrete prior distributions of product quality. Hald also employs a simple economic model along with the discrete prior distribution and the hypergeometric sampling distribution to answer a number of basic questions on costs, relationship between sample size and lot size, etc. Schaefer (1964) also considers the Bayesian operating characteristic curve. Hald (1981) has also provided an excellent comparison of classical and Bayesian theory and methodology for attributes acceptance sampling. The Bayesian approach to sequential and nonsequential acceptance sampling has been described by Grimlin and Breipohl (1972). Most such plans incorporate cost data reflecting losses involved in the decision making process to which the plan is to be

applied. An excellent review of Bayesian and non-Bayesian plans has been given by Wetherill and Chin (1975).

While the explicit specification of a prior distribution is characteristic of the classical Bayes approach, procedures have been developed to incorporate much of the philosophy and approach of Bayes without explicit specification of a prior distribution. These methods are based on the incorporation of past data into an empirical estimate of the prior, and hence the approach is called "empirical Bayes." An excellent description of this method of estimation has been presented by Krutchkoff (1972). Application of the empirical Bayes methodology to attributes sampling has been given by Martz (1975). Craig and Bland (1981) show how it can be used in variables sampling.

These ideas have been further extended by the application of shrinkage estimators to the empirical Bayes problem as described by Morris (1983). One outstanding application of such procedures is in the so-called "universal sampling plan" which has been utilized in the quality measurement plan (QMP) of American Telephone and Telegraph. Audit sample sizes are based on historical process control, economics, quality standards, and the heterogeneity of audit clusters as described by Hoadley (1981). Strictly speaking, the weights for the Stein shrinkage estimators utilized in the procedure are developed through a classical Bayes approach, and so this application is more properly viewed as Bayes empirical Bayes methodology. A method for estimating quality using data from both accepted and rejected lots based on QMP is given in Brush and Hoadley (1990).

Application of Bayesian methods has been hindered by the difficulty involved in correct assessment of the necessary prior distributions and in collecting and keeping current the required cost information. Clearly, greater reliance on prior empirical information and the potential of the computer for generating cost information should be helpful in this regard. Pitfalls in the selection of a prior distribution have been pointed out by Case and Keats (1982).

While studies have indicated that Bayesian schemes may be quite robust to errors in the prior distributions and loss functions, they nevertheless assume the prior to be stationary in the long-term sense (i.e., a process in control). Classical methods do not make this assumption. Bayesian plans are, in fact, quite application-specific, requiring extensive information and update for proper application, and like variables sampling, they are applied one characteristic at a time. Nevertheless, where appropriate, they provide yet another tool for economic sampling.

HOW TO SELECT THE PROPER SAMPLING PROCEDURES

The methods of acceptance sampling are many and varied. It is essential to select a sampling procedure appropriate to the acceptance sampling situation to which it is to be applied. This will depend upon the nature of the application itself, on quality history, and the extent of knowledge of the process and the producer. Indeed, according to Dodge (1950, p. 8):

> A product with a history of consistently good quality requires less inspection than one with no history or a history of erratic quality. Accordingly, it is good practice to include in inspection procedures provisions for reducing or increasing the amount of inspection, depending on the character and quantity of evidence at hand regarding the level of quality and the degree of control shown.

This will be discussed further in the Conclusion, below.

The steps involved in the selection and application of a sampling procedure are shown in Figure 46.25 taken from Schilling (1982). Emphasis here is on the feedback of information necessary for the proper application, modification, and evolution of sampling. As Ott and Schilling (1990) have pointed out:

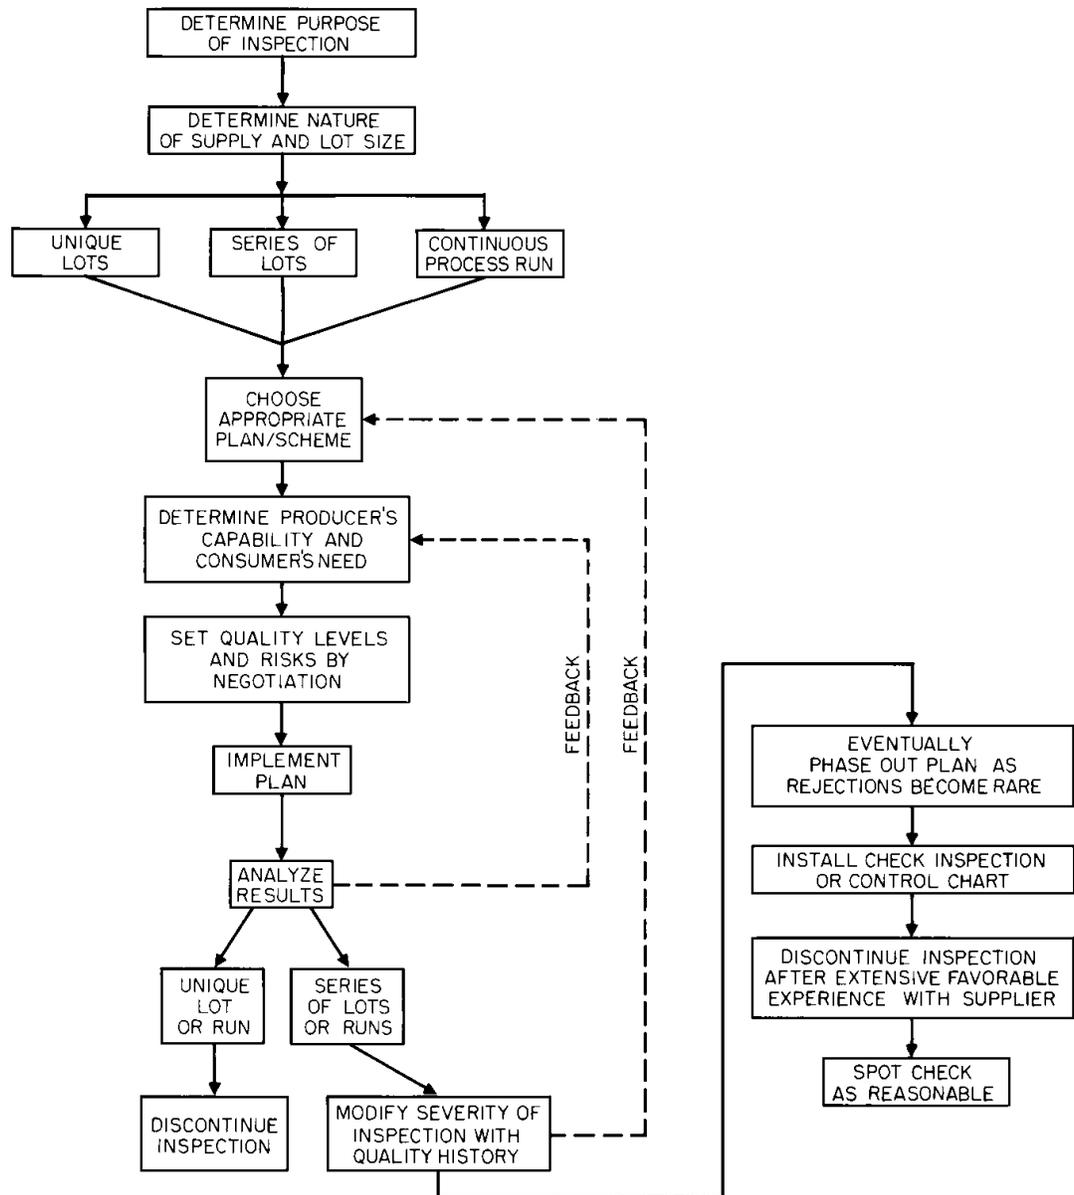
> There are two standard procedures that, though often good in themselves, can serve to postpone careful analysis of the production process:


FIGURE 46.25 Check sequence for implementation of sampling procedure.

1. On-line inspection stations (100% screening). These can become a way of life.
2. On-line acceptance sampling plans which prevent excessively defective lots from proceeding on down the production line, but have no feedback procedure included.

These procedures become bad when they allow or encourage carelessness in production. It gets easy for production to shrug off responsibility for quality and criticize inspection for letting bad quality proceed.

It is therefore necessary for sampling to be constantly subject to modification in a system of acceptance control. Each plan has a specific purpose for which it is to be applied. Table 46.29 shows the relation of plan and purpose for some of the plans which have been discussed. Those not discussed here will be found described in detail in Schilling (1982). These plans then are the elements involved in a system of acceptance control. Their effective use in a continuing effort to provide protection while reducing inspection and moving to process control is a function of the ingenuity, integrity, and industry of the user.

TABLE 46.29   Selection of Plan

Purpose	Supply	Attributes	Variables
Simple guarantee of producer's and consumer's quality levels at stated risks	Unique lot	Two-point plan (Type A)	Two-point plan (type B)
	Series of lots	Dodge-Roming LTPD Two-point plan (Type B)	Two-point plan (type B)
Maintain level of submitted quality at AQL or better	Series of lots	MIL-STD-105E ANSI/ASQC 1.4 ISO 2859	MIL-STD-414 ANSI/ASQC Z1.9 ISO 3951
Rectification guaranteeing AOQL to consumer	Series of lots	Dodge-Roming AOQL	Use measurements as go-no go
	Flow of individual units	CSP-1, 2, 3 Multilevel plan MIL-STD-1235B	
Reduced inspection after good history	Series of lots	Skip-lot Chain	Lot plot Mixed variable-attributes Narrow-limit gaging
Check inspection	Series of lots	Demerit rating	Acceptance control chart
Compliance to mandatory standards	Unique lot	Lot-sensitive plan	Mixed variables-attributes with $c = 0$
	Series of lots	TNT plan	
Reliability sampling	Unique lot	Two-point plan (type B)	MIL-HDBK-108 TR-7
	Series of lots	LTPD plan	TR-7 using MIL-STD-105D switching rules

COMPUTER PROGRAMS FOR ACCEPTANCE SAMPLING

A variety of computer programs are available for application of specific sampling plans. They have become increasingly important, particularly in the application of selected plans and in the development of plans for specific applications. Some early fundamental programs are listed in Table 46.30. It should be noted, however, that it is questionable whether these programs will ever replace hard copy procedures and standards which play a vital role in the negotiations between producer and consumer and which are immediately available for in-plant meetings and discussions at any location.

A number of commercial packages intended for quality control applications contain acceptance sampling options. In addition, various programs have been presented in the literature. For example, Guenther (1984) presents a program for determining rectifying single sampling plans while Garrison and Hickey (1984) give sequential plans, both by attributes. A program for determining the ASN of curtailed attributes plans is given by Rutemiller and Schaefer (1985). McWilliams (1990) has provided a program which deals with various aspects of hypergeometric, Type A, plans including double sampling. McShane and Tumbull (1992) present a program for analysis of CSP-1 plans with finite run length. Goldberg (1992) gives a PC program for rapid application of the sequential approach to continuous sampling. A program for selecting quick switching systems will be found in Taylor (1996). These programs supply code. Implementation of plans on spread sheets is presented in Cox (1992–1993). Expert systems are discussed in Fard and Sabuncuoglu (1990) and Seongin (1993). Thus, the computer can be expected to enhance and diversify application of sampling plans.

CONCLUSION—MOVING FROM ACCEPTANCE SAMPLING TO ACCEPTANCE CONTROL

There is little control of quality in the application of a sampling plan to an individual lot. Such an occurrence is static, whereas control implies movement and direction. When used in a system of *acceptance control,* over the life of the product, however, the plan can provide:

Protection for the consumer

Protection for the producer

Accumulation of quality history

Feedback for process control

Pressure on the producer to improve the process

Acceptance control involves adjusting the acceptance sampling procedure to match existing conditions with the objective of eventually phasing out the inspection altogether. This is much as the old-time inspector varied the inspection depending on quality history. Thus, acceptance control is "a continuing strategy of selection, application and modification of acceptance sampling procedures to a changing inspection environment" [see Schilling (1982, p. 546)]. This involves a progression of sampling procedures applied as shown in Table 46.31.

These procedures are applied as appropriate over the lifetime of the product in a manner consistent with the improvement of quality and the reduction and elimination of inspection. This can be seen in Table 46.32. For a detailed discussion and example of moving to audit sampling, see Doganaksoy and Hahn (1994).

Modern manufacturing is not static. It involves the development, manufacture, and marketing of new products as well as an atmosphere of continuing cost reduction, process modification, and other forms of quality improvement. Changes are continually introduced into the production process which are deliberate, or unexpected from an unknown source. When this happens, acceptance sampling is necessary to provide protection for the producer and the consumer until the process can be brought into control. This may take days, months, or years. Under these circumstances, the inspection involved should be systematically varied in a system of acceptance control which will reduce inspection reciprocally with the increase of the learning curve in the specific application. This can provide the protection necessary for the implementation of proper process control in a manner portrayed roughly in Figure 46.26. Acceptance control and process control are synergistic in the sense that one supports proper use of the other. As Dodge (1969, p. 156) has pointed out:

> The "acceptance quality control system"…encompassed the concept of protecting the consumer from getting unacceptable defective material and encouraging the producer in the use of process quality control

TABLE 46.31   Progression of Attribute Sampling Procedures

Past results	Quality history			Criterion
	Little	Moderate	Extensive	
Excellent	AQL plan	Chain	Demerit rating or remove inspection	Almost no (<1%) lots rejected
Average	Rectification or LTPD plan	AQL plan	Chain	Few (<10%) lots rejected
Poor	100% inspection	Rectification or LTPD plan	Discontinue acceptance	Many (≥10%) lots rejected
Amount	Fewer than 10 lots	10–50 lots	More than 50 lots	

TABLE 46.32 Life Cycle of Acceptance Control Application

Stage	Step	Method
Preparatory	Choose plan appropriate to purpose	Analysis of quality system to define the exact need for the procedure
	Determine producer capability	Process performance evaluation using control charts
	Determine consumer needs	Process capability study using control charts
	Set quality levels and risks	Economic analysis and negotiation
	Determine plan	Standard procedures if possible
Initiation	Train inspector	Include plan, procedure, records, and action
	Apply plan properly	Ensure random sampling
	Analyze results	Keep records and control charts
Operational	Assess protection	Periodically check quality history and OC curves
	Adjust plan	When possible change severity to reflect quality history and cost
	Decrease sample size if warranted	Modify to use appropriate sampling plans taking advantage of credibility of supplier with cumulative results
Phase out	Eliminate inspection effort where possible	Use demerit rating or check inspection procedures when quality is consistently good Keep control charts
Elimination	Spot check only	Remove all inspection when warranted by extensive favorable history

Source: Schilling, 1982, p. 566.

by: varying the quantity and severity of acceptance inspections in direct relation to the importance of the characteristics inspected, and in inverse relation to the goodness of the quality level as indicated by these inspections.

It is in this sense that acceptance control is an essential part of the quality system.

SECTION 47

DESIGN AND ANALYSIS OF EXPERIMENTS[1]

J. Stuart Hunter

with Mary G. Natrella, E. Harvey Barnett, William G. Hunter, and Truman L. Koehler

47.1

INTRODUCTION

Experiments, statistically designed or not, are a component of the *learning process*. We experiment to learn. Learning through experimentation is a complex mechanism combining one's hopes, needs, knowledge, and resources. How well one succeeds will be a function of adherence to the *scientific method,* the most rapid means for speeding the learning process.

The scientific method is an iterative process. Ideas based upon one's current state of knowledge lead to experiments designed to answer questions. The experiments in turn lead to data that serve to confirm and modify these initial ideas. An iterative loop is established between ideas (*hypotheses*), the design of the experiment, the production of data, and the subsequent analysis (*inference*) leading on to new ideas, new experiments, new data, and newer inferences. This iterative process continues until an adequate state of knowledge is acquired and confirmed. The entire process is always slowed by "noise," the results of "errors" of measurement and experimental "variability." We "see through the glass darkly" and thus data analyses must be conditioned by statements of *uncertainty,* by considerations of probability. Statistics is the science, the provider of the language and logic, that combines the roles of hypotheses, data, inference, and uncertainty within the scientific method.

Two famous statisticians, G. E. P. Box and W. Edwards Deming, encapsulate the fundamentals of the scientific method into four segments: Box's "conjecture, design, experiment, analysis" and Deming's "plan, do, check, act." Both statements illustrate the role of statistics as an integral part of the scientific method; see Deming (1982), Box (1976), Ishikawa (1985).

In applying the scientific method, a worker's intelligence, experience and resources dominate the speed and success of any problem-solving program. The art of statistics comes into formal play in two places: in helping design the experiments to produce data heavily laden with information and in the data analysis wherein the statistician's responsibility is to uncover all the information of value. Simply stated: The application of the statistical design and analysis of experiments accelerates the learning process.

An experiment has been defined as a "considered course of action aimed at answering one or more carefully framed questions." Framing the question and planning for action are best accomplished through a team effort. An isolated experimenter working alone has become an increasingly rare phenomenon: the resources of information germane to any problem-solving and learning activity are too vast and varied to be left to a single individual.

Computing and Analysis.   Almost 10 years have elapsed since the publication of the fourth edition of *Juran's Quality Control Handbook* (1988). This brief period has witnessed a spectacular growth in the use of the personal computer. Today the personal computer and associated software not only reduce the burdens of computations but can directly assist in the selection of an experimental

design. Computer-constructed graphical displays of data quickly assist in data analysis. The users manual accompanying many software programs is often equivalent to a reference book on the construction and analysis of statistical designs, offering help in the pathways of analysis and providing illustrative examples. Many statistical software programs go far beyond the subject of statistical design of experiments and include elements of industrial quality control, linear and nonlinear regression, reliability and nonparametric studies, and multivariate and time series analyses. The reader is encouraged to secure the use of a personal computer and software program capable of performing the analyses associated with the statistical design of experiments.

The challenge, of course, is to be wise in the use of the powerful tools of statistics and modern computation. This Handbook well serves as an introduction to the application of good statistical practices devoted to the pursuit of quality. As a further aid the Statistics Division of the American Society for Quality has produced a series of *How To* booklets (see ASQ in the references) designed to assist beginners in the applications of statistics. The best advice for those just starting out in the statistical design of experiments is KISS: Keep it simple statistician! One should first experience the design and analysis of a small program with limited amounts of data, perhaps a replicated balanced block to compare a few treatments, or a simple factorial to study the simultaneous influences of factors upon a response. Further, the beginner must recognize that there has never been a signal in the absence of "noise" and then learn to measure the noise: to estimate the variance of the observations. Beginners often confuse noise (errors) due to measurement and instrumentation with the more serious source of noise (error) caused by the failure of repeated experiments to provide identical results. Experimental error encompasses measurement error and is far more serious. A beginner will also quickly learn the importance of always plotting the data (Chambers et al. 1993; Cleveland 1993).

The methods of analysis and computation given here, and those found in most textbooks, are intended for hand or desk calculation. The modern personal computer and associated software dramatically change this environment, with some computer software programs providing levels of assistance that resemble artificial intelligence; the experimenter is asked questions and is guided through almost every stage of experimental design and analysis. Two general cautions are in order: (1) the hand-desk computing methods given here should not be literally translated into a computer program—there are alternative powerful computer-based methods of data reduction and analysis; and (2) the user of packaged statistical programs should be as critical a consumer of this as of everything else.

The journal *Applied Statistics* (The Royal Statistical Society, London) has in each issue a *Statistical Software Review* section providing careful and critical commentary on the utility of various software programs along with, usually, the reply of the producer of the software. The quarterly journal *The American Statistician,* of the American Statistical Association, has a section titled *Statistical Computing Software Reviews.* The reviews in both these journals can be of great value in judging the value of software. *Applied Statistics* also provides an additional section on *Statistical Algorithms* for those requiring special programs not commonly found in ordinary software. More general information on software for statistical purposes is provided in Section 44, Basic Statistical Methods. See also Wadsworth (1990).

Basic Definitions.   Several fundamental terms are widely used throughout this section. They may be defined as follows:

Factor.   A "factor" is one of the controlled or uncontrolled variables whose influence upon a response is being studied in the experiment. A factor may be quantitative, e.g., temperature in degrees, time in seconds. A factor may also be qualitative, e.g., different machines, different operators, switch on or off.

Level (Version).   The "levels" ("versions") of a factor are the values of the factor being examined in the experiment. For quantitative factors, each chosen value becomes a level, e.g., if the experiment is to be conducted at four different temperatures, then the factor *temperature* has four *levels*. In the case of qualitative factors, *switch on or off* becomes two levels (versions) for the switch factor; if six machines are run by three operators, the factor *machine* has six levels (versions) while the factor *operator* has three levels (versions).

Treatment.   A "treatment" is a single level (version) assigned to a single factor during an experimental run, e.g., temperature at 800 degrees. A "treatment combination" is the set of levels for all factors in a given experimental run. For example, an experimental run using an 800-degree temperature, machine 3, operator A, and switch off would constitute one treatment combination.

Experimental Units.   The "experimental units" consist of the objects, materials, or units to which treatments are being applied. They may be biological entities, natural materials, fabricated products, etc.

Experimental Environment.   The "experimental environment" comprises the surrounding conditions that may influence the results of the experiment in known or unknown ways.

Block.   A factor in an experimental program that has influence as a source of variability is called a "block." The word is derived from early agricultural usage, in which blocks of land were the sources of variability. A block is a portion of the experimental material or of the experimental environment that is likely to be more homogeneous within itself than between different portions. For example, specimens from a single batch of material are likely to be more uniform than specimens from different batches. A group of specimens from such a single batch would be regarded as a block. Observations taken within a day are likely to be more homogeneous (to have smaller variance) than observations taken across days. *Days* then becomes a block factor.

Experimental Design.   The formal plan for conducting the experiment is called the "experimental design" (also the "experimental pattern"). It includes the choice of the responses, factors, levels, blocks, and treatments and the use of certain tools called planned grouping, randomization, and replication.

Models.
Experimental designs are created to help explain the association between a response variable η (η=eta; sometimes the symbol μ=mu is used) and other factors $x = x_1, x_2, x_3, \ldots, x_k$ (sometimes called "variables") thought to influence η. We say, "η (eta) is a function of x," that is, $\eta = f(x)$. Of course, *observing* the true response η entrains "noise" or "error" and produces observations $y = \eta + \epsilon$. The "expected value" of y is η. We are now faced with a "two model" problem: every observation y requires a model for η and another for ϵ.

The Model for the Error ϵ.   The model for the ϵ usually assumed is that the errors are independent, normally distributed with an expected value of zero and a constant variance σ^2; that is, the errors are white Gaussian noise. One's ability to discern associations between a response of η and factors x and to make inferences about future performance are profoundly influenced by the ϵ, the "errors" (noise). The errors (noise) attending a series of experiments have two primary components, those due to measurement and those attending the repetition of the experiment. Considerations of *measurement* error; the precision, traceability, specificity, calibration, and cost of the measurements; and variability due to sampling are always important. However, measurement and sampling errors alone will underestimate the contribution of errors associated with running and then repeating an experiment. *Experimental* error, the failure of agreement between two or more separate experiments run under the same conditions, is of crucial importance. Experimental error includes measurement and sampling errors as components. Special experimental designs (the hierarchical designs, see below) can provide experimenters with the ability to measure separately all error components.

   The assumption that the errors ϵ are normally distributed with zero expectation and constant variance is important. Transformations of experimental data are often required to accomplish these attributes. However, the assumption of independent errors is especially crucial whenever probability statements (hypothesis tests or confidence intervals) are made. To guarantee independence, acts of randomization should be part of every experimental design protocol. Randomization also provides support for the constant variance assumption.

The Model for the Response η.   Implicit in every experiment is a *response model* $\eta = f(x)$ descriptive of how η changes as the factors x are changed. The specifics of this model are often not clear in

the mind of the experimenter; one object of the experiments is to reduce this ambiguity. Most experimental designs are constructed to provide sufficient data to estimate the parameters in a very general model, thus allowing the data to identify appropriate subsets of models for the experimenter's appraisal.

The Model for the Observations **y.**   The *observation model* is $y = \eta + \epsilon$. Thus the experimenter must separate motion among observations into two parts: one part assignable to η and ultimately to the changes in the factors *x,* and a second part assignable to ϵ, the noise. This separation of the roles of η and ϵ is formally recognized in an analysis of variance (ANOVA) table, an easy computation provided experiments are properly planned.

Tools for Good Experimentation.   Good experimentation is an art and depends heavily upon the prior knowledge and abilities of the experimenter. Some tools of importance in the statistical planning and analysis of the design of experiments follow.

Blocking (Planned Grouping).   Beyond the factors x_1, x_2, …, x_k selected for study, there are often other "background" variables that may also influence the outcome of the experimental program, variables such as raw material batches, operators, machines, or days. The influences of these variables upon the response are not under the control of the experimenter. These variables are commonly called "blocks," a legacy of the day when different blocks of land were used in agricultural experimentation. When an experimenter is aware of blocking variables it is often possible to plan experimental programs to reduce their influence. In designing experiments, wide use is made of the reduced variability occurring *within* blocks to accentuate the influences of the studied factors. Designs that make use of this uniformity within blocks are called "blocked" designs and the process is called "planned grouping."

Randomization.   The sequence of experiments and/or the assignment of specimens to various treatment combinations in a purely chance manner is called "randomization." Such assignment increases the likelihood that the effect of uncontrolled variables will balance out. It also improves the validity of estimates of experimental error variance and makes possible the application of statistical tests of significance and the construction of confidence intervals. Whenever possible, randomization is part of the experimental program.

Replication.   "Replication" is the repetition, the rerunning, of an experiment or measurement in order to increase precision or to provide the means for measuring precision. A single replicate consists of a single observation or experimental run. Replication provides an opportunity for the effects of uncontrolled factors or factors unknown to the experimenter to balance out and thus, through randomization, acts as a bias-decreasing tool. Replication also helps to detect gross errors in the measurements. In replications of groups of experiments, different randomizations should apply to each group.

  Rerun experiments are commonly called "replicates." However, a sequence of observations made under a single set of experimental conditions, under a single replicate, are simply called "repeated observations."

Reproducibility and Repeatability.   In manufacturing, reproducibility measures the variability between items manufactured on different days or on different machines. Repeatability measures sources of variability that are more local or immediate, assignable to item measurements or to the variability occurring between adjacent items manufactured in sequence.

Requisites and Tools.   Table 47.1 lists some of the requisites for sound experimentation and shows the way in which these tools contribute to meeting these objectives. A checklist that can be helpful in all phases of an experiment is given in Table 47.2. Good references are Bicking (1954), Hahn (1977, 1984), Bisgaard (1992), Bishop et al. (1982), and Hoadley and Kettenring (1990), and Coleman and Montgomery (1993).

TABLE 47.1   Some Requisites and Tools for Sound Experimentation

Requisites	Tools
1. The experiment should have carefully defined objectives. See Table 26.2.	1. The definition of objectives requires all the specialized subject matter knowledge of the experimenter, and involves such things as: *a.* Choice of factors, including their range *b.* Choice of experimental materials, procedures, and equipment *c.* Choice of the metric for the factors (e.g., temperature or log temperature) and method of measurement
2. As far as possible, effects of factors should not be obscured by other variables.	2. The use of an appropriate experimental pattern helps to free the comparisons of interest from the effects of uncontrolled variables and simplifies the analysis of results.
3. As far as possible, the experiment should be free from bias, conscious or unconscious.	3. Some variables may be taken into account by planned grouping. Use randomization. Replication helps randomization to do a better job.
4. Experiments should provide a measure of experimental error variance (precision).	4. Replication provides the measure of variance and randomization ensures its validity.
5. Precision of experiment should be sufficient to meet objectives set forth in requisite 1.	5. Greater precision may be achieved by: refinements of measurement and experimental technique, experimental pattern (including planned grouping), replication.

CLASSIFICATION OF EXPERIMENTAL DESIGNS

Statisticians by themselves do not design experiments, but they have developed a number of structured schedules called "experimental designs," which they recommend for the taking of measurements. These designs have certain rational relationships to the purposes, needs, and physical limitations of experiments. Designs also offer certain advantages in economy of experimentation and provide straightforward estimates of experimental effects and valid estimates of variance. There are a number of ways in which experiment designs might be classified, for example, the following:

1. By the number of experimental factors to be investigated (e.g., single-factor versus multifactor designs)

2. By the structure of the experimental design (e.g., blocked, factorial, nested, or response-surface design)

3. By the kind of information the experiment is primarily intended to provide (e.g., estimates of effects, estimates of variance, or empirical mappings)

Some of the common statistical experimental designs are summarized in Table 47.3. Basic features of the designs are summarized in terms of these criteria of classification, and the details of design and analysis are given under the topics that follow. The analysis for observed responses is always based on a statistical model unique to the specific design.

TABLE 47.2   Checklist for Planning Test Programs

A. Obtain a clear statement of the problem.
  1. Identify the problem area in quantitative terms.
  2. Identify the response(s) to be measured, the factors that may be varied, the factors to be held constant, and the factors that cannot be controlled.
  3. Identify the ranges or limitations of the measurements and of the experimental factors.
B. Collect available background information.
  1. Investigate all available sources of information.
  2. Tabulate data pertinent to planning the experimental program.
  3. Be quantitative.
C. Design the experimental program.
  1. Hold a conference of all parties concerned.
     a. State the propositions to be explored.
     b. Agree on magnitude of differences in the response considered worthwhile.
     c. Outline possible alternative outcomes.
     d. Choose the factors to be studied.
     e. Determine practical range of factors and specify levels.
     f. Choose the measurements and methods of measurement.
     g. Consider the effect of sampling variability and of precision of the measurement methods.
     h. Consider possible interrelationships (interactions) of the factors.
     j. Determine influences of time, cost, materials, manpower, instrumentation, and other facilities and of extraneous conditions such as weather.
     k. Consider personnel and human relations requirements of the program.
  2. Design the experimental program in preliminary form.
     a. Prepare a systematic and inclusive schedule, which includes the randomization pattern.
     b. Provide for stepwise performance or adaptation of schedule if necessary.
     c. Eliminate effect of variables not under study by controlling, balancing, or randomization.
     d. Minimize the number of experimental runs consistent with objectives.
     e. Choose the method of statistical analysis.
     f. Arrange for orderly accumulation of data.
  3. Review the experimental design program with all concerned.
     a. Adjust the program as required.
     b. Spell out the steps to be followed in unmistakable terms.
D. Plan and carry out the experimental work.
  1. Develop methods, materials, and equipment.
  2. Carry out the experimental design in some random order.
  3. Record ancillary data.
  4. Record any modifications of the experimental design.
  5. Take precautions in the collection and recording of data, especially data from extra experiments and missing experiments.
  6. Record progress of the program by date, run number, and other ancillary data.
E. Analyze the data.
  1. Review the data with attention to recording errors, omissions, etc.
  2. Use graphics: plot the data, plot averages, plot simple graphs.
  3. Apply appropriate statistical techniques.

TABLE 47.2 Checklist for Planning Test Programs (*Continued*)

F. Interpret the results.
  1. Consider all the observed data.
  2. Confine initial conclusions to strict deductions from the experimental evidence at hand.
  3. Elucidate the analysis in both graphical and numerical terms.
  4. State results in terms of verifiable probabilities.
  5. Arrive at conclusions as to the technical meaning of results as well as their statistical significance.
  6. Point out implications of the findings for application and for further work.
  7. Account for any limitations imposed by the data or by the methods of analysis used.
G. Prepare the report.
  1. Describe work clearly, giving background, pertinence of problems, meaning of results.
  2. Use tabular and graphic methods of presenting data, and consider their possible future use.
  3. Supply sufficient information to permit readers to verify results and to draw their own conclusions.
  4. Limit conclusions to objective summary of evidence.

Split Plot. When certain (major) factors are difficult to change, other (minor) factors are run in an experimental design within each of the settings of the major factors. The Taguchi inner and outer array designs are of this genre. Many split-plot designs confound minor factor interactions with major factor main effects.

Major factors are not blocks. Major factors are studied for their main effects and interactions; blocks identify random variables. Further, blocks are assumed to have no interactions with the factors under study. When both the major and minor factors are random variables, the designs are identified as "nested."

COMPLETELY RANDOMIZED DESIGN: ONE FACTOR, *k* LEVELS

The completely randomized design is appropriate when a total of N experimental units are available for the experiment and there are k treatments (or levels of the factor) to be investigated. Of the total number $N,$ it is usual to assign *randomly* an equal number of trials n to each of the k treatments.

Example. A study was made to investigate the effect of three different conditioning methods on the breaking strength T (in pounds per square inch) of cement briquettes. Fifteen briquettes were available from one batch and were assigned at random to the three methods. The results are summarized in Table 47.4. The purpose of the experiment was to investigate the effect of conditioning methods on breaking strength, and the analysis was designed to answer the question: Do the mean breaking strengths differ for the different conditioning methods?

This is an example of a randomized one-factor experiment. Only one experimental factor (method of conditioning) is under study. There are three methods; i.e., the number of treatments k equals 3. The number of units n assigned at random to each treatment is 5. The total number of experimental units N is 15.

Analysis. Almost everyone today possesses a computer and the software capable of performing the arithmetic associated with the analysis of most experimental designs. Once the data for the fully

TABLE 47.3 Classification of Designs

Design	Type of application	Structure	Information sought
Completely randomized	Appropriate when only one experimental factor is being investigated.	Basic: One factor is investigated by allocating experimental units at random to treatments (levels of the factor). Blocking: none.	1. Estimate and compare treatment effects. 2. Estimate variance.
Factorial	Appropriate when several factors are to be investigated at two or more levels and interaction of factors may be important.	Basic: Several factors are investigated at several levels by running all combinations of factors and levels. Blocking: none.	1. Estimate and compare effects of several factors. 2. Estimate possible interaction effects. 3. Estimate variance.
Blocked factorial	Appropriate when number of runs required for factorial is too large to be carried out under homogeneous conditions.	Basic: Full set of combinations of factors and levels is divided into subsets so that some high-order interactions are equated to blocks. Each subset constitutes a block. All blocks are run. Blocking: Blocks are usually units in space or time. Estimates of certain interactions are sacrificed to provide blocking.	1. Same as factorial except that certain high-order interactions cannot be estimated.

TABLE 47.3 Classification of Designs *(Continued)*

Design	Type of application	Structure	Information sought
Fractional factorial	Appropriate when there are many factors and levels and it is impractical to run all combinations.	Basic: Several factors are investigated at several levels but only a subset of the full factorial is run. Blocking: Sometimes possible.	1. Estimate and compare effects of several factors. 2. Estimate certain interaction effects (some may not be estimable). 3. Certain small fractional factorial designs may not provide sufficient information for estimating the variance.
Randomized block	Appropriate when one factor is being investigated and experimental material or environment can be divided into blocks or homogeneous groups.	Basic: Each treatment or level of factor is run in each block. Blocking: Usually with respect to only one variable.	1. Estimate and compare effects of treatments free of block effects. 2. Estimate block effects. 3. Estimate variance.
Balanced incomplete block	Appropriate when all the treatments cannot be accommodated in a block.	Basic: Prescribed assignments of treatments to blocks are made. Every pair of treatments will appear at least once in the experimental design, but each block will contain only a subset of pairs.	1. Same as randomized block design. All treatment effects are estimated with equal precision. Treatment averages must be adjusted for blocks.
Partially balanced incomplete block	Appropriate if a balanced incomplete block requires a larger number of blocks than is practical.	Basic: Prescribed assignments of treatments to blocks are made.	1. Same as randomized block design but all treatments are not estimated with equal precision.

TABLE 47.3 Classification of Designs *(Continued)*

Design	Type of application	Structure	Information sought
Latin square	Appropriate when one primary factor is under investigation and results may be affected by two other experimental variables or by two sources of nonhomogeneity. It is assumed that no interactions exist.	Basic: Two cross groupings of the experimental units are made corresponding to the columns and rows of a square. Each treatment occurs once in every row and once in every column. Number of treatments must equal number of rows and number of columns Blocking: With respect to two other variables in a two-way layout.	1. Estimate and compare treatment effects, free of effects of the two blocked variables. 2. Estimate and compare effects of the two blocked variables. 3. Estimate variance.
Youden square	Same as Latin square but number of rows, columns, and treatments need not be the same.	Basic: Each treatment occurs once in every row. Number of treatments must equal number of columns. Blocking: With respect to other variables in a two-way layout.	1. Same as Latin square.
Nested	Appropriate when objective is to study relative variability instead of mean effect of sources of variation (e.g., variance of tests on the same sample and variance of different samples).	Basic: Factors are strata in some hierarchical structure; units are tested from each stratum.	1. Relative variation in various strata, components of variance.

TABLE 47.3   Classification of Designs *(Continued)*

Design	Type of application	Structure	Information sought
Response surface	Objective is to provide empirical maps (contour diagrams) illustrative of how factors under the experimenter's control influence the response.	Factor settings are viewed as defining points in the factor space (may be multidimensional) at which the response will be recorded	Maps illustrating the nature of the response surface
Mixture designs	Same as factorial designs.	Many unique arrays. Factor settings are constrained. Factor levels are often percentages that must sum to 100%. Other factor level constraints are possible.	Same as factorial

TABLE 47.4   Breaking Strength T of Cement Briquettes, lb/in^2

	Method 1	Method 2	Method 3

Degrees of freedom	4	4	4

randomized design displayed in Table 47.4 have been placed into a computer with an appropriate statistical design of experiments software program, then graphics similar to Figure 47.1 and an analysis of variance table such as that displayed in Table 47.5 become available. Nevertheless, we include here the details of the computations for the reader. The ability to perform one's own hands-on calculations is often of great value in reducing the "black-box" approach to data analysis.

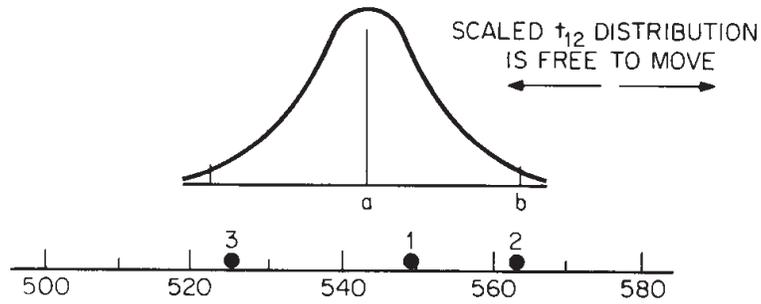
The analysis of these data begins with a plot of the three treatment averages as shown in Figure 47.1. The "reference distribution" for these averages will be explained shortly. The average responses


FIGURE 47.1   Plot of treatment averages and their reference t-distribution. (Distance from a to b = $t_{v,\,\alpha/2}\sqrt{s^2/n}$ = $t_{12,\,0.025}\sqrt{s^2/n}$ = $2.179\sqrt{545.4/5}$ = 22.8.)

TABLE 47.5   Analysis of Variance for a One-Factor Experiment

Source of variation	Sum of squares	Degrees of freedom	Mean square
Between treatments	SSB = 3,509.2	$(k - 1)$ = 2	MSB = SSB/$(k - 1)$ MSB = 3509.2/2 = 1754.6
Within treatments	SSW = 6,544.4	$k(n - 1)$ = 12	MSW = SSW/$k(n - 1)$ MSW = 6544.4/12 = 545.4
Total	TSS = 10,053.6	$(N - 1)$ = 14	

are obviously different. The key question is whether the observed differences are due solely to the inherent variability of the observations or caused by this variability plus real differences between the treatment means. (In this section on experimental design the word "mean" is used to connote the *expected value* of an average, that is, the value an average would take if an infinite number of observations were made.) The analysis of variance (ANOVA) is a basic statistical technique in the analysis of such data and is illustrated for the data in Table 47.5.

Analysis of Variance.   Referring to Table 47.4, the total T is

$$T = 8196 \qquad N = 15 \qquad n_i = 5 \qquad i = 1, 2, 3$$

Calculate the following:

The *uncorrected* total sum of squares Σy^2 = 4,488,348

$$C = \text{correction factor (a special constant)} = \frac{T^2}{N} = \frac{(8196)^2}{15} = 4{,}478{,}294.4$$

TSS=*corrected* total sum of squares

$$= \Sigma y^2 - C = 4{,}488{,}348 - 4{,}478{,}294.4 = 10{,}053.6$$

SSB = between-treatments sum of squares

$$= \sum_i \frac{T_i^2}{n} - C = \frac{22{,}409{,}018}{5} - C = 4{,}481{,}803.6 - 4{,}478{,}294.4 = 3509.2$$

SSW = within-treatments sum of squares = TSS − SSB = 10,053.6 − 3509.2 = 6544.4

(SSW is here obtained by subtraction. It may be obtained directly for the special case of the completely randomized design by calculating $\Sigma y^2 - [(\Sigma y)^2/n]$ for each treatment and summing for all treatments.)

The corrected total sum of squares TSS has $N - 1$ degrees of freedom (DF), the between-treatments sum of squares SSB has $(k - 1)$ degrees of freedom, and the within-treatments sum of squares SSW has $(N - k)$ degrees of freedom.

The mean-square column in the table is computed as follows:

$$\text{Mean square between treatments MSB} = \frac{\text{SSB}}{k - 1}$$

$$\text{Mean square within treatments MSW} = \frac{\text{SSW}}{N - k}$$

These calculated quantities are inserted in Table 47.5.

Calculate $F = \text{MSB}/\text{MSW} = 1754.6/545.5 = 3.22$. Choose α, the significance level of the test. If the calculated F exceeds $F_{1-\alpha}$ from Appendix II, Table K, for $(k - 1)$ and $k (n - 1)$ degrees of freedom, conclude that there are differences among treatment means. For example, $\alpha = 0.05$ level, $F_{0.95}$ for (2,12) degrees of freedom $= 3.89$; the calculated F does not exceed this value, and we do not have sufficient evidence to conclude that the mean breaking strength is different for the different conditioning methods. The differences between the treatment averages are thus assumed to be due to the error variance (the noise). Had the hypothesis that there are no treatment effects been rejected by the F test, then one could conclude that at last one of the mean breaking strengths differs from the others. The formal issue of comparing treatment means, the problem of "multiple comparisons," is discussed below.

In this example, the n_i are all equal. Designs that have an equal number of observations in each treatment are generally to be preferred. Such designs provide each treatment with an equal opportunity for comparison against all other treatments. On rare occasions, as when one of the treatments is a standard against which all other treatments are to be compared, more observations are placed in the standard treatment than in the alternatives. When the n_i are not all equal, use the following formula for the between-treatments sum of squares:

$$\text{SSB} = \frac{T_1^2}{n_1} + \frac{T_2^2}{n_2} + \ldots + \frac{T_k^2}{n_k} - C$$

Here SSW $=$ TSS $-$ SSB and MSW $=$ SSW/$(N - k)$ as before. The MSW (the overall estimate of variance) can also be obtained by estimating the variance within each treatment and pooling these estimates. The pooled estimate has $N - k$ degrees of freedom.

Graphical Analysis.   An approximate graphical analysis of these data is provided by sketching an appropriate "reference" distribution for the average, as illustrated in Figure 47.1. When σ^2 (the population variance) or, equivalently, σ (the population standard deviation) is known, averages may be referred to a normal distribution with standard error $\sigma/\sqrt{n}$. Here σ^2 is unknown, and its estimate s^2 must be determined from the data. Averages must be referred to a Student's t-distribution, suitably scaled by $s/\sqrt{n}$. The number of degrees of freedom in t is equal to the number of degrees of freedom in s^2. The estimate of σ^2 is obtained from the analysis of variance table ($s^2 = \text{MSW}$) or by pooling the separate estimates of variance obtained from within each treatment classification. The pooled estimate of variance is given by the weighted average of the individual estimates, the weights being their degrees of freedom. Thus

$$s^2 = \sum_i \frac{(n_i - 1)s_i^2}{N - k}$$

$$= \frac{4(145.7) + 4(626.2) + 4(864.2)}{16} = 545.5$$

$$s = 23.34 \text{ with 12 degrees of freedom}$$

A sketch of the appropriately scaled t-distribution appears in Figure 47.1. The distance from the center of the t-distribution to each extremal point equals $t_{12,\,0.025}s/\sqrt{n} = 2.18(23.35)/\sqrt{5} = 22.8$, and 95 percent of the distribution falls within the range $2(22.8) = 45.6$. The distribution is easily sketched; there is no need for great precision in its shape save that it look reasonably bell-shaped. The distribution can be moved back and forth, and has been located in this instance so that it just fits over the three averages. Thus, based on this graphical evidence, the suggestion that all three averages could have come from the same parent distribution and hence could be estimates of the identical mean seems reasonable.

This graphical interpretation is confirmed by using the F test in the analysis of variance table; that is, the computed F ratio was not statistically significant. When averages do not fit reasonably under the distribution, the graphical analysis suggests that the differences between the treatment averages reflect real differences between the treatment means. Such graphical evidence could, of course, be verified by an F test. The scaled reference distribution can be of great value in interpreting treatment averages. Often, although it is technically possible to place the reference distribution over all the averages and simultaneously to obtain a nonsignificant F test, interesting differences between groups of the averages may become clear. The F test does not consider patterns among the averages, a factor that can be of great importance to the analyst (see Box, Hunter, and Hunter 1978). Alternative approximate analysis techniques, in particular those based upon the use of the range statistic in place of the estimated standard deviation, are available [see the papers by Kurtz et al. (1965) and by Sheesley (1980)].

GENERALIZED COMMENTS ON A COMPLETELY RANDOMIZED DESIGN

The completely randomized design is simple to organize and analyze and may be the best choice when the experimental material is homogeneous and when background conditions can be well controlled during the experiment.

The advantages of the design are

1. Complete flexibility in terms of number of treatments and number of units assigned to a treatment
2. Simple analysis
3. No difficulty with lost or missing data

In planning the experiment, n units are assigned at random to each of the k treatments. When the data have been taken, the results are set out as in Table 47.6.

TABLE 47.6   Completely Randomized Design

Observations within treatments*	Treatments				
	1	2	3	$\cdots$	k
1	y_{11}	y_{12}	y_{13}	$\cdots$	y_{1k}
2	y_{21}	y_{22}	y_{23}	$\cdots$	y_{2k}
3	y_{31}	y_{32}	y_{33}	$\cdots$	y_{3k}
.	.	.	.		.
.	.	.	.		.
.	.	.	.		.
n	y_{n1}	y_{n2}	y_{n3}	$\cdots$	y_{nk}

*The entire nk observations are recorded in random order *without* regard to the treatment classifications.

Displayed this way, the results of experiments are indistinguishable from a situation in which there has been no design and no allocation at all but in which several different samples have been tested from each of several different sources of material or several observations have been made under each of several different conditions. Whether the observations come from units randomly allocated to several different treatments or from units obtained from several different sources, the data table looks the same, and in fact the analysis will be essentially the same.

This simple one-factor design is called "completely randomized" to distinguish it from other experiment designs in which either randomization is constrained or the principle of "blocking," or planned grouping, has been made part of the structure.

One-Way Analysis of Variance—Models.   The results of an experiment run according to a completely randomized design are summarized in a one-way table such as Table 47.6. The completely randomized design is called a "one-way" classification of data, whether or not the data came from a designed experiment. To discuss the associated analysis of variance, statisticians require "models" for the data. In the case of a one-way classification analysis of variance, the most appropriate model is determined by answering the question: Do the several groups (into which the data are classified) represent *unique* groups of interest to the experimenter? If they do, the model is called "Model I," the "Fixed Effects Model." If, on the other hand, the groups are considered to be a random sample from some population made up of many such groups, the model is called "Model II," the "Random Effects Model." For example, suppose that the data in Table 47.4 were not from a completely randomized design in which 15 briquettes were allocated at random to three unique conditioning treatments of interest to the experimenter. Suppose instead the column headings were "Batch 1," "Batch 2," "Batch 3," where the "batches" represented some convenient grouping of briquettes so that five briquettes were tested per batch. In the original experimental program, in which the three conditioning treatments of the designed experiment were the unique treatments of interest to the experimenter, the data may be represented by the Fixed Effects Model (Model I), whereas in the second program the three batches presumably were a random sample of batches, and hence these data are represented by the Random Effects Model (Model II).

For both Model I and Model II, the experimenter is trying to determine whether the three groups are different in mean value. For Model II the experimenter may also be interested in knowing about the "components of variance"; that is, the variance between samples from the same batch and the variance existing between batches. Knowledge of the variability of different samples within a batch and between different batches is helpful in planning how many samples to test in future experiments.

Data obtained from a designed experiment, as described for this completely randomized design, are usually considered to be represented by Model I, since presumably the experimenter includes the treatments of interest. If the data correspond to Model II, the analysis of variance table and F test are used with one extra step, which requires adding an extra column labeled "Expected Mean Square," to Table 47.5.

	Expected mean square
Between groups	$\sigma_w^2 + n\sigma_b^2$
Within groups	σ_w^2

For the data in Table 47.5, we have:

	Mean square	Expected mean square
Between groups	MSB=1754.6	$\sigma_w^2 + 5\sigma_b^2$
Within groups	MSW=545.4	σ_w^2

The quantity σ_b^2 is called the "*between* component of variance," and σ_w^2 is called the "*within* component of variance"; MSB is an estimate of the "Expected Between-Groups Mean Square"; and MSW is an estimate of the "Expected Within-Groups Mean Square." Estimates of s_b^2 and s_w^2 or σ_b^2 and σ_w^2 can be obtained as follows:

MSB is set equal to $s_w^2 + ns_b^2$ and MSW is set equal to s_w^2:

$$s_w^2 = 545.4$$

$$s_b^2 = \frac{1754.6 - 545.4}{5} = \frac{1209.2}{5} = 241.8$$

The total variance assignable to a single observation from one randomly chosen batch and a single briquette is estimated as

$$s^2 = s_b^2 + s_w^2$$

BLOCKED DESIGNS

The several levels, or versions, of a studied factor or group of studied factors are called "treatments," and the major objective of an experimenter is to study the influences of these different treatment levels upon some response. Often all the levels of the studied factors are repeated each day or with a different operator, machine, supply of raw materials, etc. Each complete replication of the set of treatments is called a "block." The experimenter should plan the treatments so as to prevent differences between the blocks from influencing the comparisons between the treatments. For example, if the blocks in the experiment are days, the first aim of the experiment is to evaluate the effects of the studied factors free of the effects of day differences. A secondary aim might actually be to measure the effects of the days to help in planning future experiments. In blocked designs it is generally assumed that blocking factors do not interact with studied factors. In the simplest block designs the data, when taken, can be summarized in a two-way table, as illustrated in Table 47.7. Note that this design is *not* a factorial design. In a factorial design all the factors (here rows and columns) are at predetermined levels, whereas in the design under consideration here, the blocking factor is not under the control of the experimenter. The blocking factor is, however, recognized as capable of influencing the response. The experimenter's objective is to remove from the influences of the studied factors any possible contributions to the response that are provided by the blocking factors. Blocking factors are commonly environmental phenomena outside the control of the experimenter.

The interest in the factor called blocks has several objectives. Some of these are:

TABLE 47.7   Schematic for a Simple Block Design

	Treatments			
	1	2	$\cdots$	k
Block 1	y_{11}	y_{12}	$\cdots$	y_{1k}
Block 2	y_{21}	y_{22}	$\cdots$	y_{2k}
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.
Block b	y_{b1}	y_{b2}	$\cdots$	y_{bk}

1. The aim of the experimenter is to estimate effects of treatments free of block effects; numerical estimates of block effects are not particularly needed. For example, if blocks are days, day-to-day differences should be eliminated as sources of variability and are of no particular interest in themselves.

2. The primary aim is to estimate effects of the treatments (the studied factors) and secondarily to have estimates of block effects.

3. Sometimes the treatment effects and the block effects are of almost equal interest. In this case "block design" is analogous to a "two-factor experiment," but the experimenter must be sure that the studied and blocking factors do not interact before using a block design data analysis. If interaction between factors exists or is suspected, the design and analysis for a factorial experiment must then be used.

The simplest design with one-way blocking is the "randomized block design."

RANDOMIZED BLOCK DESIGN

In comparing a number of treatments, it is clearly desirable that all other conditions be kept as nearly constant as possible. Unfortunately, the required number of tests is often too large to be carried out under similar conditions. In such cases, the experimenter may be able to divide the experiment into blocks, or planned homogeneous groups. When each such group in the experiment contains exactly one observation on every treatment, the experimental plan is called a randomized block plan. The treatments are run *in a random order* within the blocks.

There are many situations in which a randomized block plan can be profitably utilized. For example, a comparison of several levels of some factor may take several days to complete. If we anticipate that the different days may also have an influence upon the response, then we might plan to observe all of the factor levels on each day. A day would then represent a block. In another situation, several operators may be conducting the tests, and differences between operators may be expected. The tests or observations made by a given operator can be considered to represent a block. The size of a block—that is, the number of tests contained within the block—may be restricted by physical considerations. In general, a randomized block plan is one in which each of the treatments appears exactly once in every block. The treatments are allocated to experimental units at random within a given block. The results of a randomized block experiment can be exhibited in a two-way table such as Table 47.8, in which we have $b = 4$ blocks and $k = 6$ treatments. Since each treatment occurs exactly once in every block, the treatment totals or averages are directly comparable without adjustment.

Example.   The data in Table 47.8 represent the conversion gain of four resistors measured under six different conditions. The response, conversion gain, is defined as the ratio of available current-noise power to applied dc power expressed in decibel units and is a measure of the efficiency with which a resistor converts dc power to available current-noise power. Each test condition involves the same four resistors. The experimenter is interested in comparing differences between conditions (the studied factor) clear of possible influences due to the resistors (the blocking factor). A quick review of Table 47.8 indicates large differences between the resistors, i.e., between the block averages. The key question is whether, with this resistor variability eliminated, the experimenter can now detect real differences between the test conditions since the differences between the observed condition averages are small and may merely reflect experimental error.

Analysis.   Some computer software programs may title the analysis of variance associated with the randomized block experiment as a "two-way" analysis of variance. In a randomized block experiment primary interest rests in the treatment averages and their standard errors. Block averages are always of interest, but since blocks cannot be controlled by the experimenter (they represent environ-

TABLE 47.8 Randomized Block Design Response: Conversion Gain of Resistors

Resistor (blocks)	Test set (treatments)						Row total	Row average
	1	2	3	4	5	6		
1	138.0	141.6	137.5	141.8	138.6	139.6	$B_1 = 837.1$	$b_1 = 139.52$
2	152.2	152.2	152.1	152.2	152.0	152.8	$B_2 = 913.5$	$b_2 = 152.25$
3	153.6	154.0	153.8	153.6	153.2	153.6	$B_3 = 921.8$	$b_3 = 153.63$
4	141.4	141.5	142.6	142.2	141.1	141.9	$B_4 = 850.7$	$b_4 = 141.78$

Column totals

$T_1 = 585.2$ $T_2 = 589.3$ $T_3 = 586.0$ $T_4 = 589.8$ $T_5 = 584.9$ $T_6 = 587.9$ Grand total
$G = 3523.1$

Column averages

$\bar{y}_1 = 146.30$ $\bar{y}_2 = 147.32$ $\bar{y}_3 = 146.50$ $\bar{y}_4 = 147.45$ $\bar{y}_5 = 146.22$ $\bar{y}_6 = 146.98$

ments within which the treatments have been randomly run) their importance is commonly secondary to that of the treatments. Of course, comparisons between averages requires an estimate of the variance σ^2. The primary reason for the analysis of variance computations is to get an estimate of the variance (to quantify the noise) clear of all assignable causes. Plots of the averages are always required.

The analysis of a randomized block experiment depends on a number of assumptions. We assume that each of the observations is the sum of four components. If we let y_{ij} be the observation on the ith treatment in the jth block, then

$$y_{ij} = \eta + \phi_i + \beta_j + \epsilon_{ij}$$

The term η is the grand mean, ϕ_i is the effect of treatment i, β_j the effect of block j, and ϵ_{ij} the experimental error associated with the measurement y_{ij}. (The subscripts $i = 1, 2, ..., k$ and $j = 1, 2, ..., b$.) The mean for the ith treatment equals $\eta + \phi_b$ and the mean for the jth block equals $\eta + \beta_j$. The terms ϕ_i and β_j represent, respectively, the unique contributions (effects) of treatments and blocks. The estimate of the mean η is given by $\bar{y}$, the grand average. Letting $\bar{y}_i$ equal the average for the ith treatment, the estimate of treatment effect ϕ_i is $\bar{y}_i - \bar{y}$. Similarly, $\bar{y}_j - \bar{y}$ estimates the block effect β_j.

In order to make interval estimates for or tests of hypotheses on the treatment or block contributions, we assume that the values of the experimental error ϵ_{ij} are independently and normally distributed with constant variance. If the experiment is randomized properly, failure of these assumptions will, in general, not cause serious difficulty.

A more serious difficulty occurs when count data are recorded. Count data are frequently Poisson-distributed, and hence the variance of the observations is linked directly to their mean. In such circumstances, it is best first to take the square roots of the count data and then to proceed with the estimation of effects and the analysis of variance.

Reference Distribution for Treatment Averages.   The plot of the $k = 6$ treatment averages is displayed in Figure 47.2

To construct the appropriate reference distribution to judge these averages and to test hypotheses, an estimate of the experimental error variance σ^2 is required. Using the model, the associated analysis of variance table can now be constructed.

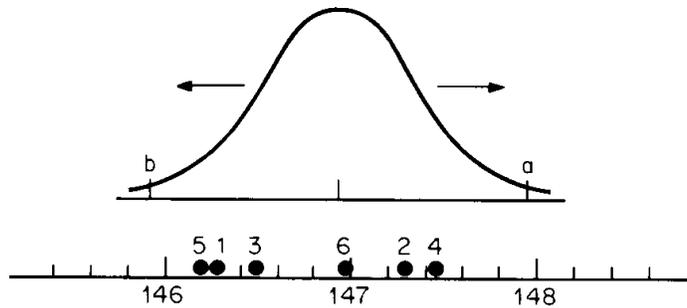
Randomized Block Analysis of Variance.   The analysis of variance table for this randomized block experiment data with $k = 6$ treatments and $b = 4$ blocks is given in Table 47.9.


FIGURE 47.2   Plot of $k=6$ treatment averages and their reference
t-distribution. (Distance from a to $b = 2ts/\sqrt{b} = 2.02$.) Numbers
above scale are treatment numbers from Table 47.8.

TABLE 47.9   Analysis of Variance Table: Randomized Block Design

	Sum of squares (SSq)	Degrees of freedom (DF)		Mean square
Blocks: SSB	927.665	$(b-1)$	3	309.222
Treatments SST	5.598	$(k-1)$	5	1.120
Residual SSR	13.467	$(b-1)(k-1)$	15	$0.898 = s^2$
Total corrected SSq	946.730	$(bk-1)$	23	

The details of these computations are as follows:

Let $N = bk$ = total number of observations. Here $N = (4)(6) = 24$.

Let G = grand total of all the observations. $G = 3523.1$.

Let Σy_{ij}^2 = sum of the $y_{ij}^2 = 518{,}123.13$.

Total corrected $\text{SSq} = \Sigma y_{ij}^2 - G^2/N = 518{,}123.13 - (3523.1)^2/24$.

Let B_i = total for block i, $i = 1, 2, \ldots, b$. Here $b = 4$.

Blocks: $\text{SSB} = \Sigma_i B_i^2/k - G^2/N = 518{,}104.065 - G^2/N = 927.665$.

Let T_j = total for treatment j, $j = 1, 2, \ldots, k$. Here $k = 6$.

Treatments $\text{SST} = \Sigma_j T_j^2/b - G^2/N = 517{,}181.998 - G^2/N = 5.598$.

The residual SSR is obtained by subtraction.

The "mean squares" = (sum of squares)/(degrees of freedom).

An excellent explanation of these computations can be found in Box, Hunter, and Hunter (1978).

To test the hypothesis that all the treatment means are equal select an α risk level (commonly 0.05) and perform an $F_{\alpha,v1,v2}$ test. Thus

$$F_{v1,v2} = F_{5,15} = \frac{\text{SST}/(k-1)}{s^2} = \frac{1.120}{0.898} = 1.247$$

The critical $\alpha = 0.05$ value of $F_{0.05,5,15} = 2.90$. (Critical values of the F ratio are found in Table K, Appendix II.) The computed F is less than the critical F and we therefore declare there is insufficient evidence to lead to the rejection of the hypothesis that all treatment effects are zero. We may not actually believe this hypothesis, but we cannot reject it. A similar test that all block effects are zero gives:

$$F_{v1,v2} = F_{3,15} = \frac{\text{SSB}/(b-1)}{s^2} = \frac{309.222}{0.898} = 344.345$$

The computed F is far greater than the critical $F_{0.05,3,15} = 3.29$, and the hypothesis that there are zero block effects is rejected.

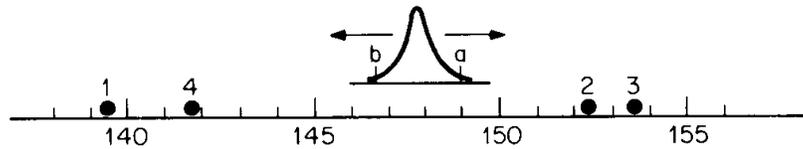
Figure 47.2 shows the plot of the six treatment averages and their associated "reference distribution." The reference distribution for averages is a normal distribution scaled by $\sqrt{\sigma^2/n}$ when σ^2 is known. When, as in this case, only $s^2 = 0.898$ with $v = 15$ degrees of freedom is known, the refer-


FIGURE 47.3   Plot of $b = 4$ block averages from Table 47.8 and their reference t-distribution. (Distance from a to $b = 2ts/\sqrt{k} = 1.65$.)

ence distribution for averages becomes a t-distribution scaled by $\sqrt{s^2/n}$. The distribution displayed in Figure 47.2 is the bell-shaped t curve, 95 percent of its area contained within the interval

$$2t_{\alpha,v}\sqrt{s^2/n} = 2(2.131)\sqrt{(0.898)/4} = 2.02$$

(The number of observations in a treatment average is $n = b = 4$.) The curve can be sketched in by hand; great precision is not required. One imagines this bell-shaped t-distribution to move back and forth horizontally. If two or more averages appear to be nested under a single location of the distribution, the inference is that differences between these averages may be due solely to the variance of the observations, a graphical test analogous to a nonsignificant F test. If some of the averages, individually or in clusters, seem to aggregate beyond the bell curve, this is taken as a signal that real differences exist, analogous to a significant F test.

Figure 47.3 displays the $b = 4$ block averages and their reference t-distribution. Once again, 95 percent of the distribution contained in the interval is given by

$$2t_{\alpha,v}\sqrt{s^2/n} = 2(2.131)\sqrt{(0.898)/6} = 1.65$$

(The number of observations in a block average is $n = k = 6$.) It is obvious from viewing Figure 47.3 that the reference distribution, wherever horizontally positioned, cannot reasonably account for the four averages. Block averages 1 and 4 are distinctly different from 2 and 3 and from one another. There is some indication, though slight, that averages 2 and 3 may be from a single distribution and hence merely reflections of the variability of averages about their expected mean value.

MULTIPLE COMPARISONS

An alternative graphical device for comparing treatment averages is the *analysis of means,* originated by Ott (1967). A plot similar to the Shewhart control chart is constructed. The control limits for the charts are easily obtained using special tables that adjust for the multiple comparisons that are possible. See Ott (1967), Schilling (1973), Nelson, L. (1983), Ott and Schilling (1990), Nelson, P. (1993), and, for good examples, Ramig (1983).

The graphical technique of a sliding reference distribution is subjective, the experimenter's eye and good judgment called into play. Many alternative formal techniques are available to demonstrate whether differences exist between the treatment means. Commonly, special intervals are computed such that averages appearing together within an interval may not be declared statistically significantly different. One approach is to compute the *least significance difference* (LSD) where

$$\text{LSD}_\alpha = t_{v,\alpha/2}\sqrt{\left(\frac{1}{n_i} + \frac{1}{n_j}\right)s^2}$$

If the absolute value of the difference between any two averages is greater than the LSD, the two treatment averages may be declared statistically significantly different. Of course, in comparing k averages there are $k(k-1)/2$ possible pairs, and many other comparisons (contrasts) are possible when k is modestly large. In LSD comparisons a fixed α risk (usually $\alpha = 0.05$) is maintained for each comparison regardless of the number of comparisons made. The overall α risk is considerably

increased when multiple tests are performed. For a fixed overall α risk for all possible *pairs* of treatments, one may wish to use the Tukey Studentized range statistic (Tukey 1949). Dunnett's method (Dunnett 1964; Bechofer and Tamhane 1983) is used for all $(k - 1)$ differences from a standard. The Scheffé test is used to make *all* possible comparisons (Scheffé 1953). Other multiple comparison methods are the Bonferroni interval (Dunn and Clark 1987); and the Duncan multiple range (Duncan, D. B., 1955). The Bonferroni and Duncan multiple range procedures can be found in most computer software programs. A good overall reference to the problems of multiple comparisons is Miller (1981). For multiple comparison of variances see Spurrier (1992).

BALANCED INCOMPLETE BLOCK DESIGNS

In an incomplete block design, all the treatments cannot be accommodated within a single block. To illustrate, consider a production manager who wishes to study the differences between the products supplied by six different suppliers. Unfortunately, personnel and equipment limit the number of suppliers that can be studied to three a day. The production manager is concerned that day-to-day differences might upset comparisons between suppliers and wishes to block the contributions of days, but the individual blocks are not large enough to encompass all six treatments. The appropriate experimental design to use is a "balanced incomplete block design," as illustrated in Table 47.10. The six suppliers (treatments) labeled A, B, C, D, E, and F are then studied in groups of three within each day (block). The blocks and the sequence of trials within the blocks are to be chosen in some random order.

Note that in the design displayed in Table 47.10 every letter supplier is tested the same number of times and every pair of letters appears within a block the same number of times. Another design appropriate to the case of six treatments constrained to be studied three at a time is the "combinatoric" design, that is, a design consisting of all combinations of six things taken three at a time. The combinatoric balanced incomplete block would have required 20 blocks; the design illustrated in Table 47.10 requires only 10.

One consequence of using an incomplete block design is that each treatment average must be adjusted for the blocks in which it appears and the differences between the *adjusted* treatment averages appraised. The computations are straightforward but go beyond what can be accommodated in this handbook. Interested readers are referred to Cochran and Cox (1957), Natrella (1963), and Box, Hunter, and Hunter (1978).

To enumerate the situations in which it is possible to construct a balanced incomplete block design, the quantities *r, b, t, k, L, E,* and *N* are defined as follows:

r = number of replications (the number of times a treatment appears)

b = number of blocks in the plan

TABLE 47.10 A Balanced Incomplete Block Design

Days	Before randomization	After randomization	Six treatments A B C D E F
1	ABE	DBC	t = 6 treatments
2	ABF	CDA	b = 10 blocks
3	ACD	FBD	k = 3 treatments/block
4	ACF	CEB	r = 5 replicates/treatment
5	ADE	DEF	L = 2, i.e., each
6	BCD	EBA	treatment pair
7	BCE	AFB	appears twice
8	BDF	DEA	
9	CEF	FCE	
10	DEF	CFA	

t = number of treatments

k = block size, i.e., the number of treatments that can appear in each block

L = number of blocks in which a given treatment pair appears: $L = r(k-1)/(t-1)$

E = a constant used in the analysis: $E = tL/rk$

N = total number of observations: $N = tr = bk$

Plans are indexed in Table 47.11 for $4 < t < 10$ and $r < 10$. For an extensive listing of the designs and many worked examples see Cochran and Cox (1957) and Natrella (1963).

General Comments on Block Designs.
In the simplest type of block design, Randomized Blocks, each block is large enough to accommodate all the treatments one wishes to test. In Incomplete Block Designs, the block size is not large enough for all treatments to be tested in every

‡"Comb" indicates plans constructed by taking all possible combinations of t treatments in groups (block size) of k.

block. In Balanced Incomplete Block Designs, treatments are assigned to blocks that lead to equal precision in the estimation of differences between treatments.

If Randomized Block and Balanced Incomplete Block Designs do not meet the needs of the experimenter with regard to number of blocks, size of blocks, number of treatments, etc., other kinds of plans are available, for example, *partially* balanced incomplete block designs (Clatworthy 1973), and "chain block" designs, which are useful whenever observations are expensive and the experimental error is small. [See Natrella (1963) and Fleiss (1986) for the structure and details of analysis.]

General-purpose software programs written initially for statisticians employing mainframe computers rapidly perform the computations associated with the incomplete block designs. Only the more advanced personal computer design of experiments software programs offer lists of balanced incomplete block designs and assistance in their analysis. Despite their obvious importance and value, the application of these designs within industry is slight.

LATIN SQUARE DESIGNS

A Latin square design (or a Youden square plan, described later) is useful when it is necessary to investigate the effects of different levels of a studied factor while simultaneously allowing for two specific sources of variability or nonhomogeneity, i.e., two different *blocking* variables. Such designs were originally applied in agricultural experimentation when the sources of nonhomogeneity in fertility were simply the two directions on the field, and the "square" was literally a square plot of ground. Its usage has been extended to many other applications in which there are two sources of nonhomogeneity (two blocking variables) that may affect experimental results—for example, machines and positions or operators and days. The studied variable, the experimental treatment, is then associated with the two blocking variables in a prescribed fashion. The use of Latin squares is restricted by two conditions:

1. The numbers of rows, columns, and treatments must all be equal.
2. There must be *no* interactions between the row, the column, and the studied factors (see Factorial Experiments—General, for discussion of interaction).

As an example of a Latin square, suppose we wish to compare four materials with regard to their wearing qualities. Suppose further that we have a wear-testing machine that can handle four samples simultaneously. The two blocking variables might be the variations from run to run and the variations among the four positions on the wear machine. A 4 × 4 Latin square will allow for both sources of homogeneity. The Latin square plan is shown in Table 47.12 (the four materials are labeled A, B, C, and D). Note that every letter (treatment) appears once in every row and once in every column. Examples of Latin squares from size 3 × 3 to 7 × 7 are given in Table 47.13.

Strictly speaking, every time we use a Latin square we should choose a square at random from the set of all possible squares of its size. The tables of Fisher and Yates (1964) give complete collections of all the squares from 3 × 3 up to 12 × 12. Once a given square is chosen, permute the

columns at random, permute the rows at random, and assign the letters randomly to the treatments to provide a completely randomized design.

The analysis of the Latin square design is discussed in most textbooks and is available on most design of experiments personal computer software programs. The analysis of variance table is a simple extension of the randomized block table. Plots of the treatment averages and their reference distribution and/or multiple comparison hypothesis tests are the major objective of the analysis. Plots of the block averages and estimates of block effects are always informative, but since blocks cannot be controlled by the experimenter, their importance is only tangential to the analysis of the treatments. The reader is warned, firmly, that the mathematical model underlying the analysis of a Latin square (or any of its associated designs, the Graeco-Latin and the hyper Graeco-Latin square) assumes that *no interactions* exist between rows, columns, or any of the treatment classifications. Failure to meet this "no interactions" requirement leads to biased estimates of the treatment effects and the row and column (block) effects, and also biases the estimate of the variance σ^2. Unbiased estimates of σ^2 can be obtained by repeating the entire design or by partial replication [see Youden and Hunter (1955)].

The Latin square is *not* a factorial design, i.e., a design that allows for interactions between the separate factors composing the design. If there are interactions likely, the experimenter is advised to use a factorial or fractional factorial design and associated mode of data analysis. The 3×3 Latin square design is sometimes called the L9 orthogonal array. See Hunter (1989) for an example of the dangers that can arise from the misuse of the Latin squares.

YOUDEN SQUARE DESIGNS

The Youden square, like the Latin square, allows for two experimental sources of inhomogeneity. The conditions for the use of the Youden square, however, are less restrictive than those for the Latin square. The use of Latin square plans is restricted by the fact that the number of rows, columns, and treatments must all be the same. Youden squares have the same number of columns and treatments, but a fairly wide choice in the number of rows is possible. We use the following notation:

t = number of treatments to be compared

b = number of levels of one blocking variable (columns)

k = number of levels of another blocking variable (rows)

r = number of replications of each treatment

L = number of times that two treatments occur in the same block

In a Youden square, $t = b$ and $k = r$.

Some Youden square plans are given in Table 47.14. The analysis of the Youden squares must be carefully handled; in particular, the treatment averages must be adjusted for the rows in which they appear *before* they can be compared. Further, the standard error of the adjusted averages requires special computation. Reference should be made to the textbooks listed at the end of this section for the numerical details.

PLANNING INTERLABORATORY TESTS

We present here only a few simple techniques found useful in the planning and analysis of interlaboratory (round-robin) tests. The very early article by Wernimont (1951) remains an excellent introduction to the general problem. Other early contributors to the field are Youden (1967) and Mandel (1964), both members of the early National Bureau of Standards. An overall view of the importance of interlaboratory comparisons can be found in Hunter (1980). The best source of detailed information on round-robin procedures can be found in the publications of committee E11 of the American Society for Testing and Materials (ASTM). The text by Moen, Nolan, and Provost (1991) has several worked examples including a graphical method of analysis due to Snee (1983). Repeatability and Reproducibility (R&R) studies are often part of an interlaboratory testing program; see Barrentine (1991), Montgomery (1991), and Automotive Industry Action Group (1990).

A Rank Sum Test for Laboratories. In almost any set of interlaboratory test data, some of the reported results fall so far out from the main body of results that there is a real question as to whether these data should be omitted in order to avoid distortion of the true picture. It is always a difficult problem to decide whether or not outlying results should be screened. One does not wish to discard a laboratory's results without good reason; on the other hand, if a laboratory is careless or not competent, one does not wish to "punish" the test method. A ranking test for laboratories due to

Youden (1963) is described here. This is only one of several nonparametric ranking procedures that may be of interest to the reader. Excellent references on these nonparametric approaches are the texts by Hollander and Wolfe (1973), Conover (1980), Gibbons and Chakraborti (1992), and Iman (1994).

An interlaboratory test usually involves sending several materials containing some particular chemical element or compound or possessing some physical quality to each of several laboratories. The ranking test for laboratories uses the recorded measured responses of the materials to rank the laboratories. The data from the interlaboratory test are summarized in a two-way table with materials as rows and laboratories as columns (or vice versa).

For each material, the laboratory having the largest result is given rank 1, the next largest rank 2, etc. (Tied values are treated as is usual in ranking procedures, each tied value being given the average of those ranks that would have been assigned if the values had differed.)

For each laboratory, the assigned ranks are summed over all materials. A laboratory that is consistently high in its ability to measure the response will show a lower rank sum, and a laboratory that is consistently low will show a higher rank sum than the average or expected rank sum. The question is whether such rank sums are excessively high or excessively low. To decide this, tables have been provided (see Table 47.15).

A Ruggedness Test for Use by the Initiating Laboratory. Very often a test method is judged to have acceptable precision by the original laboratory, but when the test is performed by several laboratories, the results are disappointing. The reason is usually that the original laboratory has carefully controlled conditions and equipment and that the operating conditions in other laboratories are slightly different. (There are always slight deviations, which are permissible within the instructions contained in the standard procedure for the test method.) Youden (1967) proposed that the initiating laboratory investigate the effects of such deviations by deliberately introducing small variations in

Note: Let L laboratories test each of M materials. Assign ranks 1 to L for each material. Sum the ranks to get the score for each laboratory. The mean score is $M(L + 1)/2$. The entries are lower and upper limits that are included in the approximate 5% critical region.

the method, a "ruggedness test," so as to be prepared for the variations resulting when the test is used by other laboratories. In order to minimize the extra work required for the original laboratory, he proposed that the Plackett-Burman designs for 7, 11, 15 factors be used to detect such effects. If significant effects result from such variations of conditions in a single laboratory, the method needs further refinement before interlaboratory tests are run. (See Thomas and Kiwanga 1993.)

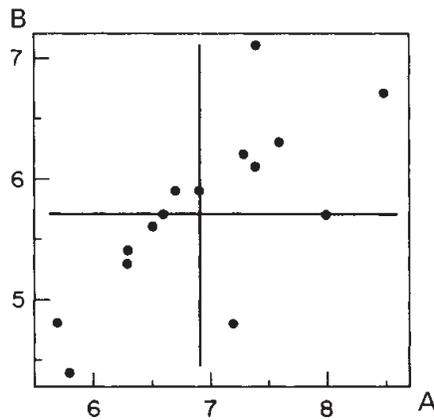
Youden Two-Sample Plan.   A simple plan to investigate the performance of laboratories and of the test procedure itself was suggested by Youden (1959) and reprinted in Ku (1969). Samples of two materials (*A* and *B*) are sent to each laboratory in the program. The two materials should be similar in kind and in the value of the property to be measured. The laboratories should have the same internal precision. The pairs of results are used to plot a graph on which the *x* and *y* scales are equal and each laboratory is represented by one point. A laboratory's result on sample *A* is the *x* coordinate and its result on sample *B* is the *y* coordinate of that point. There will be as many points as there are laboratories. For graphical diagnosis, a vertical line is drawn through the median of all points in the *x* direction and a horizontal line through the median of all points in the *y* direction. The lines could be drawn through the *x* and *y* averages just as well, but the medians are convenient for quick graphical analysis.


FIGURE 47.4   Percent phthalic anhydride in two paint samples—Youden plot showing systematic differences.

Individual points that are very far removed from the main body of the results indicate laboratories that should probably be screened from the analysis. The two intersecting median lines divide the space into four quadrants, and the first (and often revealing) step in the analysis is to look at the distribution of points among the quadrants. If only random errors of measurement were operating, there would be a circular scatter of points with roughly equal numbers in each quadrant. The plots of most real-life interlaboratory data, however, show concentrations in the upper right and lower left quadrants (see Figure 47.4). If a laboratory is high on both samples, its point will lie in the upper right; if a laboratory is low on both samples, its point will lie in the lower left. Being high (or low) on both samples is an indication that a laboratory has somehow put its own stamp on the procedure, i.e., that there are systematic differences between the laboratories. Where these systematic differences exist, the points will tend to lie along a long, narrow ellipse. Assuming that the two materials are similar in kind and in value of the property measured, as prescribed, and that the scatter in results for sample *A* does turn out to be approximately the same as the scatter for sample *B,* we can calculate an estimate of the standard deviation of a single result as follows:

1. Calculate the "signed differences" $d = A - B$ for each laboratory; that is, compute the difference and keep the sign (for the *i*th laboratory $d_i = A_i - B_i$).
2. Calculate $\bar{d}$, the algebraic average of the *d*'s.
3. Calculate $d'_i = d_i - \bar{d}$.
4. Take the absolute d' values and calculate their average; that is, drop the signs before averaging.
5. Multiply this value by 0.886 to get an estimate *s* of the standard deviation of a single result. (The value 0.886 is $1/d_2$, Appendix II, Table A, for $n = 2$.)

A circle can now be drawn that is expected to contain any stated percentage of the points. The circle is centered at the median point and its radius (for the stated percentage to be contained within it) is obtained by multiplying *s* (from Step 5) by the factor given in Table 47.16.

TABLE 47.16   Radius of Circle on Youden Plot
in Terms of Multiples of the Standard Deviation

Percent of points within circle	Multiple of the standard deviation
90	2.146
95	2.448
99	3.035

Points lying outside the circle usually indicate laboratories with systematic differences. Further deductions are possible from such plots (see Youden, 1959); they have been used in a wide variety of applications, including chemical and engineering tests and standards comparisons.

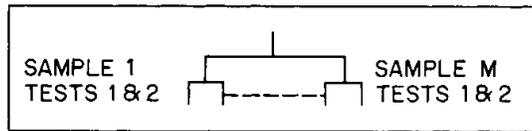
NESTED (COMPONENTS OF VARIANCE) DESIGNS


FIGURE 47.5   A two-stage balanced nested design.
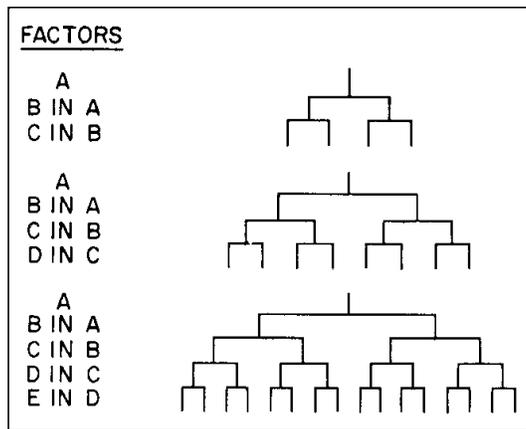
(*Reprinted with permission from Bainbridge 1965.*)


FIGURE 47.6   Balanced nested designs for three, four, and five factors. (*Reprinted with permission from Bainbridge 1965.*)

Most experimental designs are primarily intended to provide estimates of the means and differences or other comparisons between the means of experimental treatments. However, in investigations associated with interlaboratory comparisons, or the repeatability and reproducibility of measuring instruments, sources of variability become the studied factors, and the primary knowledge sought concerns the relative importance of these sources. Such investigations are called "components of variance" studies. Designs intended to provide estimates of the components of variance arising from various sources are called "nested" or "hierarchical" designs. A simple nested design is shown in Figure 47.5 wherein M samples are taken and then within each sample duplicate tests are made. The variance of all the observations is then partitioned into two components: that assignable uniquely to the samples and that uniquely to the duplicates. This is a two-stage balanced nested design. Three or more classifications can be nested, as illustrated in Figure. 47.6.

The analysis of nested designs and estimation of components of variance is based upon a "random effects" model for the observations in which, except for a single constant term, all elements are random variables. (See further discussion under the sections One-Way Analysis of Variance—Models and Split-Plot Factorial Experiments.) Needed are the expected values of the mean squares obtained from an analysis of variance table; see Snee (1974). The designs and their analysis is described in most textbooks on experimental design [for example, Dunn and Clark (1987); Neter, Wasserman, and Kutner (1990); Hogg and Ledolter (1992); Montgomery (1991); and Burdick and Graybill (1992)]. An example of the estimation of components of variance that does not evoke the analysis of variance is given in Box, Hunter, and Hunter (1978). A Bayesian method for estimating variance components is given in Box and Tiao

(1973). An entire textbook devoted to the subject is Searle, Casella, and McCulloch (1992). Most design of experiments software programs will provide the expected values of the mean squares needed to determine the components of variance for the simple balanced designs.

In Figure 47.6, at each stage only two subunits of each unit are taken, but the total number of tests multiplies rapidly as the number of stages increases. Because of the rapidly increasing total number of tests, only a few units are usually used at the top levels. In other words, balanced nested designs tend to provide too little information on the upper levels (the initial stages, or factors *A* and *B*) and often provide more than enough information at the bottom levels (factors *E*, for example). Bainbridge (1965) has considered alternative "unbalanced" nested designs with a fixed number of tests. He prefers a design, which he calls a "staggered nested design" that is easy to administer and provides about the same number of degrees of freedom for each factor. Bainbridge shows staggered nested designs for three, four, five, and six factors (see Figure 47.7 for the designs and their analysis).

PLANNING THE SIZE OF THE EXPERIMENT

Methods for determining the number of observations required for estimating the mean and variance with certain precision, or for comparing two sets of data with regard to mean and variance with certain risks of error, are given in Section 44, Basic Statistical Methods. A method for determining the number of observations required for comparing several groups is given here.

For example, the analysis of variance *F* test (see Completely Randomized Design: One Factor, *k* Levels) is designed to test the hypothesis that all group means are the same, i.e., $\eta_1 = \eta_2 ... \eta_k = \eta$. The corresponding averages $\bar{y}_1, \bar{y}_2, ..., \bar{y}_k$ computed from the recorded data will, of course, be different. The outcome of the test of hypothesis depends on the significance level α at which the test is performed, the true variability of individual observations, the number of observations per average, and the size of the true difference (if any) between group means. When planning experiments, if there are no restrictions on the number of observations that can be made, one should specify the size of those differences in means that are considered important from a practical standpoint. When the significance level at which the test is to be made is also specified, existing tables or charts can be used to determine the necessary sample size (number of observations per average) for achieving a stated probability $(1 - \beta)$ of detecting differences between the means of the required size. To use such tables, we compute a quantity

$$\phi^2 = \frac{n \sum_i (\eta_i - \eta)^2}{k\sigma^2} = \frac{n\Sigma\delta_i^2}{k\sigma^2}$$

where n = number of observations per group (to be determined)
   k = number of groups
   σ^2 = true value of within-group variance (assumed same for all groups; can be estimated from previous similar work)
   η_i = mean for *i*th group
   η = grand mean

Let $(\eta_i - \eta) = \delta_i$. The sum of the δ_i values must equal zero.

Appendix II, Table DD gives values ϕ^2 for $\alpha = 0.01$ and $\beta = 0.2$, $(1 - \beta = 0.80)$, and DF$_1$ and DF$_2$ degrees of freedom. In the simple case used in the example, DF$_1 = k - 1$ and DF$_2 = k(n - 1)$. Other charts and tables are available in slightly different form and for additional values of α and β. See, for example, Dixon and Massey (1969), Owens (1962), or Odeh and Fox (1991).

Example.   Consider the experiment shown in Table 47.4. Suppose that another experiment is to be run and that we wish to determine beforehand how many briquettes to test using each method in

$$(3) = \frac{\Sigma\,(a+b)^2}{2} \qquad (7) = \frac{\Sigma\,(a+b+c+d)^2}{4} \qquad (11) = \frac{\Sigma\,(a+b+c+d+e+f)^2}{6}$$

$$(4) = \Sigma c^2 \qquad (8) = \Sigma e^2 \qquad CF = \frac{(\text{Grand Total})^2}{\text{Total No. of Tests}}$$

FIGURE 47.7 Staggered nested designs for three, four, five, and six factors. (*Reprinted with permission from Bainbridge 1965.*)

order to achieve a certain discrimination between the means for the three methods. If the statistical test is to be done at the $\alpha = 0.01$ level and if we want the probability of detecting the postulated differences to be at least 0.8, we can use Appendix II, Table DD. Assume $\sigma^2 = 545$, an estimate of the variance determined from the previous experiment. Suppose the following differences between the means are considered practically important:

$$\delta_1 = \eta_1 - \eta = -30$$

$$\delta_2 = \eta_2 - \eta = +20$$

$$\delta_3 = \eta_3 - \eta = +10$$

(Obviously, many different values for the δ's will yield the same value for $\Sigma\delta^2$ and therefore the same ϕ^2.)

The δ's chosen should be meaningful for each experimental situation. Here we have postulated three particular differences; in other situations the pattern of the differences might take on special meanings. For example, if the groups were increasing levels of a quantitative variable such as temperature, a meaningful pattern for the δ's might be a constant change in mean from one level to the next higher one. (Remember that the δ_i's must sum to zero.)

$$\phi^2 = \frac{n\Sigma\delta_i^2}{k\sigma^2}$$

$$\phi^2 = \frac{n(1400)}{3(545)} = \frac{1400n}{1635} = 0.86n$$

$$DF_1 = k - 1 = 3 - 1 = 2$$

$$DF_2 = k(n - 1) = 3n - 3$$

Using Appendix II, Table DD, we must find two values of n, one that gives ϕ^2 larger than required and one that gives a smaller value than required:

n	$DF_2 = 3n - 3$	Tabled ϕ^2	Desired $\phi^2 = 0.86n$
7	18	6.05	6.02
8	21	5.83	6.88

The "tabled ϕ^2" for $n = 8$ was obtained by linear interpolation. The solution lies between $n = 7$ and $n = 8$, and we take the larger n. Eight observations per group will give us an 80 percent chance of detecting the postulated differences when we do an F test at the $\alpha = 0.01$ level.

This method may be used for multifactor experiments provided the proper values for DF_1 and DF_2 are used. It is used when the purpose of the experiment is to compare group averages, and it works for any number of groups provided the number of observations per group is large enough. In this case and in the case described below, equal numbers of observations should be taken in each group.

For another kind of experiment, in which the purpose is to compare the between-group variance with the within-group variance (see discussion of Model II, Random Effects Model, under One-Way Analysis of Variance—Models), a *minimum* number of *groups* is required to achieve desired discrimination in terms of the relative variability. For example, see Table 47.17, where α and β are the risks of the two kinds of error, δ_0 is an "acceptably small" value of the ratio σ_b/σ_w (large enough to achieve a significant result), and δ_1 is an unacceptably large value for σ_b/σ_w.

TABLE 47.17 Minimum Number of Groups—Random Effects Model

$\alpha = \beta = 0.05$		$\alpha = \beta = 0.01$	
δ_1/δ_0	Minimum number of groups	δ_1/δ_0	Minimum number of groups
1.5	35	1.5	68
2.0	14	2.0	25
2.5	9	2.5	16
3.0	7	3.0	12

Useful discussions on determining the number of observations are given in the texts by Cochran and Cox (1957), Cox (1958), and Odeh and Fox (1991). Extensive tables are given in the papers by Kastenbaum, Hoel, and Bowman (1970).

FACTORIAL EXPERIMENTS—GENERAL

Factorial designs are most frequently employed in engineering and manufacturing experiments. In a factorial experiment several factors are controlled at two or more levels, and their effects upon some response are investigated. The experimental plan consists of taking an observation at each of all possible combinations of levels that can be formed from the different factors. Each different combination of factor levels is called a "treatment combination."

Suppose that an experimenter is interested in investigating the effect of two factors, amperage (current) level and force, upon the response y, the measured resistivity of silicon wafers. In the past, one common experimental approach has been the so-called one-factor-at-a-time approach. This experimental strategy studies the effect of first varying amperage levels at some constant force and then applying different force levels at some constant level of amperage. The two factors would thus be varied one at a time with all other conceivable factors held as constant as possible. The results of such an experiment are fragmentary in the sense that we learn about the effect of different amperage levels only at one force level and the effect of different force levels at only one amperage level. The effects of one factor are conditional on the chosen level of the second factor. The measured resistivity of the wafer at different current levels may, of course, be different when a different force level has been chosen. Similarly, any observed relation of resistivity to force level might be quite different at other amperage levels. In statistical language, there may be an "interaction effect" between the two factors over the range of interest, and the one-at-a-time procedure does not enable the experimenter to detect the interaction.

In a factorial experiment, the levels of each factor are chosen, and a measurement is made at each of all possible combinations of levels of the factors. Suppose that five levels of amperage and four levels of force are chosen. There would thus be 20 possible combinations of amperage and force, and the factorial experiment would consist of 20 trials. In this example, the term "level" is used in connection with quantitative factors, but the same term is also used when the factors are qualitative.

In the analysis of factorial experiments, one speaks of "main effects" and "interaction effects" (or simply "interactions"). Estimated main effects of a given factor are always functions of the average yield response at the various levels of the factor. When a factor has two levels, the estimated main effect is the difference between the average responses at the two levels, i.e., the averages computed over all levels of the other factors. In the case in which the factor has more than two levels, there are several main effect components (linear, quadratic, cubic, etc.), the number of estimable main effect components being one less than the number of levels. Other comparisons, called treatment "contrasts," are possible. If the difference in the expected response between two levels of factor A remains constant over the levels of factor B (except for experimental error), there is no interaction between

A and *B*; that is, the *AB* interaction is zero. Figure 47.8 shows two examples of response, or yield, curves; one example shows the presence of an interaction and the other shows no interaction. If there are two levels each of the factors *A* and *B*, then the *AB* interaction (neglecting experimental error) is the difference in the average yields of *A* at the second level of *B* minus the difference in the average yields of *A* at the first level of *B*. If there are more than two levels of either *A* or *B*, then the *AB* interaction can be composed of more than one component. If we have *a* levels of the factor *A* and *b* levels of the factor *B*, then the *AB* interaction has $(a - 1)(b - 1)$ independent components. A two-factor interaction (e.g., *AB*) is also called a "second-order" effect or "coupled" effect.

For factorial experiments with three or more factors, interactions can also be defined. For example, the *ABC* interaction is the interaction between the factor *C* and the *AB* interaction (or, equivalently, between the factor *B* and the *AC* interaction or between *A* and the *BC* interaction). A three-factor interaction (e.g., *ABC*) is a "third-order" effect.

FACTORIAL EXPERIMENT WITH TWO FACTORS

A two-factor experiment is the simplest kind of multifactor experiment; i.e., all possible combinations of the levels of the two factors are run. For example, measurements of the response resistivity of a silicon wafer are usually made at a standard amperage level while using 150 g of force. Let us consider an investigation in progress to see what happens when other values of force and amperage are employed. Four values of force are to be investigated (25, 50, 100, 150 g), along with five levels of amperage (levels 1, 2, 3, 4, and 5, where level 3 is the standard level). An experimental trial is made at each of the $4 \times 5 = 20$ possible combinations. The data can be displayed in a two-way array, as in Table 47.18. This is an unreplicated two-factor multilevel factorial experiment. Some textbooks will describe it as having two "crossed" factors.

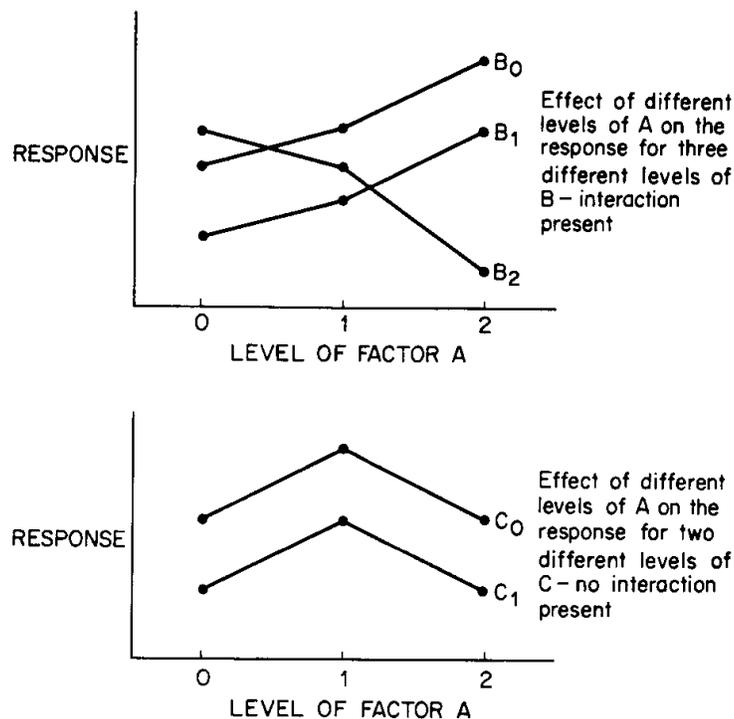
Analysis.   The data for this 4×5 factorial are displayed in Table 47.18. The first stage of the analysis is to compute, plot, and review both the column and row averages shown in Table 47.19.


FIGURE 47.8   Response curves showing presence or absence of interaction.

TABLE 47.18 Resistivity Measurements

Force, g	Current level 1	2	3	4	5	Row totals R_i
25	11.84	11.83	11.84	11.81	11.96	$R_1 = 59.28$

100	11.77	11.80	11.80	11.81	11.88	$R_3 = 59.06$
150	11.79	11.80	11.80	11.80	11.87	$R_4 = 59.06$
Column totals C_j	47.24	47.31	47.32	47.29	47.61	$T = 236.77$

TABLE 47.19 Table of Averages and Effects

Row number	Row average	Row effect
1	11.8560	0.0175
2	11.8740	0.0355
3	11.8120	−0.0265
4	11.8120	−0.0265

Column number	Column average	Column effect
1	11.8100	−0.0285
2	11.8275	−0.0110
3	11.8300	−0.0085
4	11.8225	−0.0160
5	11.9025	0.0640

Plots of the response versus the factor levels are always useful; in this case they would point up the noticeably higher resistivity values at amperage level 5 and the apparent changes in the resistivity with increasing force, particularly at the outer values of amperage. When the factors are quantitative and the levels equally spaced, there are simple methods to check on various types of trends (linear, quadratic, etc.) in the response measurements as a function of varying levels of a factor (see Hicks 1982).

The analysis of variance can be used to test two hypotheses: (1) the mean resistivity at all levels of force is the same and (2) the mean resistivity at all levels of amperage is the same.

The construction of the analysis of variance table would proceed as follows:

$$r = \text{number of rows} = 4$$

$$c = \text{number of columns} = 5$$

$$T = \text{grand total} = \sum_j C_j = \sum_i R_i = 236.77$$

$$N = \text{total number of observations} = r \times c = 20$$

$$C = \text{the correction factor} = \frac{T^2}{N} = 2803.001645$$

$$\text{SSR} = \text{row sum of squares} = \frac{\sum_i R_i^2}{c} - C = 0.014855$$

$$\text{SSC} = \text{column sum of squares} = \frac{\sum\limits_{j} C_j^2}{r} - C = 0.021430$$

$$\text{TSS} = \text{total corrected sum of squares}$$

$$= (\text{all observations squared}) - C$$

$$= 2803.043500 - 2803.001645 = 0.041855$$

$$\text{SSE} = \text{error (or residual) sum of squares}$$

$$= \text{TSS} - \text{SSR} - \text{SSC} = 0.005570$$

The analysis of variance table for this (unreplicated) two-factor crossed factorial is shown in Table 47.20. Tests of hypotheses that no treatment effects exist are now possible. For rows conclude that statistically significant effects exist between rows if $F =$ (row mean square)/(error mean square) is greater than $F_{1-\alpha}$ for $(r-1)$ and $(r-1)(c-1)$ degrees of freedom (from Appendix II, Table K). Similarly, for columns conclude that statistically significant effects exist if $F =$ (column mean square)/(error mean square) is greater than the tabulated value of F for $(c-1)$ and $(r-1)(c-1)$ degrees of freedom. In this example, both F tests reject the hypothesis that no effects exist.

The analysis of variance table and its associated tests of hypotheses are only one part of the analysis of data from a factorial design. The model postulated for the data assumes that the force and amperage factor effects are additive. Thus there can be no interactions; that is, the effects of force upon resistivity remain unchanged whatever the levels of the second factor. One way to check this assumption is to compute Tukey's one-degree-of-freedom test for nonadditivity (see Snedecor and Cochran 1967 or Box, Hunter, and Hunter 1978). The test for nonadditivity here proved to be nonsignificant.

Table 47.19 has been extended to include the estimated row and column *effects* (an estimated row effect is the row average minus the grand average; an estimated column effect is the column average minus grand average). The row and column effects can then be used to make a two-way table of "residuals" in which the residual for the cell in the ith row and jth column is equal to the observation in that cell minus the sum of the grand average, the ith row effect, and the jth column effect. The table of residuals, Table 47.21, is examined for individual large values (indicating a possibly erroneous observation) and for unusual patterns in sign and size (indicating possible interaction effects). The residuals should be plotted in the time order in which the treatment combinations were run; any indication of trends indicative of other factors disturbing the response. The residuals can also be plotted on normal probability paper as a check on the normality assumption.

The discussion thus far assumes that only one determination per cell was made. To obtain a truly valid estimate of the error variance from this experiment, the cell's observations must be replicated. When experiments are replicated (ideally with each cell containing the same number of observations), it is useful to have a table similar to Table 47.18, where now in each cell both the average and the estimate of variance are recorded. Homogeneity of variance tests may be made (see Snedecor and Cochran 1967; Duncan 1974; Dyer and Keating 1980), although it is well to remember that such

TABLE 47.20   Analysis of Variance of Resistivity Measurements Given in Table 47.18

TABLE 47.21 Residuals, Row and Column Effects, Grand Average

Force, g	Amperage, A					Force effects
	Level 1	Level 2	Level 3	Level 4	Level 5	
25	0.0125	−0.0150	−0.0075	−0.0300	0.0400	0.0175
50	−0.0055	0.0170	0.0145	0.0120	−0.0380	0.0355
100	−0.0135	−0.0010	−0.0035	0.0140	0.0040	−0.0265
150	0.0065	−0.0010	−0.0035	0.0040	−0.0060	−0.0265
Current effects	−0.0285	−0.0110	−0.0085	−0.0160	0.0640	11. 8385 $= \bar{y}$

tests require near exact normality if they are to be useful. The analysis of variance assumes these variance estimates to be homogeneous and pools them.

A plot of each cell average versus cell estimate of variance (or standard deviation) is often revealing. Individual outlying points or a pattern of dependence of variability on average value should be looked for. (In the latter case, the need for a transformation of the data should be considered; see Box, Hunter, and Hunter 1978.)

In this experiment, replicate measurements were made in each cell of the table since the investigator was interested in finding out about possible interactions and whether the variance of the resistivity measurements would be constant at the extreme values of the factors. In this original experiment, no significant interactions were found, nor was the variance nonhomogeneous.

The analysis of variance of a replicated two-factor crossed factorial design experiment is easily modified from that of the unreplicated one. The procedure is to calculate the following quantities and insert them in Table 47.22:

$$r = \text{number of rows}$$

$$c = \text{number of columns}$$

$$k = \text{number of determinations per cell}$$

$$N = \text{total number of observations} = krc$$

$$T = \text{grand total}$$

$$C = T^2/N$$

$$\text{SSR} = \text{row sum of squares} = \frac{\sum_i R_i^2}{kc} - C$$

$$\text{SSC} = \text{column sum of squares} = \frac{\sum_j C_j^2}{kr} - C$$

$$\text{SSI} = \text{Interaction sum of squares}$$

$$= \frac{\sum_{ij} (\text{cell}_{ij} \text{ total})^2}{k} - \text{SSR} - \text{SSC} - C$$

$$\text{TSS} = \text{total sum of squares} = \Sigma y^2 - C$$

$$\text{SSE} = \text{error sum of squares} = \text{TSS} - \text{SSR} - \text{SSC} - \text{SSI}$$

TABLE 47.22   Analysis of Variance Table for Two-Factor Factorial (k Replicates per Cell)

Source of variation	Sum of squares	Degrees of freedom	Mean square		F
Rows	SSR	$r - 1$	$SSR/(r - 1)$	$= MSR$	MSR/MSE
Columns	SSC	$c - 1$	$SSR/(c - 1)$	$= MSC$	MSC/MSE
Interaction	SSI	$(r - 1)(c - 1)$	$SSI/(r - 1)(c - 1)$	$= MSI$	MSI/MSE
Error	SSE	$rc(k - 1)$	$SSE/rc(k - 1)$	$= MSE$	
Total	SST	$krc - 1$			

The above instructions will fill in all the cells in the "Sum of squares" column of the analysis of variance table (Table 47.22), but the similarities to Table 47.5 should be noted. The value of the mean square error (MSE) in Table 47.22 can also be obtained by pooling the ($r \times c$) estimates of the within-cell variance.

SPLIT-PLOT FACTORIAL EXPERIMENTS

In general a factorial design is a program of experiments consisting of all possible combinations of levels (versions) of k different factors (variables). There can be m_1 levels of factor 1 combined with m_2 levels of factor 2,…, combined with m_k levels of factor k to give a total of $N = m_1 \times m_2 \times … \times m_k$ experimental trials.

Care must be taken that the N experimental trials composing a factorial design are all run in a random sequence. Consider for example an experimental program for studying temperature and pressure each at three levels along with four different versions of catalyst, that is, a $3 \times 3 \times 4$ factorial design in $N = 36$ trials. To be a standard factorial all 36 runs would be performed in random order. However, it is very likely that the experimental design will be run in a split-plot (nested) arrangement; that is, the nine temperature-pressure runs will be randomly performed for each catalyst separately. The analysis of a split-plot factorial design, most particularly the computation of correct confidence intervals and tests of hypotheses concerning treatment means, usually requires the attention of a professional statistician. In this handbook only fully randomized designs are discussed.

Split-plot designs are alike in structure to the "nested" designs discussed earlier. Commonly, the designs are called "split-plot" when the objective is the study of treatment means and called "nested" when the objective of the experimenter is to estimate components of variance. Statisticians, and most computer software programs, distinguish between these two forms of experimental design with their different objectives. The factorial split-plot arrangement requires a "Type I" analysis of variance while that for the nested designs requires a "Type II." Occasionally, experimental designs are employed in which estimates of both means and components of variance are required. The subtleties of analysis become important and one should seek the advice of a professional statistician.

FACTORIAL EXPERIMENTS WITH k FACTORS (EACH FACTOR AT TWO LEVELS)

The 2^k factorial designs have widespread industrial applicability. The designs permit the separate estimation of the individual effects and the interaction effects of the k factors in an experimental program in which all k factors are varied simultaneously in a carefully organized pattern of trials.

Symbols.   A factorial experiment with k factors, each at two levels, is known as a 2^k factorial experiment. The experiment consists of 2^k trials, one trial at each combination of levels of the fac-

TABLE 47.23 Different Notations for the 2^3 Factorial Design

Run no.	Geometric notation			Alternative notation			Japanese notation			Classical notation		
	A	B	C	A	B	C	A	B	C	A	B	C
1	$-$	$-$	$-$	0	0	0	1	1	1	1		
2	$+$	$-$	$-$	1	0	0	2	1	1	a		
3	$-$	$+$	$-$	0	1	0	1	2	1	b		
4	$+$	$+$	$-$	1	1	0	2	2	1	ab		
5	$-$	$-$	$+$	0	0	1	1	1	2	c		
6	$+$	$-$	$+$	1	0	1	2	1	2	ac		
7	$-$	$+$	$+$	0	1	1	1	2	2	bc		
8	$+$	$+$	$+$	1	1	1	2	2	2	abc		

tors. To identify the individual trials, different notations are used, as illustrated in Table 47.23. One convention is to label each factor by a letter (or numeral) and then to denote the two levels (versions) of each factor by a plus ($+$) and a minus ($-$) sign. Commonly the minus sign refers to the lower level, the standard conditions, or the absence of the factor. Thus, if there are three factors labeled A, B, and C, the eight trials comprising the 2^3 factorial design are as shown in Table 47.23. The ($+$, $-$) notation is sometimes referred to as "geometric." For example, the eight ($\pm$, $\pm$, $\pm$) factor settings for the 2^3 design may be interpreted as giving the (± 1, ± 1, ± 1) coordinates of the eight vertices of a cube. Alternative notations are to employ 0 and 1, respectively, or, following the Japanese tradition earlier established by Taguchi, 1 and 2 for the two versions of each factor. The classical convention is to denote the two versions of each lettered factor by the presence and absence of its corresponding lowercase letter, as is also illustrated in Table 47.23. Here the trial in which all factors are at their "low" level is denoted by a 1. The sequence of trials in Table 47.23 is written in standard or "Yates" order. The trials would, of course, be run in random order.

Example.   The data in Table 47.24 are taken from a larger experiment on fire-retardant treatments for fabrics. The excerpted data are intended only to provide an example for demonstrating the technique of analysis. The experiment has four factors, each at two levels, i.e., it is a 2^4 factorial. Note that all factors are qualitative in this experiment. The experimental factors and levels (versions) are

Factors	Levels
A—Fabric	$-$ Sateen
	$+$ Monk's cloth
B—Treatment	$-$ Treatment x
	$+$ Treatment y
C—Laundering	$-$ Before laundering
	$+$ After one laundering
D—Direction	$-$ Warp
	$+$ Fill

The observations reported in Table 47.24 are inches burned, measured on a standard-sized sample after a flame test. For convenience, alternative design notations representing the treatment combinations appear beside the resulting observation.

Estimation of Main Effects and Interactions.   Obtaining the estimates of main effects and interactions from a 2^k factorial design (and 2^{k-p} fractional factorial designs) is available on

TABLE 47.24 Results of Flame Test of Fire-Retardant Treatments (a 2^4 Factorial Experiment)

almost all design of experiments software programs. The computations are simple to do by hand but become quickly tedious and hence ideal work for a computer (see Bisgaard 1993a). Further, the associated analysis of variance table is similarly easy and hence widely available. Nevertheless, we include here a description of the hand computations for the interested reader, since they are also easily done on a spread sheet.

The 2^k factorial designs permit the estimation of all k main effects (first-order effects), all $k(k − 1)/2$ two-factor interactions, all $k(k − 1)(k − 2)/3!$ three-factor interactions, etc. Each estimated effect is a statistic of the form $\bar{y}_+ − \bar{y}_-$; that is, it is expressed by the difference between two averages, each containing $2^{k−1}$ observations. For a 2^4 design the analyst would thus be able to estimate, in addition to the grand average, four main effects, six two-factor interactions, four three-factor interactions, and a single four-factor interaction, giving a total of 16 statistics. Remarkably, all these statistics are "clear" (orthogonal) of one another; that is, the magnitudes and signs of each statistic are in no manner influenced by the magnitude and sign of any other.

The question as to which observations go into which average for each estimated effect is determined from the k columns of + and − signs that together form the experimental design (the design column "vectors"). Additional column vectors of + and − signs are then constructed for each interaction, as illustrated in Table 47.25. For example, the vector of signs labeled AB is obtained by algebraically multiplying, for each row, the + or − sign found in column A by the + or − sign found in column B.

Table 47.25 also contains the column of observations. To estimate the AB interaction effect, all the observations carrying a + sign in the AB column are placed in $\bar{y}_+$ and those with a minus sign in $\bar{y}_-$. The estimated AB interaction effect ($\bar{y}_+ − \bar{y}_-$) is therefore:

$$\frac{4.2 + 2.9 + \ldots + 2.3}{8} − \frac{3.1 + 4.5 + \ldots + 5.0}{8} = \frac{27.0}{8} − \frac{30.5}{8} = \frac{−3.5}{8} = −0.4375$$

Yates' Algorithm. An alternative and more rapid method for obtaining estimates of main effects and interactions for two-level factorials, called "Yates' algorithm," applies to all two-level factorials and fractional factorials. The first step in Yates' algorithm is to list the observed data in Yates order, as illustrated in Table 47.26. The generation of the values in Table 47.26 proceeds as follows:

1. A two-level factorial with r replicates contains $N = r2^k$ runs. The associated Yates' algorithm table will have $k + 2$ columns, the first of which contains the experimental design, i.e., the 2^k treatment combinations in standard (Yates) order.

2. In column 2, enter the observed yield corresponding to each treatment combination listed in column 1. If the design is replicated, enter the total for each treatment combination.

3. In the top half of column 3 enter, in order, the sums of consecutive *pairs,* of entries in column 2, i.e., the first plus the second, the third plus the fourth, and so on. In the bottom half of column 3 enter, in order, the differences between the same consecutive pairs of entries, i.e., second entry minus first entry, fourth entry minus third entry, etc. Change the sign of the top (first of the pair) and algebraically add.

4. Obtain columns 4, 5, ..., $k+2$, in the same manner as column 3, i.e., by obtaining in each case the sums and differences of the pairs in the preceding column in the manner described in step 3.

5. The entries in the last column (column $k + 2$) are labeled $g(T)$, $g(A)$, $g(B)$, $g(AB)$, etc. The letters in the parentheses correspond to the + signs in the geometric notation. The first value $g(T)$ is divided by N to give the grand average. Estimates of the remaining main effects and interactions are obtained by dividing each $g(...)$ by $N/2$. (*Note:* The remaining steps of this procedure are checks on the computations.)

6. The sum of all the individual responses (column 2) should equal the total given in the first entry of column 6, i.e., $g(T)$ must equal the grand total.

7. The sum of the squares of the quantities in column 2 should equal the sum of the squares of the entries in column $(k + 2)$ divided by 2^k.

8. Each $g(...)$ in the last column equals the sum of observations carrying a + sign minus the sum of observations carrying a − sign when the columns of signs displayed in Table 47.25 are employed.

Sum of squares 219.15   3506.40/16=219.15

The corresponding estimated effects are given by $g(\ldots)/(N/2)$. The algorithm is best explained with an example.

Example.   The example shown in Table 47.24 has 2^4 runs. Thus the associated Yates algorithm will have six columns, as shown in Table 47.26. The grand average is $\bar{y} = 57.5/16 = 3.5938$. The next entry in column 6 is $g(A) = -12.9$. The estimated main effect of factor A is then

$$A \text{ effect} = \frac{-12.9}{8} = -1.6125$$

The estimate of the main effect of A can be checked by taking the average of the responses recorded on the high $(+)$ side of the factor A and subtracting the average response on the low $(-)$ side to give $\bar{y}_+ - \bar{y}_- = 22.3/8 - 35.2/8 = -12.9/8 = -1.6125$.

The remaining effects are similarly computed. Thus, the estimated AD interaction effect $= -2.5/8 = -0.3125$.

The following steps are checks on the computations in Table 47.26:

6. The sum of column 2 equals $g(T)$.

7. The sum of squares of the entries in column 2 equals 219.5. The sum of squares in column 6 divided by $2^4 = 3506.4/16 = 219.15$.

Testing Main Effects and Interactions.   The grand average and 15 estimated effects obtained from the 2^4 design appear in the right-hand column of Table 47.26. The standard error (SE) of each estimated effect is given by

$$SE(\text{effect}) = SE(\bar{y}_+ - \bar{y}_-) = 2s\backslash\sqrt{N}$$

where N=total number of observations. The $100(1-\alpha)$ percent confidence limits are given by

$$\text{Effect} \pm t_{\alpha/2}[SE(\text{effect})]$$

Needed is s^2, the estimate of the experimental error variance σ^2. An estimate of σ^2 can always be obtained from truly replicated trials, each set of replicates providing a single estimate of variance and then all the estimates pooled. However, in this example each trial was performed only once and some alternative procedure for securing an estimate of σ^2 is needed. We turn now to the analysis of variance table for the 2^k factorial design.

The Analysis of Variance for the 2^k Factorial.   It is a rare design of experiments computer software program that omits the computations for a factorial design analysis of variance table. The computations are easy, though lengthy, when done by hand. We use our 2^4 example to demonstrate these computations for the interested reader. They are easily done with a computer spread sheet program.

The total variability of the observations is measured by $\Sigma(y_i - \bar{y})^2 = \Sigma y_i^2 - (\Sigma y_i)^2/N$, $i = 1, 2, \ldots, N$. In this example $\Sigma(y_i - \bar{y})^2 = 219.15 - (57.5)^2/16 = 12.51$. If this variability could be completely assignable to random errors, then the estimate of the variance σ^2 is given by $s^2 = \Sigma(y_i - \bar{y})^2/(N-1)$ with $(N - 1)$ degrees of freedom. However, some of the movement amongst the observation y_i is likely caused by the influences of the controlled factors which make up the experimental design. The contribution of each factorial effect is given by its "sum of squares" $= N(\text{effect})^2/4$, labeled SSq, with one degree of freedom, as illustrated in Table 47.27.

The residual sum of squares represents variability remaining after all assignable causes have been subtracted. In Table 47.27 all 15 degrees of freedom with their associated SSq "sum of squares" are present, and thus the residual sum of squares and degrees of freedom are both zero.

To estimate the variance σ^2 in this unreplicated factorial design, we must declare some of the estimated effects to be manifestations of noise, i.e., not real effects and likely equal to zero. The most

TABLE 47.27 Analysis of Variance Table: 2^4 Factorial

Source of variation	SSq	DF
Total $= \Sigma(y_i - \bar{y})^2$	12.509375	15
A effect $= 16\,(-1.6125)^2/4$	10.400625	1
B effect $= 16\,(+0.3125)^2/4$	0.390625	1
C effect $= 16\,(-0.1125)^2/4$	0.050625	1
D effect $= 16\,(-0.1125)^2/4$	0.050625	1
AB effect $= 16\,(-0.4375)^2/4$	0.765625	1
AC effect $= 16\,(-0.0625)^2/4$	0.015625	1
AD effect $= 16\,(-0.3125)^2/4$	0.390625	1
BC effect $= 16\,(+0.1625)^2/4$	0.105625	1
BD effect $= 16\,(+0.0125)^2/4$	0.000625	1
CD effect $= 16\,(-0.0625)^2/4$	0.015625	1
ABC effect $= 16\,(+0.0625)^2/4$	0.015625	1
ABD effect $= 16\,(-0.2375)^2/4$	0.225625	1
ACD effect $= 16\,(-0.1125)^2/4$	0.050625	1
BCD effect $= 16\,(-0.0875)^2/4$	0.030625	1
$ABCD$ effect $= 16\,(+0.0125)^2/4$	0.000625	1
Residual sum of squares	0	0

reasonable collection of such effects is the three and four factor interactions. We thus sum their sum of squares and degrees of freedom and compose an estimate of variance $s^2 = 0.323125/5 = 0.064625$ with $\nu = 5$ degrees of freedom. The estimated standard deviation is $s = 0.254$. The standard error of an effect is then SE(effect) $= 2s/\sqrt{N} = 0.127$, and the $100(1 - \alpha)$ percent confidence limits for an effect are

$$\pm t_{\nu\alpha/2}\text{SE(effect)} = \pm\, t_{5,0.025}(0.127) = \pm 2.571(0.127) = \pm 0.326$$

Thus, an (approximate) 95 percent confidence interval for all remaining effects is given by effect $\pm\ 0.326$. Any estimated effect whose confidence interval "effect $\pm\ 0.3265$" includes zero may be declared not statistically significant. Of the estimated effects in this example only A and AB can be declared statistically significant and the effects B and AD nearly so. Computer software programs will perform analysis of variance F tests (or equivalent t tests) and compute their probabilities. These tests provide identical inferences. The analyst is advised to look at the interval statements rather than try to judge the differences between small probabilities. It is a rare individual who can really appreciate the true meaning of probabilities such as 0.07 versus 0.035.

A less formal analysis is to plot the absolute values of the estimated effects into a Pareto diagram. Here a Pareto diagram of the estimated effects indicates that factors $A, AB, AD,$ and B are the "vital few." A Pareto diagram will identify "significant" effects almost as well as a collection of confidence intervals or a set of F tests in an ANOVA table (Hunter, W.G. 1977; Lenth 1989; Schmidt and Launsby 1991).

Collapsing the 2^k Factorials. Collapsing 2^k designs into lower "dimensionality" is an important strategy in the application of factorial designs. In practice it is very unlikely that all the possible main effects and interactions are real when the number of factors $k \geq 3$. In fact, particularly in screening situations where many factors are being co-studied, several individual factors may have no detectable main effect or interaction influences upon a response. Factorial designs for k modestly large are thus said to have "hidden replication," that is, an excess of degrees of freedom over and

TABLE 47.28   Collapsed 2^4 Giving a Replicated 2^3

A B D	Responses	Difference	
− − −	4.2, 3.9	0.3	
+ − −	3.1, 2.8	0.3	
− + −	4.5, 4.6	−0.1	
+ + −	2.9, 3.2	−0.3	$s^2 = \Sigma d^2/2n_d$
− − +	4.0, 4.0	0	
+ − +	3.0, 2.5	0.5	$s^2 = 0.57/2(8)$
− + +	5.0, 5.0	0	$= 0.03560$
+ + +	2.5, 2.3	0.2	

beyond those necessary to explain the response. Thus, when a factorial design is unreplicated, many estimated effects and their associated sums of squares and degrees of freedom may become available to employ in the estimate of variance. In this 2^4 example it appears that factor C makes no large contribution to the response, either as a main effect or as an interaction. The factor's effects are so small over its region of exploration as to be indistinguishable from noise. The 2^4 factorial now collapses into a replicated 2^3 design in the effective factors A, B, and D. The collapsed design is displayed in Table 47.28.

The estimated effects for factors A, B, and D remain unchanged. An estimate of variance can now be obtained from the repeated runs. When there are pairs of observations, a shortcut computation for s^2 is given by:

$$s^2 = \frac{\sum_i d_i^2}{2n_d}$$

where the d_i are the differences between the $i = 1, 2, \ldots, d$ pairs of observations and n_d is the number of differences. This estimate of variance has $\nu = n_d$ degrees of freedom. Thus, for this example:

$$s^2 = \frac{0.57}{(2)(8)} = 0.0356$$

with $\nu = 8$ degrees of freedom and $s = 0.1887$. The standard error of each effect (excluding all those carrying the label C, of course), is

$$SE(\text{effect}) = \frac{2s}{\sqrt{N}} = \frac{2(0.1887)}{\sqrt{16}} = 0.0943$$

Using t with $\nu = 8$ degrees of freedom, the 95 percent confidence limits for the estimated effects are given by

$$(t_{\alpha/2})SE(\text{effect}) = \pm 2.306(0.0943) = \pm 0.2175$$

Half-Normal Plots.   Daniel (1959) proposed a simple and effective technique for use in the interpretation of data from the two-level factorial designs. This technique consists of plotting the absolute values of the estimated effects on normal probability paper (dropping the effect's signs), leading to "half-normal" plots. Effects indistinguishable from noise will fall along a straight line; effects that are statistically significant will fall well off the line. Full-normal plots consisting of the estimated effects *with* their signs are also possible; see Box, Hunter, and Hunter (1978). Normal probability plot routines are found in most statistical software programs. Half-normal plots are a particularly useful diagnostic tool offering evidence of wild observations and other conditions

that violate the assumptions of homogeneous variance, normality, and randomization. "Guardrails" can be used to judge the divergence of the plotted effects from the line; see Zahn (1975) and Taylor (1994). The Lilliefors (1967) test for normality can be helpful in judging all normal plots. For this and other nonparametric methods see Iman (1994).

EVOP: EVOLUTIONARY OPERATION

An important application of experimental design in the production environment was proposed by Box (1957). Essentially, a simple experimental design, run repeatedly, provides a routine of small systematic changes in a production process. The objective is to force the process to produce information about itself while simultaneously producing product to standards. Only small changes in the process factors are allowed, and the consequences of these changes must be detected in the presence of the many natural variabilities that surround the process. The repetition of an experimental design, commonly a 2^2 factorial with center point, permits the blocking of many of the disturbances that commonly influence production. Through the process of replication, the design provides steadily improving estimates of the main effects and interactions of the studied factors.

Response Surface.   A response surface (see Box 1954) is a graphical representation of the connection between important independent variables, controlled factors, and a dependent variable. (An independent variable is a factor that is, or conceivably could be, controlled. Examples are flow rate and temperature. The value of a dependent variable is the result of the settings of one or more independent variables.) Most processes have several dependent variables, such as yield, impurities, and pounds per hour of a byproduct. These responses are usually smooth and may be graduated approximately by simple contours such as a family of lines or arcs. We ordinarily work on processes that have unknown response surfaces—if they were known, the work would not be necessary. See Response Surface Designs below.

A response surface for a process might look like the one in Figure 47.9, which shows the yield of a catalytic oxidation as a function of temperature and feed rate of hydrocarbon. If this information were known, the pounds per hour of product could be determined and better operating conditions selected for any desired production rate. The response surface is initially unknown, but improvement can be made if we only find out which way is up. Multiple regression can be used to approximate the response contours (see Section 44, under Multiple Regression).

EVOP Technique.   The problem, then, is to increase profit in an operating plant with minimum work and risk and without upsetting the plant. These are the steps:

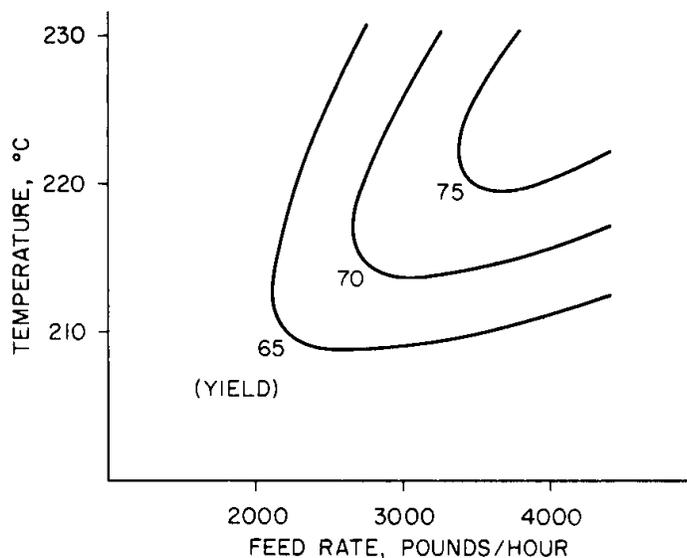
1. Survey company reports and open literature on the process. Study cost, yield, and production records.
2. Study this section on EVOP and preferably the definitive text (Box and Draper 1969).
3. Obtain agreement and support from production management. Organize a team and hold training sessions.
4. Select two or three controllable factors that are likely to influence the most important response.
5. Change these factors in repeated small steps according to a plan.
6. After the second repetition of the plan (Cycle 2) and each succeeding cycle, estimate the effects.
7. When one or more of the effects is significant, move to the indicated better operating conditions and start a new EVOP program, perhaps with new ranges or new factors.
8. After eight cycles, if no factor has been shown to be effective, change the ranges or select new variables (Box and Draper 1969).
9. Continue moving the midpoint of the EVOP plan and adjust the ranges as necessary.


FIGURE 47.9 Typical response surface: yield as a function of feed rate and temperature for a catalytic reactor.

10. When a maximum has been obtained, or the rate of gain is too slow, drop the current factors from the plan and run a new plan with different factors.

The following topics explain these steps in detail.

Literature Search. Sources of information include the process instructions, company reports, manufacturers' literature, patents, textbooks, and encyclopedias of technology. Do not neglect people. Company personnel, consultants, and operators can all contribute. Search for information on

1. Important independent variables

2. Test methods for intermediate and final results

3. Recommended procedures

4. Records of good and bad results and their causes

5. Long-term history of results; plant production rate and yield by week or month and similar data; effect of past changes in equipment and conditions

When information is contradictory, an EVOP program is an ideal strategy for resolving the conflict. Always consider the physical and chemical principles that apply.

The EVOP Design. EVOP uses planned runs that are repeated over and over (replicated). One plan in wide use is the two-level complete factorial. There are important reasons to maintain observations on a known set of conditions, called a "reference point." For simplicity in the present discussion, let this point be the center of the square formed by the vertices of the factorial.

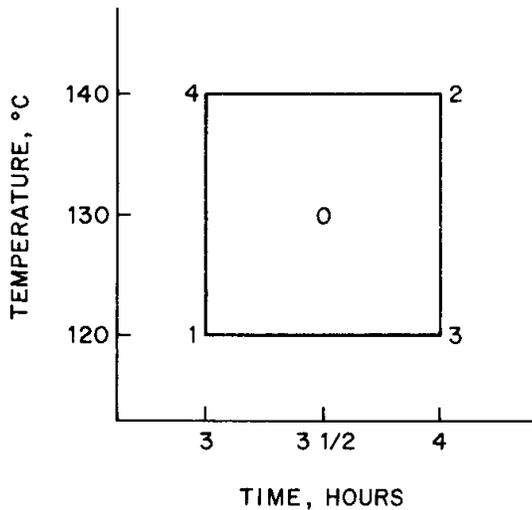
Example. This example shows coded data from an actual EVOP program (Barnett 1960). The problem involved a batch organic reaction, and after the steps above were followed, the two factors and their ranges were selected as shown in Figure 47.10. The response Y is a coded yield in pounds per batch and should be maximized. In this diagram, the reference run (batch) was made at 130°C for $3^{1}/_{2}$ h. The next batch was made at 120°C for 3 h, and so on. The first *cycle* contains five runs, one at each of the conditions. Samples were taken from each batch and analyses were obtained. If the process were continuous, it would be allowed to stabilize after each change of conditions.


FIGURE 47.10   An EVOP plan. Numbers are in run order; 0 is the reference run.

Warning: It is not unusual to have difficulty in obtaining a representative sample. Procedures and tests are discussed in Sections 44 and 46.

Effects can be estimated at the end of Cycle 1, but in the absence of repeated trials, no estimate of error variance is available. At the conclusion of Cycle 2 both estimated effects and error variance are possible. The estimated effects and their confidence intervals may be computed on a form such as Figure 47.11, which shows this example. The form helps reduce the work and minimizes mistakes. Instructions should be printed on the reverse side (see Figure 47.12).

The error term that puts the magnitude of effects into perspective is obtained from the range by use of factor K first derived by Box and Hunter (1959). The uncertainty in estimating the effects is stated as a confidence interval and the Change-in-mean effect (CIM) is calculated by comparing the results at the outer four corners with the result in the center. The use of this last information is discussed below.

A "phase" is defined as all the cycles that use the same settings of the same factors. The phase average shows the general level of the response and can be used to compare different phases.

The left part of the form is used to record data and estimate effects. It also has the scaled diagram of the phase. The right third is used to determine the error limits of effects and corner aver-

FIGURE 47.11   Calculations form at the end of Cycle 2. (*Modified from Barnett 1960.*)

Differences	Subtract new observations from old averages. Note the algebraic sign of the difference. (938 − 792 = 146)
New Sums	Add the new observations to the old sums. (938 + 792 = 1,730)
New Averages	Divide the new sums by *N*, the number of the cycle. (1730/2 = 865)
Calculation of Effects	(For example, the *A* effect)
	Write the new averages for operating conditions 2 and 3 opposite (C) and (D). Add these two to get the number in space (F). Carry out corresponding operations to get the number for space (G).
	The next operation is subtraction. If (F) is larger than (G), recopy (G) under (F) and subtract (G) from (F). If (G) is larger than (F), recopy (F) under (G) and subtract (F) from (G). In either case divide by 2 and the sign of quotient is shown on the form. (The A effect is +66.)
Change-in-mean effect	Copy (F) and (G) as shown and add these two. (A) is multiplied by 4. The next operation is subtraction as above. Divide by 5. (The Change-in-mean effect is +25.)
Average phase	Copy (H) and (A) from Change-in-mean box, add them, and divide by 5. (The phase mean is 890.)
Calculation of Standard Deviation	Range. The range is the algebraic difference between the most positive and most negative differences. The range is always positive. (The range of +146, −174, +221, +79, and −48 is 395.) The standard deviation is estimated by taking the range times *K*.
Constants	Read *K*, *L*, and *M* factors from the table.
Note:	The numerical illustrations apply to the data of Fig. 47.11.

FIGURE 47.12 Instructions for EVOP form.

ages. The error limits are called "2 S.E." for "two standard errors." The estimated effect ±2 S.E. covers the usual 95 percent confidence region. Caution should be exercised in claiming statistical significance until after two or three cycles.

For the present example, at the end of Cycle 2 the *A* effect (time) is estimated as 66 ± 166; it lies somewhere between −100 and +232. Thus, the true value of this effect could be negative, positive, or nil. The *B* (temperature) effect, however, is estimated to be 174 ± 166, or in the range of +8 to 340. Technically, it is likely to be a positive real effect. The interaction *AB* is small, and so is the change in mean. Since the confidence region for *B* is so close to zero and following the advice above to be cautious at Cycle 2, another cycle is run. Its results are shown in Figure 47.13.

After Cycle 3, the *B* effect (temperature) was declared statistically significant, since its likely values fall in the range of 169 ± 92, or +77 to +261. It does not appear that data from more cycles would change the conclusion that temperature should be increased to increase the response *y*.

When statistical significance is found for one factor but not for the other, *move* the plan in the desirable direction for the "discovered" important factor and increase the range for the second (nonsignificant) one. Possible old and new phases of an EVOP program are shown in Figure 47.14. When significance is found for both variables, the center of the plan is moved in both directions in proportion to the size of the effects. This is the direction of steepest ascent (see Determine Direction of Steepest Ascent below, under First-Order Strategy). Whenever the plan is changed, a new *phase* is started. During the second and later phases, the previous estimate of standard deviation is often used since it was obtained under the current operating method.

Moves.   To be conservative, as EVOP should be, moves are contiguous; i.e., one or more of the points in the old phase and new phase coincide. This limits the moves to those types shown in Figure 47.14.

There is nothing "magic" about drawing these plans as squares—1 h does not equal 20°C anyway. A particularly strong signal may justify a move to a plan that does not adjoin the previous one.

Change-in-Mean.   The Change-in-mean effect is the difference between the results at the center point and the average of the other four peripheral points. It is therefore a signal of curvature as shown

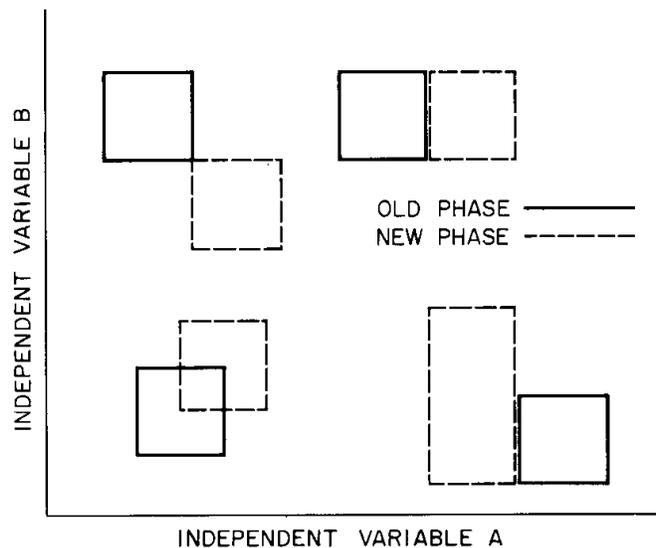
FIGURE 47.13 Calculation form after Cycle 3.


FIGURE 47.14 Possible relations of old phase and new phase.
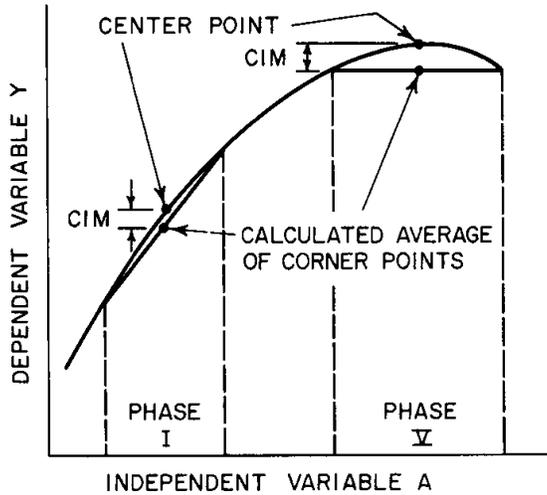

FIGURE 47.15 Cross section through a response surface. CIM indicates curvature.

in Figure 47.15. It is used in conjunction with the effects to indicate when a maximum (or a minimum) has been reached and to indicate the sensitivity of the response to changes in the independent factors. In the Taguchi literature the response would be termed "robust" to changes in the independent variable (Taguchi 1978). In rare cases it may happen that the first phase is located symmetrically about the maximum with respect to the two independent factors chosen. In this case the factors should be nonsignificant but the Change-in-mean may be significant.

Blocking. A process response ordinarily changes slightly with time, reflecting changes in sources of raw material, changes in air temperature from day to night, and so on.

Runs made close together in time are expected to be more nearly alike than those over a longer interval. Blocking is used to minimize the trouble caused by temporal changes of this type. For the EVOP calculations shown here, a block is one cycle. Changes in average level that occur between cycles are completely eliminated from the estimated effects, as can be seen by adding a constant to the five runs of Cycle 3, and recalculating the effects. (The phase average is changed, of course.)

Multiple Dependent Responses.   So far the explanation has been in terms of a single dependent response. This is rather unrealistic, except for the profit variable. Most processes have several dependent responses that must be measured or calculated, such as yield, production rate, percent impurity, or pounds of byproduct. A calculation sheet is made for each dependent response, and statistical significance may be noted on one dependent sheet but not on others. In this case, it may be well to run another cycle or two to get more information on the other dependent responses before a move is made.

The most troublesome case occurs when the indicated directions for improvement of two responses (say production rate and percent impurity) do not agree. The EVOP program has brought information from the production process. Decisions as to what to do next now rest upon information supplied by the EVOP program coupled with information to be supplied by the subject matter experts.

BLOCKING THE 2^k FACTORIALS

Experimenters often find difficulty in maintaining a homogeneous experimental environment for all the experiments required in a 2^k factorial. For example, an experimenter might need 2 days to run the eight trials required in a 2^3 factorial. The question is how to choose the trials to be run each day so as not to disturb the estimates of the major effects of the three factors, i.e., how to "block" the design into two blocks of four runs each. Here blocking is accomplished by sacrificing the interaction estimate of least concern, i.e., the three-factor interaction. The procedure to be followed is illustrated in Table 47.29, part *a,* for a 2^3 factorial. First, the plus and minus signs of the 2^3 design are written down. Next, the columns of plus and minus signs commonly used to estimate the *ABC* interaction is constructed and labeled the block "generator." Those runs carrying a plus sign in the block generator column form the first block; those carrying a minus sign form the second block.

When this design is employed, the estimate of the three-factor interaction (abbreviated 3fi) cannot be distinguished from the block effect; the block effect and 3fi effect are "confounded." All other estimated effects are clear of the block effect.

TABLE 47.29   Partitioning the 2^3 Factorial Design

a. Partitioning the 2^3 into two blocks of four runs

2^3			ABC = block generator	2^3 in two blocks			
				(+) Block		(−) Block	
A	B	C		A B C		A B C	
−	−	−	−−	+ − −		− − −	
+	−	−	+	− + −		+ + −	
−	+	−	+	− − +		+ − +	
+	+	−	−	+ + +		− + +	
−	−	+	+				
+	−	+	−				
−	+	+	−				
+	+	+	+				

b. Partitioning the 2^3 into four blocks of two runs

2^3			Block generators	
A	B	C	AB	BC
−	−	−	+	+
+	−	−	−	+
−	+	−	−	−
+	+	−	+	−
−	−	+	+	−
+	−	+	−	−
−	+	+	−	+
+	+	+	+	+

+ + Block			− + Block			+ − Block			− − Block		
A	B	C	A	B	C	A	B	C	A	B	C
−	−	−	+	−	−	+	+	−	−	+	−
+	+	+	−	+	+	−	−	+	+	−	+

To partition the design into four blocks of two runs each, the proper block generators are provided by the two columns of plus and minus signs associated with the interactions *AB* and *BC* as illustrated in Table 47.29, part *b.* Note that the generators produce four combinations of minus and plus signs, each combination identifying a block of two runs. In this particular design all 2fi (two-factor interactions) are confounded with blocks.

The block generators must be carefully chosen. The blocking arrangements for the 2^3, 2^4, and 2^5 designs appear in Table 47.30. A more complete table and description of factorial design blocking appears in Box, Hunter, and Hunter (1978).

FRACTIONAL FACTORIAL EXPERIMENTS (EACH FACTOR AT TWO LEVELS)

If there are many factors, a complete factorial experiment, requiring all possible combinations of the levels of the factors, involves a large number of tests—even when only two levels of each fac-

TABLE 47.30   Blocking Arrangements for the 2^k Factorials

k = number of factors	Block size	Block generators	Interactions confounded with blocks
3	4	ABC	ABC
	2	AB,BC	AB,BC,AC
4	8	$ABCD$	$ABCD$
	4	ABC, ACD	ABC, ACD,BD
	2	AB,BC,CD	all 2fi and 4fi
5	16	$ABCDE$	$ABCDE$

	4	ABC,BCD,CDE	$ABC,BCD,CDE, AD, ABDE, BE, ACE$
	2	AB,BC,CD,DE	all 2fi and 4fi

tor are being investigated. In these cases, it is useful to have a plan that requires fewer tests than the complete factorial experiment. The fraction is a carefully prescribed subset of all possible combinations. The analysis of fractional factorials is relatively straightforward, and the use of a fractional factorial does not preclude the possibility of later completion of the full factorial experiment.

Confounding (Aliasing, Biasing).   In a complete factorial experiment we have 2^k experimental trials. The 2^k experiments can be used to give independent estimates of all 2^k effects. In a fractional factorial (say the fraction $1/2^p$) there will be only 2^{k-p} experiments, and therefore only 2^{k-p} independent estimates are possible. In designing the fractional plans (i.e., in selecting an optimum subset of the 2^k total combinations), the goal is to keep each of the 2^{k-p} estimates as unbiased or "clear" as possible, i.e., to keep the estimates of main effects and if possible second-order interactions mutually unbiased, or nearly so.

To explain, consider the following 2^{3-1} fractional (the one-half, 2^{-1}, of the 2^3 factorial):

$A\ B\ C$	Observed
$-\ -\ +$	$y_1 = 8$
$+\ -\ -$	$y_2 = 11$
$-\ +\ -$	$y_3 = 9$
$+\ +\ +$	$y_4 = 14$

The main effects are given by the statistics $\bar{y}_+ - \bar{y}_-$, where once again the plus and minus subscripts of each letter in the design identify the observations entering each average. Thus, the main effect of A is estimated to be $(11 + 14)/2 - (8 + 9)/2 = 4.0$. The main effects of B and C are, respectively, $(9 + 14)/2 - (8 + 11)/2 = 2$ and $(8 + 14)/2 - (11 + 9)/2 = 1.0$. Now consider the estimate of the two-factor interaction AB. The analyst will find that the signs required to estimate the AB interaction are identical to those already employed to estimate the main effect of C. The main effect of C and the two-factor interaction AB are *confounded*. Said another way, the statistic $\bar{y}_+ - \bar{y}_- = 1.0$ has an "alias" structure; that is, the statistic may be identified as either C or AB. In fact, the expected value of the statistic equals $C+AB$, the sum of the two effects, and in the absence of clear information on the main effect of C, we cannot tell whether the AB effect is plus, minus, large, or small. The reader will note that estimate A is confounded with BC, as is B with AC.

When some or all main effects are confounded with two-factor interactions, the fractional factorial design is said to be of "Resolution III." When one or more of the main effects are confounded

with (at least) three-factor interactions, the fractional is said to be a "Resolution IV" design. Fractionals with main effects confounded with (at least) four-factor interactions are of "Resolution V," etc. (See Box and Hunter 1959).

DESIGNING A FRACTIONAL FACTORIAL DESIGN

Let N equal the number of runs and k the number of factors to be investigated. When $N = 2^k$, we have a full factorial design. When $N = 2^{k-p}$, we have a $(1/2)^p$ replicate of the 2^k factorial; for example, a 2^{7-3} is a one-eighth replicate of a 2^7 factorial and contains 16 runs.

To design a one-half replicate design in N runs, first write down (Yates order is best) the full factorial design in $(k - 1)$ factors. Next write down the column of signs associated with the highest-order interaction. These signs are now used to define the versions of the kth factor. For example, to construct the 2^{4-1} design, begin with a 2^3 factorial in factors A, B, and C as illustrated in Table 47.31. Next to the columns for A, B, and C write down the column of signs associated with the ABC interaction. Use these signs to identify the two versions of factor D. (The other one-half fraction is obtained by reversing the signs of the column ABC.)

TABLE 47.31   Constructing the 2^{4-1} Fractional Factorial*

Generator				Principal design				Alternative design†			
A	B	C	$ABC = D$	A	B	C	D	A	B	C	D

−	+	−	+	−	+	−	+	−	+	−	−
+	+	−	−	+	+	−	−	+	+	−	+
−	−	+	+	−	−	+	+	−	−	+	−
+	−	+	−	+	−	+	−	+	−	+	+
−	+	+	−	−	+	+	−	−	+	+	+
+	+	+	+	+	+	+	+	+	+	+	−

*Example run: Run no. 2 requires the experimenter to hold factor A at +, factor B at −, factor C at −, and factor D at +.
†The alternative fraction is obtained by reversing the signs of the ABC vector, that is, by setting $D = -ABC$.

To construct a one-quarter replicate design, two columns of signs are required in addition to the standard factorial in N runs; the one-eighth replicate design requires three additional columns, etc. The columns of signs to be used must be carefully chosen; they are listed in Table 47.32 for designs up to $k = 7$ factors. Table 47.32 is an adaptation of a much more extensive table given in Box, Hunter, and Hunter (1978). Extensive listings of fractional factorial designs can also be found in Diamond (1989).

Most design of experiment software programs provide two-level fractional factorial designs of any desired resolution along with the alias-confounding patterns associated with each estimated effect. Given below is an example of the construction of a 2^{4-1} and design and analysis of a 2^{6-2} factorial.

Example.   To construct a fractional factorial design for $k = 6$ factors in $N = 16$ runs, first write down the full factorial 2^4 design in factors A, B, C, and D. Consulting Table 47.32, the vectors of plus and minus signs associated with the interaction ABC are now used to define the versions of factor E. The signs of the BCD interaction are similarly used to define the versions of factor F. The completed 2^{6-2} design is displayed in Table 47.33 along with observed responses, Yates' algorithm, and identified effects.

TABLE 47.32 Vectors Used for the Construction of Fractionals

Number of runs N	Number of factors k				
	3	4	5	6	7
4	2^{3-1} $\pm AB = C$	NA	NA	NA	NA

*Obs.=observations.
†Expected value of the effect from the defining relation.

Identifying the Estimates.   The 2^{6-2} design was generated by setting $E = ABC$ and $F = BCD$. A simple procedure for identifying the biases (aliases) of the effects estimable from this design is as follows. Multiply the expression $E=ABC$ by E and the expression $F=BCD$ by F. This gives $E^2 = ABCE$ and $F^2 = BCDF$. Now adopt the rule that whenever a symbol appears squared, it is replaced by an I, the "identity," a symbol equivalent to the numeral 1. We now have for the design "generators" $I = ABCE$ and $I = BCDF$. Multiplying the generators together gives the *defining relation* $I = ABCE = BCDF = AB^2C^2DEF$, which reduces to $I = ABCE = BCDF = ADEF$.

When Yates' algorithm is applied to the 16 runs of the 2^{6-2}, the algorithm estimates 15 effects and provides each with its initial name, as illustrated in Table 47.33. The defining relation is now employed to determine the additional names (aliases or biases) of each of these statistics. Thus, the statistic labeled the "main effect" of A actually equals $A = BCE = ABCDF = DEF$, an expression obtained by multiplying through the defining relation by the symbol A. Similarly, the statistic initially called the "ABC interaction" actually estimates $ABC = E = ADF = BCDEF$. The estimates and their full names are given in Table 47.33.

Five of the estimates appear unusually large and are good candidates for measured phenomena distinguishable from natural variability (noise). Using only their first- and second-order names we have: -17.375 estimates $AB + CE$, 11.625 estimates C, 21.125 estimates E, 16.375 estimates D, and 15.375 estimates $DE + AF$. A reasonable interpretation of these statistics is that factors C, D, and E have detectable important influences upon the response over their studied ranges, while factors A and B do not. This conclusion obviously needs confirmation, but it represents a good first guess. The 2^{6-2} design now collapses into a 2^3 factorial repeated in factors C, D, and E.

OTHER FRACTIONAL FACTORIALS

Although the 2^{k-p} fractional factorial designs discussed here are the most frequently used, many other fractionals exist. For example the Plackett and Burman (1966) designs are two-level fractional factorials whose number of runs N is not a power of 2 but a multiple of 4. The $N = 12$ design for $k \leq 11$ factor design is displayed in Table 47.34. The templates for producing the designs for $N = 20$, 24, 28, and 36 can be found in Box and Draper (1987) and Myers and Montgomery (1995).

All Plackett and Burman designs are Resolution III. The alias structure associating main effects and two factors interactions is not as readily available as those of the regular 2_{III}^{k-p} designs. However, *every* Resolution III design can be made into a Resolution IV design by the principle of "fold-over."

TABLE 47.34   A Plackett and Burman Design

($k = 11$ factors, $N = 12$ runs)

A	B	C	D	E	F	G	H	I	J	K
+	−	+	−	−	−	+	+	+	−	+
+	+	−	+	−	−	−	+	+	+	−
−	+	+	−	+	−	−	−	+	+	+
+	−	+	+	−	+	−	−	−	+	+
+	+	−	+	+	−	+	−	−	−	+
+	+	+	−	+	+	−	+	−	−	−
−	+	+	+	−	+	+	−	+	−	−
−	−	+	+	+	−	+	+	−	+	−
−	−	−	+	+	+	−	+	+	−	+
+	−	−	−	+	+	+	−	+	+	−
−	+	−	−	−	+	+	+	−	+	+
−	−	−	−	−	−	−	−	−	−	−

To "fold over" a design one merely writes it down again with all signs reversed. A fold-over design combined together with its original Resolution III design forms a design of Resolution IV.

Fractional factorials are not limited to the 2^{k-p} designs. The 3^3 factorial design can be reduced into a variety of fractions including the Latin Square, see Hunter (1985*a*) for graphical displays. Mixed level fractional factorials are also available; see Addelman (1962). Many novel fractionals have been published: Hahn and Shapiro (1966), Webb (1968*a, b*), Margolin (1969), Anderson and Thomas (1978), and Rechtschaffner (1967). Fractional factorials when the number of runs is less than the number of variables, "supersaturated" designs, are also possible; see Booth and Cox (1962) and Lin (1993, 1995).

Several design of experiments computer software programs will construct unique fractional factorial designs, allowing the experimenter to not only choose the number of runs, but also the number of factors and levels. The reader can only be warned that the application of designs with small numbers of runs and many factors assumes great simplicity in the mathematical model for the response function under study, most particularly that only main effects exist and that all interactions are either zero or truly near zero. One is also well advised to leave some redundancy in one's design, i.e., extra runs to provide degrees of freedom that can be employed in estimating the experimental error variance σ^2 [see Snee (1985) and Berk and Picard (1991)]. (There has never been a signal in the absence of noise, and one should plan on measuring the noise as well as possible signals.

Screening Experiments.   The saturated 2^{k-p}_{III} designs for studying k factors in $N = k + 1$ runs can be of value in early screening efforts to detect important factors among many candidates. The possible biasing influences of interactions is very serious in these applications and should always be kept in mind. Certain software programs can construct fractional factorial designs to provide estimates of all k main effects and certain prechosen two-factor interactions. However, the assumption that all interactions of importance can be announced prior to the experimental program being designed and run can be naive when one considers the number of such interactions that may be possible. Furthermore, the discovery of interactions can easily be as important as the identification of main effects. Conservative practice in the use of fractional factorials generally requires designs of Resolution IV, i.e., the ability to separate main effects from two-factor interactions. See Hurley (1994); Tang and Tang (1994); and Haaland and O'Connell (1995).

Orthogonal Arrays.   The terminology "orthogonal array," used by the earliest creators of balanced block experimental designs, has been popularized by Taguchi (1987); see below. All the 2^k, 2^{k-p}, Plackett and Burman, and Latin square type designs can be called "orthogonal arrays." The number of runs associated with each orthogonal array is often identified by the notation $L(N)$, as for example the $L8$ orthogonal array is the 2^3 (or 2^{7-4}) two-level factorial and the $L9$ and the $L27$ are the 3^2 and 3^3 factorials. The $L36$ can be viewed either as a three-level design or as a 6×6 Latin square.

The classification "orthogonal array" is appropriate to any experimental design that can provide estimates of effects having zero correlations. The designs are sometimes described as "main effect clear" designs, although they are often adapted to take into account certain interactions. The 2^{k-p} and 3^{k-p} fractionals, the Latin square designs (and the Graeco-Latin and Hyper-Graeco-Latin square designs) thus qualify, as do the mixed-level factorials and fractional factorials and the balanced block designs. The Box and Behnken (1960) designs form novel fractions of the three-level orthogonal arrays. The terminology "orthogonal arrays" recognizes the geometric multidimensional nature of all these designs; that is, in the N-dimensional space of the observations, the vectors representing the effects to be estimated are all mutually perpendicular. One orthogonal array design popularized by Taguchi is the $L9$ design, the 3^{4-2} for studying four factors each at three levels in nine runs. A critique of the application of this and other three-level orthogonal arrays is found in Hunter (1985).

In listing orthogonal array designs the Taguchi literature uses the notation (1, 2) and (1, 2, 3) to identify the levels (versions) of each variable instead of the geometric notation $(-1, +1)$ and $(-1, 0, +1)$. Examples of the analysis of orthogonal arrays employing the Taguchi terminology and methodology are provided by Barker (1990, 1994), Kacker (1985), Phadke et al. (1983), Phadke (1989), and Taguchi (1978, 1987). These authors pay particular attention to the use of "inner" and

"outer" orthogonal arrays, or in a parallel terminology, to "design" and "noise" matrices. The designs are similar in structure to the classical split-plot designs.

To construct unique designs for estimating main effects and *selected* interactions, Taguchi employs "linear graphs" associated with each orthogonal array; see Kacker and Tsui (1990), Wu and Chen (1991), and Wu, Mao, and Ma (1990). Linear graphs provide a geometric analogue to the use of fractional factorial defining relations (see Identifying the Estimates under Designing a Fractional Factorial Design, above). Almost always, classical methods employing defining relations can provide experimental designs identical to or better than those provided by the application of linear graphs.

TAGUCHI OFF-LINE QUALITY CONTROL

The Japanese engineer–quality expert Genechi Taguchi must be credited with much of today's interest in the use of factorial and fractional factorial designs on the part of the automotive, communication, and assembly industries; see Taguchi (1978). Within these industrial environments experiments are run to identify the settings of both product design parameters and process variables that will simultaneously provide a manufactured item whose response is robust to process variability while meeting the customer's product expectations and possible environmental challenges. The adaptation of statistical experimental design to these objectives has its origins in Taguchi's early work in the communications industries in Japan in the 1950s. The strategy is called "parameter design" or "robust design." It is important to note that the word "design" takes differing connotations: product design, process design, and statistical design.

Taguchi requires manufactured products be created to meet the following criteria:

1. To protect the product from sources of variability occurring within the manufacturing process

2. To have minimum variability about the customer's target values

3. To be robust to environmental factors encountered by the customer

More formally, a product's response y is considered to be a function of "controllable" factors x and "noise" factors z. The objective is to choose settings of x that will make the product's response y insensitive to variability associated with both x and z and still meet target specifications with least variability.

Inner and Outer Arrays.   The statistical designs associated with the Taguchi approach to product and process design usually contain both an "inner" and "outer" array, or "design matrix" and "noise matrix," each constructed from the orthogonal arrays. (See previous section.) The inner array consists of a statistical experimental design employing the controllable factors x, while the outer array is a statistical experimental design in the noise factors z which are now intentionally varied. (Occasional x factors may also be included as "noise" factors in an outer array.) The entire design forms a split-plot-like experimental array with the z outer array repeated within each of the settings of the x inner array. For example, if the inner array were a $L16 = 2^{8-4}$ and the outer array a $L9 = 3^{4-2}$ there would be a total of $16 \times 9 = 144$ experiments, each of the 16 runs of the $L16$ containing its own 9-run $L9$ design. Experimental designs providing for inner and outer arrays that employ fractional factorial arrangements are also possible; see Shoemaker, Tsui, and Wu (1991) and Montgomery (1991).

At each setting of the inner array Taguchi now determines a "signal to noise" statistic composed from the outer array, noise matrix, observations. Taguchi focuses on a quadratic loss function $Q = (\eta - \theta)^2 + \sigma^2$, where η is the expected product response, θ the target value (the quantity $\eta - \theta$ is bias), and σ^2 the variance of the observed responses. To aid in minimizing the loss function, Taguchi defines the "signal to noise" ratio SN, where commonly SN $= 10 \log_{10} (\eta/\sigma)^2$, $\eta = E(y)$, and $\sigma^2 = \text{Var}(y)$. At each setting of the inner array the statistic SN $= 10 \log_{10} (\bar{y}/s)^2$ is computed using the n observations from the outer array occurring only at that setting. Other definitions for

SN are also suggested. For example, when a higher response is preferred, Taguchi proposes SN$=10$ $\log_{10}[(y_1^2 + y_2^2 + \cdots + y_n^2)/n]$ and, for lower desired response, the statistic SN $= 10 \log_{10}[(1/y_1^2 + 1/y_2^2 + \cdots + 1/y_n^2)/n]$, where $y_1, y_2, \ldots, y_n$ are the n observations from the outer array unique to each setting of the inner array.

Most statisticians recommend that the averages and estimated variances obtained at each of the points of the inner array be separately analyzed. Members of the Taguchi school continue to recommend the analysis of the various signal to noise statistics. No closure to the debate seems imminent. One thing is clear. The fraternity of quality engineers and statisticians is indebted to Prof. Taguchi for proposing the concept of the design of robust products (parameter design) and for adapting the arts of statistical design of experiments to that end use.

A large body of literature exists describing and offering examples of the Taguchi approach. An excellent summary and critique of the methodology identified with Prof. Taguchi, and possessing an extensive bibliography, appears in a discussion organized by Nair (1992). Major authors identified with the Taguchi approach are Taguchi (1978, 1986, 1987); Kacker (1985); Kacker and Shoemaker (1986); Kacker and Tsui (1990); Barker (1990, 1994); Phadke (1989); Phadke et al. (1983); Leon, Shoemaker, and Kacker (1987); and their various coworkers. Authors who have discussed the Taguchi work include Bisgaard (1993*b*), Box (1988), Box and Jones (1986), Box and Myers (1986), Easterling (1985), Goh (1993), Grove and Davis (1991*b*), Hunter (1985*a,* 1989), Hurley (1994), Lucas (1985), Miller et al. (1993), Montgomery (1991), Nair and Shoemaker (1990), Stephens (1994), Tribus and Sconyi (1989), and Vining and Myers (1990).

RESPONSE SURFACE DESIGNS

Response Surface Methodology (RSM) has been successfully used to optimize many different kinds of industrial units, processes, and systems. It is an experimental approach and has been applied in research and development laboratories and sometimes on actual plant equipment itself. In the latter situation, however, Evolutionary Operation is often more appropriate. Evolutionary Operation is an alternative form of RSM that is useful for both objectives of screening and optimizing.

RSM experimental designs require that important factors influencing a process, identified perhaps by a screening experiment, be varied in a carefully chosen pattern of experiments. Commonly two controlled variables and a single response variable are studied. The data obtained are then analyzed with the primary objective of providing a rough map (usually a contour representation) of the response surface over the region of the controlled variables investigated. The mathematical models employed are the first-order and second-order polynomials. Thus, the fitted response surface may be planar (a first-order approximation to the "true" surface) or nonplanar or curved (a second-order approximation). The fitted models are obtained using ordinary least squares estimation procedures (regression analysis). Often a fitted response surface will suggest alternative levels of a factor to provide better yields. Thus, a program of RSM may go through several stages of mapping before "best" conditions are identified. When more than two controlled variables are studied, contour surfaces are employed. See Box and Draper (1987). Nor is it necessary to map only a single response. Two or more responses can be separately mapped and their maps superimposed to identify regions of "optimum" operability. Finding "optimum" operating conditions does not always mean finding the factor settings that give the biggest or smallest response. Suggestions for further reading include Box, Hunter, and Hunter (1978); Box and Draper (1987); Khuri and Cornell (1987); Mason, Gunst, and Hess (1989); Haaland (1989); and Myers and Montgomery (1995). A history of RSM appears in Myers, Khuri, and Carter (1989).

Modern computers and software programs have made RSM a most useful and valuable statistical tool. Not only are the burdens of computation minimized, but the ability of computers to display maps of the fitted response surfaces provides the analyst with vivid insights into the nature of the responses and factors under investigation. Most software programs will allow an experimenter to obtain a first- or second-order mapping of an unknown response surface employing almost any collection of data; all that is needed is a good least-squares regression program. However, good experimentation

requires a careful selection of points. A poorly designed response surface program is analogous to viewing a scene through an astigmatic lens. The consequence is a warped view. In most circumstances a first- or second-order rotatable (nonastigmatic) response surface design offers the best strategy. Fitting response surfaces to haphazardly acquired data is called PARC analysis by some statisticians (PARC: Practical Accumulated Records Computations, or Planning After Research is Completed.) The use of the standard first- and second-order RSM designs for $k = 2$ factors and a single response is described here.

In implementing RSM, a number of statistical procedures discussed in other sections of this Handbook are used. The concept of RSM was first developed and described by Box and Wilson (1951). At first RSM was used primarily as an experimental optimization technique in the chemical industry. Since then, however, it has found application in many other fields (see Hill and Hunter 1966).

RSM can be usefully regarded as consisting of two stages:

1. First-order stage, in which a first-order mathematical model is contemplated, a factorial or other first-order design performed, the data fitted, the contours of the response drawn, and the direction of steepest ascent determined and pursued

2. Second-order stage, in which a second-order mathematical model is contemplated, a central-composite or other second-order design performed, the data fitted, the contours drawn, a canonical analysis performed, and an optimum located

Response Surface Methodology is actually more flexible than these brief definitions indicate. A skeletal outline, which shows some of the possible paths through an RSM study, is given in flow-diagram form in Figure 47.16.

Weakness of One-Variable-at-a-Time Approach.

A popular method of experimentation is the one-factor-at-a-time approach. Each factor, in turn, is varied while all the rest of the factors are held at some fixed, constant levels. One trouble with this approach is that a false optimum can be reached. Consider the following hypothetical illustration.

Example.

Under study is a chemical reaction in which there are two factors of interest, the concentration of one of the reactants and the reaction time. What settings for these two factors will maximize the yield? The best known settings, at the outset of the investigation, are a concentration of 25 percent and a time of 1 h (see Figure 47.17).

Following a one-factor-at-a-time approach, the engineer first runs a series of experiments by varying the time, while holding the concentration at 25 percent. The results show that a maximum yield of about 65 percent is obtained when the time is 1.9 h (position E on the line A to B in Figure 47.17). Holding the time fixed at this value, varying concentration along the line C to D, and obtaining a maximum at 25 percent, the engineer reaches the conclusion that the maximum yield (65 percent) is achieved when the concentration is 25 percent and the time is 1.9 h. This conclusion, however, is incorrect.

Response Surface Approach.

The actual situation, unknown to the experimenter, is shown in Figure 47.17. Here the yield is shown as a function of both concentration and time. The solid curved lines in the figure are contour lines of constant yield. For example, there is an entire set of conditions of concentration and time that give an 80 percent yield. The contour surface can be viewed as a mountain; the peak of the mountain is the point P. The contours of 90, 80, and so forth, can be viewed as altitudes. These numbers represent the percentage yields.

The engineer's objective was to find those settings for the concentration and time that would give the maximum yield. Viewed geometrically, what the engineer was trying to do was to climb to the highest point on the mountain. The attempt failed for a fairly simple reason.

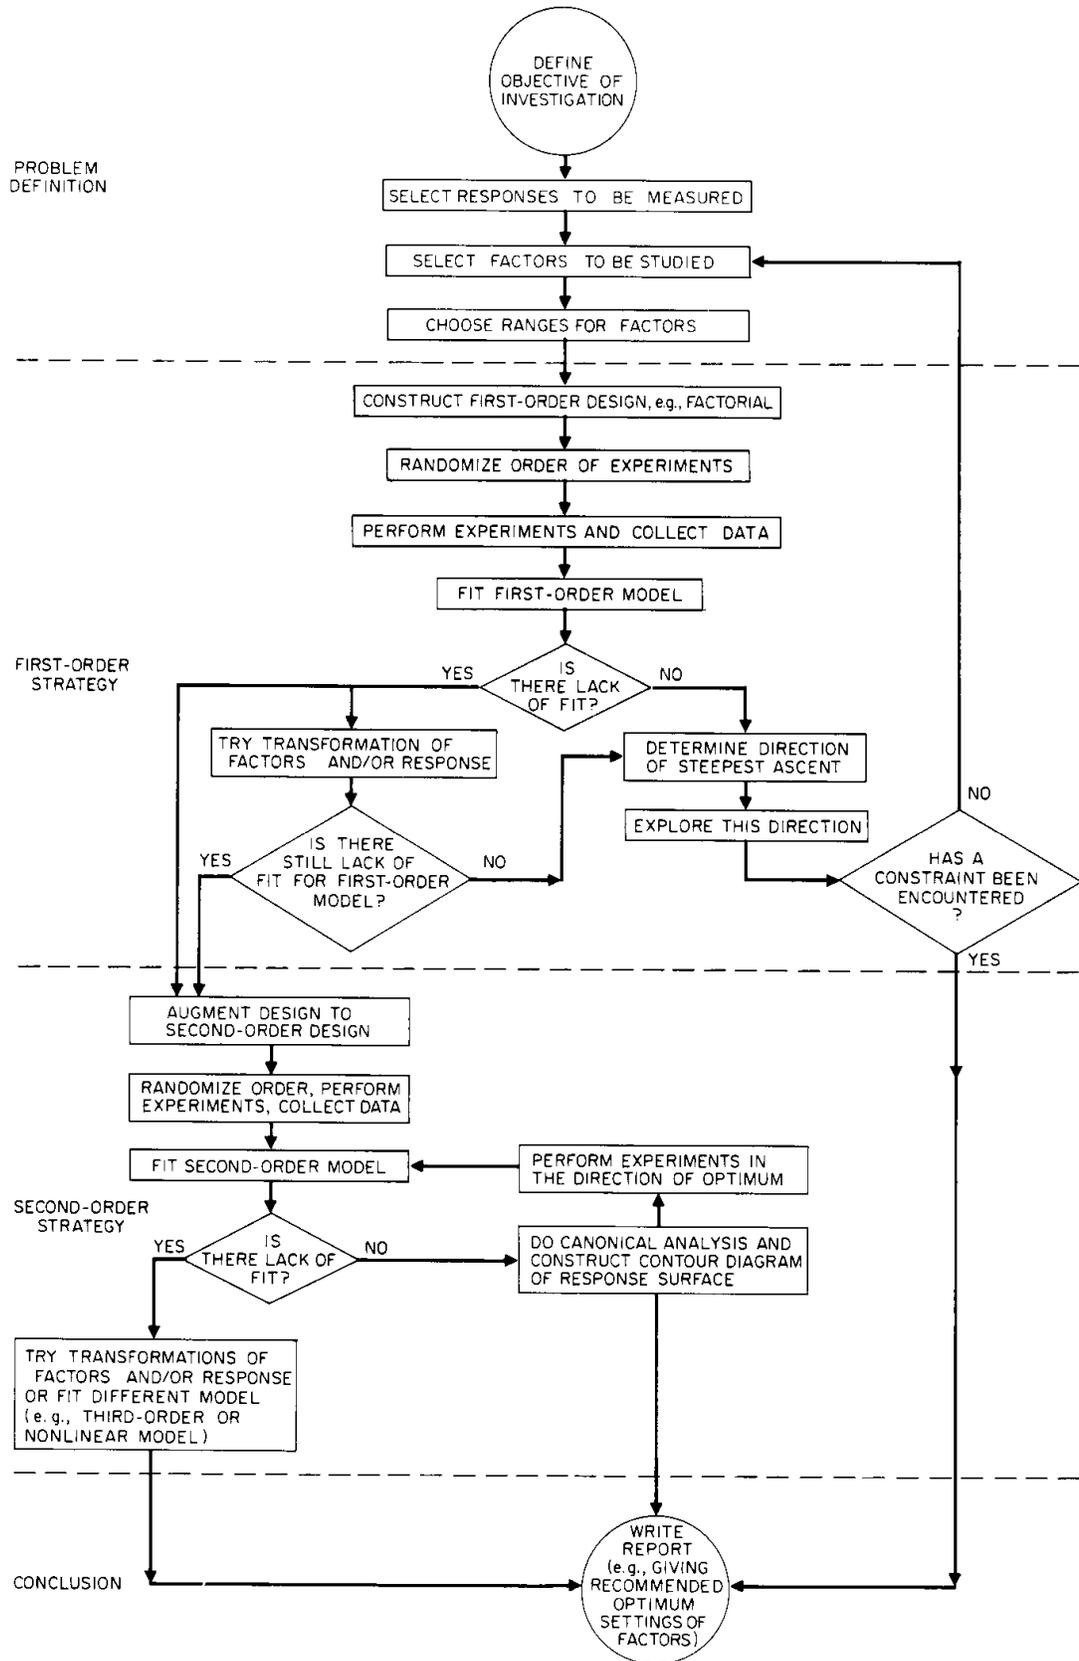
Figuratively speaking, by varying time, the engineer first traversed the hill going along a path from point A to point B (see Figure 47.17). Between A and E the path led up the mountain, but then


FIGURE 47.16 Outline of main ideas of Response Surface Methodology.
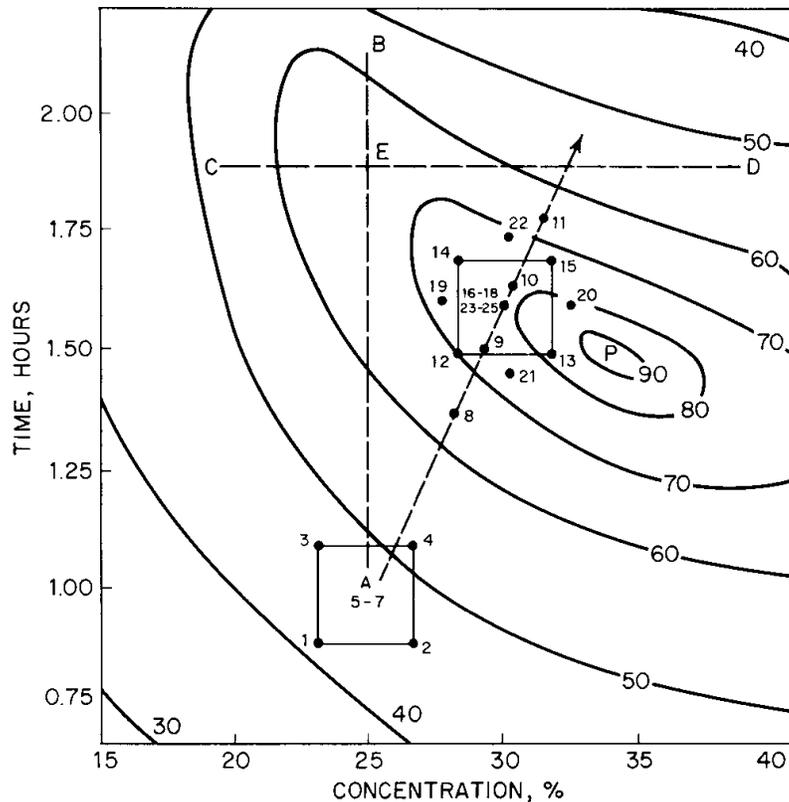

FIGURE 47.17 Response surface showing yield of a chemical reaction as a function of concentration and time.

at point E it started to go down the other side. From point E to point B the engineer was walking down the other side of the hill. The traverse for varying concentration (C to E to D) is shown.

The experimenter has achieved a yield of only 65 percent (at E), whereas a yield in excess of 90 percent (at P) is possible. This higher yield can be achieved by *simultaneously* increasing concentration and decreasing time from the experimenter's reported "optimum" values.

If the contours of the hill were circular and there were no experimental error, this one-at-a-time procedure would have taken the engineer to the highest point on the hill. In general, the contours of real response surfaces are not circular nor experimental error (noise) absent, and thus what is needed is a more sophisticated experimental strategy such as RSM.

Beginning of Program.　The RSM approach (see Figure 47.16) will now be applied to the example of maximizing the yield.

Define Objective of Investigation.　It is of the utmost importance to define clearly the objective of the study to be undertaken. It is surprising how often in practice this step is either ignored or not given the careful attention it deserves. This often leads to difficulties later on. In the present example the objective is to maximize the yield. The objective, in general, may involve multiple criteria, that is, to maximize yield while simultaneously meeting other objectives such as minimizing impurity and obtaining an acceptable range of viscosity.

Select Factors and Ranges.　The next step is to select the factors to be studied together with the ranges over which they are to be studied. It is necessary to understand the technical aspects of the experimental situation for this to be done intelligently. The specific *scale* over which each factor is to be studied must also be chosen. For example, instead of varying time linearly in units of hours, the experimenter might choose the basic scale to be the logarithm of the number of

hours. In the present example, the variables concentration and time are selected. Initially, it is decided to vary concentration from 23 to 27 percent and time from 0.9 to 1.1.

First-Order Strategy

Construct Design and Collect Data.   The 2^2 factorial design with three center points, shown in Tables 47.35, is constructed. [Further discussion of the number of center points and other matters on setting up the design is given in Cochran and Cox (1957), Hunter (1959), Box and Draper (1987), and Myers and Montgomery (1995).] The order of the seven runs is randomized, the experiments are performed, and the results shown in Table 47.35 are obtained. The results are displayed in Figure 47.18.

Fit First-Order Model and Check for Lack of Fit.   The analysis of these results can be carried out in either one of two equivalent ways. The effects and interaction of the factorial design can be calculated with their associated 95 percent confidence intervals, as is also shown in Table 47.35.

TABLE 47.35   Results of First-Order Design

Run number	X_1 = concentration		X_2 = time		Y = yield
	%	Coded units	Hours	Coded units	%
1	23	−1	0.9	−1	43.7
2	27	+1	0.9	−1	44.5
3	23	−1	1.1	+1	47.2
4	27	+1	1.1	+1	51.8
5	25	0	1.0	0	46.8
6	25	0	1.0	0	45.9
7	25	0	1.0	0	45.3

Calculation of main effects

Concentration: $(-Y_1 + Y_2 - Y_3 + Y_4)/2 = (-43.7 + 44.5 - 47.2 + 51.8)/2 = 2.7$
Time: $(-Y_1 - Y_2 + Y_3 + Y_4)/2 = (-43.7 - 44.5 + 47.2 + 51.8)/2 = 5.4$
Interaction: $(+Y_1 - Y_2 - Y_3 + Y_4)/2 = (43.7 - 44.5 - 47.2 + 51.8)/2 \quad = 1.9$
Curvature: $(+Y_1 + Y_2 + Y_3 + Y_4)/4 - (Y_5 + Y_6 + Y_7)/3 = 46.8 - 46.0 = 0.8$

Calculation of confidence intervals

Concentration: $\pm 2ts/\sqrt{n} = \pm 2(4.30)(0.755)/\sqrt{4} = \pm 3.25$
Time: $\pm 2ts/\sqrt{n} = \pm 2(4.30)(0.755)/\sqrt{4} = \pm 3.25$
Interaction: $\pm 2ts/\sqrt{n} = \pm 2(4.30)(0.755)/\sqrt{4} = \pm 3.25$
Curvature: $\pm ts\sqrt{(1/n) + (1/n_0)} \equiv \pm(4.30)(0.755)\sqrt{(\frac{1}{4}) + (\frac{1}{3})}$
$= \pm 2.48$

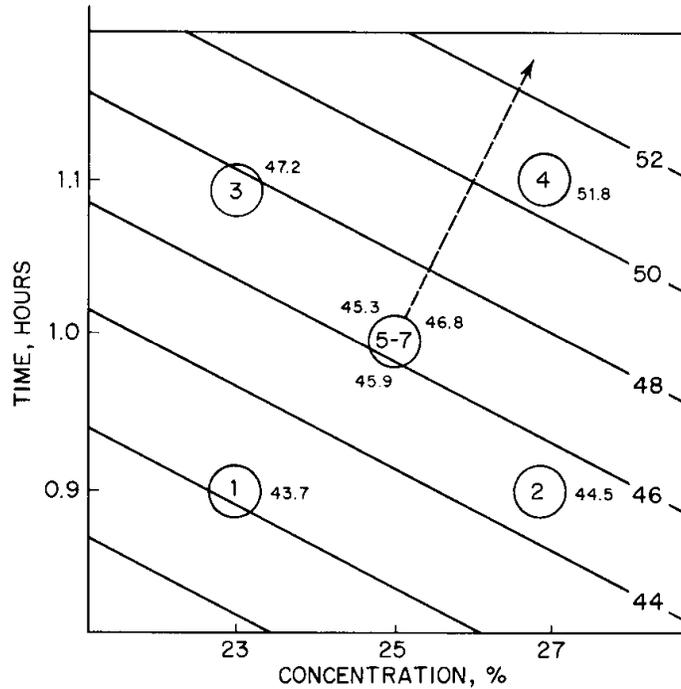
Effects	Calculated 95% confidence interval, % yield
Concentration	2.7 ± 3.25
Time	5.4 ± 3.25
Interaction	1.9 ± 3.25
Curvature	0.8 ± 2.48


FIGURE 47.18 Results of first-order design with fitted first-order (planar) response surface.

As the center-point conditions have been repeated three times, an estimate of the variance can be readily obtained. (If repeat runs have not been performed, it might be possible to obtain an appropriate estimate in some other way, for example, from some external source, past experience, or from a technique like half-normal plots; see Daniel 1959.) With the three values 46.8, 45.9, and 45.3, $s^2 = 0.57$ is calculated as an estimate of the variance of an individual observation with two degrees of freedom.

Employing the estimated standard deviation $s = 0.755$ with two degrees of freedom, the confidence intervals suggest that the main effects of concentration and time are significant while the estimates of second-order effects (interaction and curvature) are indistinguishable from zero. We are thus able to employ as an approximation to the unknown response surface the first-order model

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \epsilon$$

where Y is the observed response and the β's are coefficients to be estimated from the data. The quantities X_1 and X_2 are independent variables representing the experimental factors concentration and time, where

$$X_1 = \frac{\text{concentration}(\%) - 25}{2}$$

$$X_2 = \frac{\text{hours} - 1.0}{0.1}$$

These expressions for X_1 and X_2 code the original settings of concentration and time to match those of the 2^2 factorial design with center point given in Table 47.37 and displayed in Figure 47.18. For example, when concentration = 23 and time = 0.9 hours, $X_1 = -1$ and $X_2 = -1$. The quantity ϵ in the model is assumed to be a random error normally distributed, independent, with constant variance σ^2. Although standard regression techniques (see Section 44) can be used to fit the

first-order model, estimates of the β's are readily obtained as a consequence of the 2^2 factorial design with center point. The estimate of β_0 is is the average, the estimate of β_1 one half the concentration effect, and the estimate of β_2 one half the time effect. Thus the fitted equation becomes

$$\hat{Y} = 46.46 + 1.35X_1 + 2.70X_2$$

The equation in terms of the original variables is

$$\hat{Y} = 28.23 + 0.675[conc\%] + 1.35[hours]$$

Setting $\hat{Y} = 44.0$ will produce the straight line contour labelled 44 in Figure 47.18. The fitted contours suggest the response surface to be well represented by the plane.

$$\hat{Y} = B_0 + B_1X_1 + B_2X_2 = 46.46 + 1.35X_1 + 2.70X_2$$

in the X_1, X_2 coordinate system.

A second method for evaluating the fit is to use the analysis of variance. The resulting ANOVA table (Table 47.36) indicates that the first-order model (above equation) adequately fits the data. (See Section 44; also Draper and Smith 1981.) The ratio of the lack of fit mean square divided by the pure error mean square is 4.13, and since this value is less than $F_{2,2}(0.95) = 19.0$, there is no evidence of lack of fit of the first-order model. Since there is no evident lack of fit, it is reasonable to study the implications of the fitted first-order model (above equation). The plane described by this equation is represented in Figure 47.18 by the straight contour lines.

Determine Direction of Steepest Ascent.   The direction of steepest ascent is indicated in Figure 47.18. (For further details on direction of steepest ascent, see Cochran and Cox 1957, p. 357, and Box and Draper 1987.) It is perpendicular to the contour lines. Four experiments (numbers 8 to 11) in this direction indicate that the center of a second design should be approximately at a concentration of 31 percent and a time of 1.6 h. The design employed and the data obtained after performing the runs in random order are shown in Table 47.37 as runs 12 to 18. An analysis of the data shows apparent lack of fit (Table 47.38). The ratio of the lack of fit mean square divided by the pure error mean square is 26.8, and since this value is greater than $F_{2,2}(0.95) = 19.0$, there is evidence of lack of fit of the first-order model.

Second-Order Strategy

Construct Design and Collect Data.   Since lack of fit is detected, the design is augmented by adding runs 19 to 25 to form the second-order (central composite) design shown in Table 47.37. In general,

TABLE 47.36   ANOVA Table: First-Order Model, First Design*

Source	Sum of squares	Degrees of freedom	Mean square
Mean b_0	15,107.86	1	
b_1	7.29	1	7.29
b_2	29.16	1	29.16
Lack of fit	4.71	2	2.36
Pure error	1.14	2	0.57
Total	15,150.16	7	

*In the literature of response surface methodology, it is customary that the ANOVA table include a term for the sum of squares for the mean. In other uses of ANOVA, some authors and computer software programs exclude the sum of squares for the mean.

TABLE 47.37 Results of Second-Order Design

Run number	Concentration (coded units)X_1	Time (coded units)X_2	Yield Y, %
	First-order design		
12	-1	-1	69.3
13	$+1$	-1	85.1
14	-1	$+1$	72.8
15	$+1$	$+1$	73.6
16	0	0	80.9
17	0	0	78.4
18	0	0	80.4
	Augmenting runs		
19	$-\sqrt{2}$	0	71.4
20	$+\sqrt{2}$	0	78.9
21	0	$-\sqrt{2}$	73.9
22	0	$+\sqrt{2}$	69.1
23	0	0	76.4
24	0	0	78.5
25	0	0	76.3

TABLE 47.38 ANOVA Table: First-Order Model, Second Design

Source	Sum of squares	Degrees of freedom	Mean square
Mean b_0	41,734.32	1	
b_1	68.89	1	68.89
b_2	16.00	1	16.00
Lack of fit	94.12	2	47.06
Pure error	3.50	2	1.75
Total	41,916.83	7	

if a model does not fit, it may be advantageous, instead of immediately considering a higher-order model, to consider transformations of the factors and/or the responses. See Box and Cox (1964), Box and Tidwell (1962), and Draper and Hunter (1967).

Fit Second-Order Model and Check for Lack of Fit. The fitted second-order equation obtained by least squares is

$$\hat{Y} = 78.50 + 3.40X_1 - 1.85X_2 - 3.75X_1X_2 - 1.21X_1^2 - 3.03X_2^2$$

The contours of this equation are shown in Figure 47.19 with the second-order design results. No lack of fit is evident from either visual inspection or statistical calculation (see Table 47.39). The form of the above equation can be simplified so the shape of the response surface can be better appreciated. It is difficult to visualize the surface from the equation because it contains six constants. A canonical analysis, which involves a translation and rotation of the coordinates from the original (X_1, X_2) axes to the new (Z_1, Z_2) axes, gives an equation containing only three constants:

$$Y - 173.83 = -0.0332Z_1^2 - 8.4075Z_2^2$$

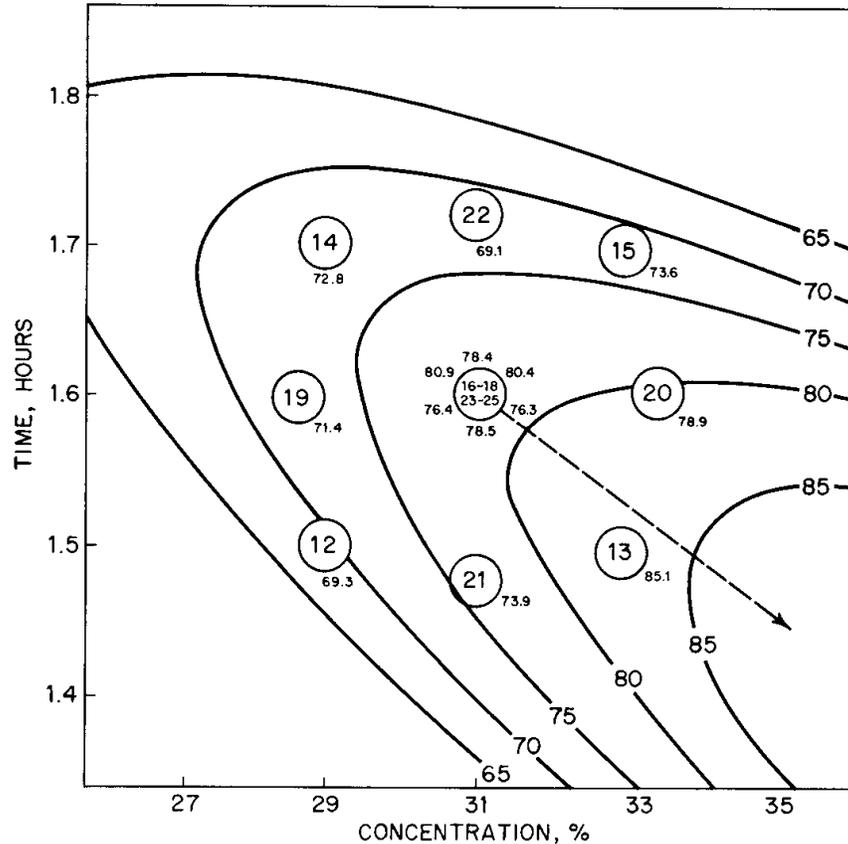
This equation indicates that because of the negative coefficients for Z_1^2 and Z_2^2, the fitted response surface has a maximum point. A direction in which to proceed at the next stage to search for the maximum is indicated by the arrow in Figure 47.19. The arrow points toward the "top of the mountain." The investigation might terminate after experimenting in this direction, perhaps with a few added points in the vicinity of the maximum. In some situations it may be useful to perform a full


FIGURE 47.19   Results of second-order design with fitted second-order (nonplanar) response surface.

TABLE 47.39   ANOVA Table: Second-Order Model

Source	Sum of squares	Degrees of freedom	Mean square
Mean b_0	81,016.07	1	
First-order b_i	119.87	2	59.94
Pure second-order b_{ii}	80.73	2	40.37
Mixed second-order b_{ij}	56.25	1	56.25
Lack of fit	2.23	3	0.74
Pure error	21.77	5	4.35
Total	81,296.92	14	

Note: The ratio of the lack of fit mean square divided by the pure error mean square is 0.17, and since this value is less than $F_{0.95}$ for 3, 5 degrees of freedom (5.41), there is no evidence of lack of fit of the second-order model.

second-order design near the final optimum. [For further details on canonical analysis and RSM in general, see Box and Draper (1987) and Myers and Montgomery (1995).]

Many response surface experimental designs are available, in particular the three-level factorials, the central composite, the rotatable designs, and Box-Behnken designs. For response surface designs using a minimum number of runs while preserving many of the qualities of the larger designs see Draper (1985) and Draper and Lin (1990). Some computer software programs can provide unique response surface designs (commonly *D*-optimal) constructed to match special constraints provided by the experimenter.

MIXTURE DESIGNS

In some experiments with mixtures, the property of interest depends on the proportions of the mixture components and not on the amounts (volume or weight) of the individual components. For example, stainless steel is a mixture of different metals, and its tensile strength depends on the proportions of the metallic elements present; gasoline is ordinarily a blend of various stocks, and the octane rating of the final blend depends on the proportions going into the blend. The proportions of the components of a mixture must add up to unity, and in the most general case the proportion of any component may range from zero to unity. An important reference text is Cornell (1990).

In the design of mixtures, the factor space available for experimentation is constrained, since the proportions used must sum to unity. It has been shown that if the number of components in the mixture is q, the available factor space becomes a regular $(q - 1)$-dimensional simplex (e.g., a triangle for $q = 3$), a tetrahedron for $q = 4$).

A natural approach would be to take a uniformly spaced distribution of experimental points over the available factor space. This results in the simplex lattice designs proposed by Scheffé (1958). A (q, m) lattice, for example, is a lattice for q components, where the proportions for each component have $m+1$ equally spaced values from 0 to 1, i.e., the values 0, $1/m$, $2/m$, etc. For three components, the proportions of each component would be 0, $1/2$, 1 when $m=2$; and 0, $1/2$, $2/3$, 1 when $m = 3$. The lattice resulting when $m = 2$ is called the quadratic lattice, the lattice resulting when $m = 3$ is called the cubic lattice, etc. (see Figure 47.20).

In addition, modified lattices can be made by adding center points to the two-dimensional face or faces of the quadratic lattice. This provides a useful design called the "special cubic lattice."

The number of points k required for any lattice except the special cubic is found by using the formula

$$k = \frac{(m + q-1)!}{m!(q - 1)!}$$

The number of points required for the special cubic is

$$k = \frac{q(q + 1)}{2} + \frac{q(q - 1)(q - 2)}{6}$$

The number of points required for several values of m and q is given in Table 47.40.

The property of interest is measured at each of the design points (corresponding to mixtures of different proportions). Simplified polynomials are used to relate the response variable y to the various mixture proportions used.

Another useful design called the "special cubic" by Scheffé (1958) requires seven points for three-component mixtures—the six points of a $(q = 3, m = 2)$ lattice plus a seventh point at $X_1 = 1/3$, $X_2 = 1/3$, $X_3 = 1/3$.

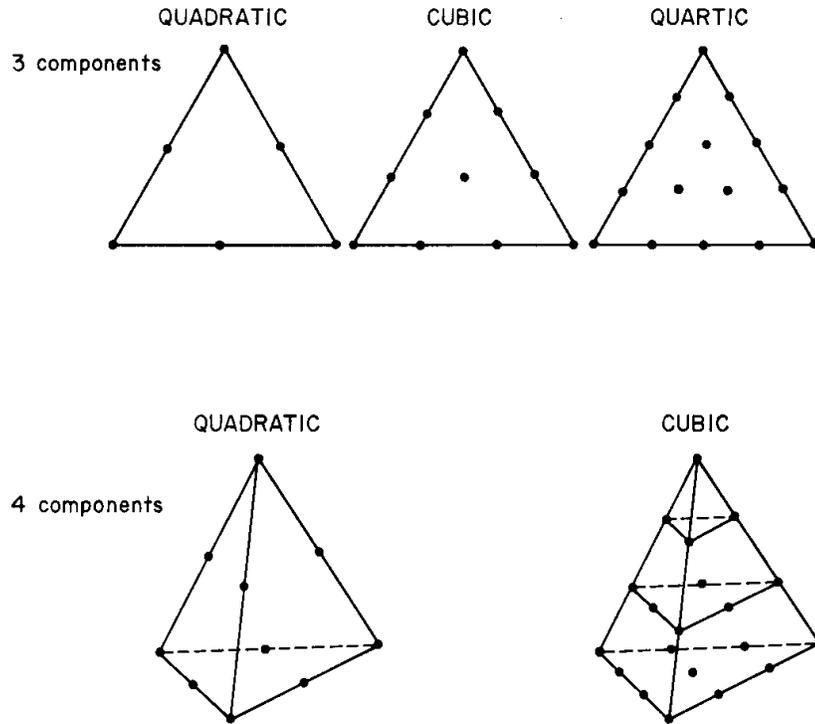
The seven mixtures are the three pure components, the three binary mixtures, and the ternary mixture, as shown in Table 47.41.


FIGURE 47.20 Lattice designs for three- and four-component mixtures. (*Reprinted with permission from Gorman and Hinman 1962.*)

TABLE 47.40 Number of Points Required for Lattice Designs

| | Type of lattice | | | |
Number of components q	Quadratic, $m = 2$	Special cubic, $m = 2$	Cubic, $m = 3$	Quartic, $m = 4$
3	6	7	10	15
4	10	14	20	35
5	15	25	35	70
6	21	41	56	126
8	36	92	120	330

TABLE 47.41 Design Points for Special Cubic (Three-Component Mixture)

Point number	x_1	x_2	x_3	Response
1	1	0	0	y_1
2	0	1	0	y_2
3	0	0	1	y_3
4	½	½	0	y_4
5	½	0	½	y_5
6	0	½	½	y_6
7	⅓	⅓	⅓	y_7

The "special cubic" corresponds to the equation:

$$y = B_1 X_1 + B_2 X_2 + B_3 X_3 + B_{12} X_1 X_2 + B_{13} X_1 X_3 + B_{23} X_2 X_3 + B_{123} X_1 X_2 X_3$$

The computed coefficients are

$$b_1 = y_1 \qquad b_2 = y_2 \qquad b_3 = y_3$$

$$b_{12} = 4y_4 - 2(y_1 + y_2)$$

$$b_{13} = 4y_5 - 2(y_1 + y_3)$$

$$b_{23} = 4y_6 - 2(y_2 + y_3)$$

$$b_{123} = 27y_7 - 12(y_4 + y_5 + y_6) + 3(y_1 + y_2 + y_3)$$

The subject of mixture designs now has a vast body of literature, and many computer software programs devote attention to both their design and analysis. Computer printouts of contour representations are particularly valuable. Factors composing mixture designs are often constrained to fall within narrow ranges, thus forming isolated mixture regions and requiring novel experimental designs difficult to obtain without a computer. Constrained factors are sometimes combined with factors not constrained, once again leading to unique designs and analyses. The designs may also be blocked and run sequentially. The textbook by Cornell (1990*a*) is devoted entirely to the topic of mixture experiments. See also Myers and Montgomery (1995). Important papers are Gorman and Hinman (1962), Thompson and Myers (1968), Snee (1973, 1979), Crosier (1984), Piepel and Cornell (1994), and Draper et al. (1993).

GROUP SCREENING DESIGNS

Novel experimental designs for finding the few effective factors out of a very large number of possible factors have been called "group screening designs." These designs have the following structure: groups are formed, each containing several factors; the groups are tested; and individual factors of the groups that prove to contain significant factors are then separately tested. Such designs, proposed by Connor (1961) and further studied by Watson (1961), are intended to minimize the amount of experimentation required.

The experimental variables are divided into groups, and each group is treated as a single variable until an effect on the response variable is shown.

The following assumptions are made:

1. All factors initially have the same probability of being effective.

2. The factors do not interact.

3. The directions of effects, if they exist, are known.

The number of factors is $f = gk$, where g = number of groups and k = number of factors per group. For example, consider an experiment with nine factors, which are divided into three groups of three factors each (i.e., $g = 3$, $k = 3$). The upper and lower levels of the groups are defined as follows:

1. Group factor X consists of factors *A, B, C.*

   Level 1:   All three factors at lower level (0, 0, 0)

   Level x: All three factors at upper level (1, 1, 1)

2. Group factor Y consists of factors *D, E, F.*

   Level 1:   All three factors at lower level (0, 0, 0)

Level y: All three factors at upper level (1, 1, 1)

3. Group factor *Z* consists of factors *G, H, I.*

Level 1:   All factors at lower level (0, 0, 0)

Level z: All factors at upper level (1, 1, 1)

The first-stage design studies the *group* factors, for example by using a half-replicate of a 2^3 factorial. This requires the four group treatment combinations *x, y, z,* and *xyz* corresponding to treatment combinations for the nine factors as follows:

$$x(1,1,1 \ 0,0,0,0,0,0)$$

$$y(0,0,0 \ 1,1,1 \ 0,0,0)$$

$$z(0,0,0 \ 0,0,0 \ 1,1,1)$$

$$xyz(1,1,1 \ 1,1,1 \ 1,1,1)$$

The results of the first-stage experiment will indicate which group factors contain at least one effective factor. A second-stage experiment, which may consist of a half-replicate of a 2^3, will then be run on each effective group factor to determine which of the individual factors are effective. For further details, see Watson (1961). Patel (1962) gives detailed procedures for two-, three-, and four-stage screening tests.

The application of group screening designs that has been discussed here is to the identification of effective experimental factors, but there is extensive literature relating to the screening of effective responses, e.g., to compounds and drugs, and to the group testing of individuals. Papers of interest are by Ehrenfeld (1972), Pocock (1983), Mundel (1984), Hwang (1984), and Hayre (1985). An excellent review of the entire problem of group screening is provided by Tang and Tang (1994).

SECTION 48

RELIABILITY CONCEPTS AND DATA ANALYSIS

William Q. Meeker
Luis A. Escobar
Necip Doganaksoy
Gerald J. Hahn

INTRODUCTION

Relationship between Quality and Reliability.   Rapid advances in technology, development of highly sophisticated products, intense global competition, and increasing customer expectations have put new pressures on manufacturers to produce high-quality products. While producers often think of high quality in terms of minimizing scrap and rework, customers are concerned with

functionality, reliability, and overall product lifetime. Customers expect a purchased product to meet or exceed life expectations and to be safe. Technically, reliability is often defined as the probability that a system, vehicle, machine, device, or other product will perform its intended function under some specified operating conditions, for a specified period of time. Improving reliability is an important part of the larger overall goal of improving product quality. There are many definitions of quality, but there is general agreement that an unreliable product is *not* a high-quality product. Condra (1993) emphasizes that "reliability is quality over time."

Modern programs for improving reliability of existing products and for assuring continued high reliability for the next generation of products require quantitative methods for predicting and assessing product reliability and for providing early signals and information on root causes of failure. In many cases this will involve the collection and analysis of reliability data from studies such as laboratory tests (or designed experiments) of materials, devices, and components, tests on early prototype units, careful monitoring of early-production units in the field, analysis of warranty data, and systematic longer-term tracking of product in the field. This frequently also involves the careful planning of such programs so as to ensure that the most meaningful information is obtained. Reliability evaluations often present a challenge beyond that normally encountered in quality evaluations because there is usually an elapsed time between when the product is built and when the reliability information is forthcoming.

Applications of Reliability Data Analysis.   Some major goals in obtaining reliability data include:

1. Obtaining early identification of failure modes and understanding and removing their root causes— and thereby improving reliability.
2. Obtaining field failure information to help improve the product design, perhaps for the next product release.
3. Determining how long each unit should be run prior to shipment (and at what conditions) in order to avoid premature field failures. This is sometimes referred to as "burn-in."
4. Quantifying reliability to determine whether or not a product is ready for release; i.e., does the product meet the specified level of reliability?
5. Predicting warranty costs.
6. Deciding on the need for recall of a product in the field (and, if so, the extent of the recall).

Although the last four objectives are the ones that analysts are asked to respond to most often, concentrating on them is sometimes premature. The first objective is the most fundamental since one cannot demonstrate a high level of reliability if, in fact, it does not exist, and clearly it is desirable to avoid expensive burn-in and field recalls. However, much of the discussion in this section addresses the last four goals. Section 3 (The Quality Planning Process) and Section 19 (Quality in Research and Development) consider the entire process of assuring high reliability.

Sources and Types of Reliability Data.   It is important to distinguish between the following types of reliability data:

- A sequence of reported system repair times (or the times of other system-specific events) for a repairable system.
- The time of failure (or other clearly specified event) for nonrepairable units or components (including *nonrepairable* components within a *repairable* system).

When reliability tests are conducted on larger systems and subsystems (even those that may be repaired), it is essential that detailed component-level information on cause of failure be obtained. This is especially important if the purpose of the data collection is improvement of system reliability, as opposed to mere assessment of overall system reliability. Subsequent subsections describe methods for data analysis for nonrepairable units or components as well as for analyzing system repair data.

Reliability data arise from many different kinds of situations. Examples include:

- Laboratory tests to study durability, wear, or other lifetime properties of particular materials, components, or subsystems.
- Operational life tests on complete systems or subsystems, conducted before a product is released to customers.
- Field operation by customers.

Reliability data are typically censored, i.e., some units remain unfailed, and (at best) only their survival times, but not their failure times, are known. The most common reason for censoring is the need to analyze data before all units fail. The analysis of censored data is more complicated when the censoring times of unfailed units differ. This would happen when different units of the product are placed on test or enter into the field at different times, as is usually the case in analyzing field failure data. It may also be the case when units have different degrees of exposure over time or when one is evaluating failures due to a particular failure mode (in which case failures from other independent modes are treated as censored observations in the data analysis). An important assumption needed for standard analysis of censored data is that the censoring time for a unit is independent of when that unit would have failed. For example, if a unit were removed from the field because it is about to fail, treating it as a censored observation would bias the analysis.

Computer Software. In this section we focus on the methods and applications of reliability data analysis. We provide formulas only when they provide insight and will help readers to understand how to use the method.

Although it is possible to do some of the simplest reliability data analyses by hand, for maximally effective analyses, computer processing along with display using modern high-resolution graphics should be used.

Unfortunately, only a few of the best-known standard data analysis computer packages have adequate capabilities for doing reliability data analysis. As software vendors become more aware of their customers' needs, capabilities in commercial packages can be expected to improve.

SAS PROC RELIABILITY (SAS Institute 1996), SAS JMP (SAS Institute 1995), S-Plus (Statistical Sciences 1996), Minitab 12 (Minitab 1997), and a specialized program called WinSMITH (Abernethy 1996), can do product life data analysis for the simple (single-distribution) situation for which all life data are assumed to be in a single common environment. Ease of use and the character of the user interface vary widely over these packages. In addition, each of these programs, except WinSMITH, can do regression and accelerated life test analyses. SAS JMP can also analyze data with more than one failure mode. SAS PROC RELIABILITY can, in addition, do the nonparametric repairable systems analyses described in this section. Meeker and Escobar (1998) describe S-Plus functions that can be used to do all of the analyses described in this section.

LIFE DATA MODELS

This section deals mainly with nonrepairable components or other products that are replaced rather than repaired upon failure (or time to first failure on repairable products). The following are described:

1. Statistical models for representing time to failure of nonrepairable products.
2. Methods for estimating quantities of interest (e.g., failure probabilities, distribution quantiles) from time-to-failure data, with and without making any distributional assumptions.

We discuss initially models that deal with time to failure in a single-use environment. In our subsequent discussion of accelerated life tests we will describe corresponding regression models that explain the effect that factors like temperature have on life.

Time-to-Failure Model Concepts.   The distribution of time to failure T of a product can be characterized by a cumulative distribution function (cdf), a probability density function (pdf), a survival function (sf), or a hazard function (hf). The cdf and pdf are common ways of describing a statistical model in many applications (and are treated in elementary statistics courses). The hf, on the other hand, is not as well known, but it has particular applicability to product life data analysis. These functions are described below and illustrated (for one possible time-to-failure distribution) in Figure 48.1. The choice of which function or functions to use depends on the specific practical problem that is being addressed. All of these functions are important for one purpose or another.

The cdf for T, $F(t) = \Pr(T \leq t)$, gives the *probability* that a unit, selected at random from the population or process, will fail before time t. Alternatively, $F(t)$ can be interpreted as the *proportion* of units in the population (or from some stationary process) that will fail before time t. (Here a stationary process is defined as one that generates units that have a $F(t)$ that does not change over time.)

The sf (also known as the *reliability function*) is the complement of the cdf, $S(t) = \Pr(T > t) = 1 - F(t) = \int_t^\infty f(x)\, dx$, and gives the probability of surviving until time t.

The pdf for a continuous random variable T is defined as the derivative of $F(t)$ with respect to t: $f(t) = dF(t)/dt$. Thus, for a positive random variable, $F(t) = \int_0^t f(x)\, dx$. The pdf can be used to represent relative frequency of failure times as a function of time and can be thought of as a smoothed histogram of a large number of observed failure times.

The hf (also known as the hazard rate, the instantaneous failure rate function, and by various other names) is defined by:

Cumulative Distribution Function

Probability Density Function

Survival Function

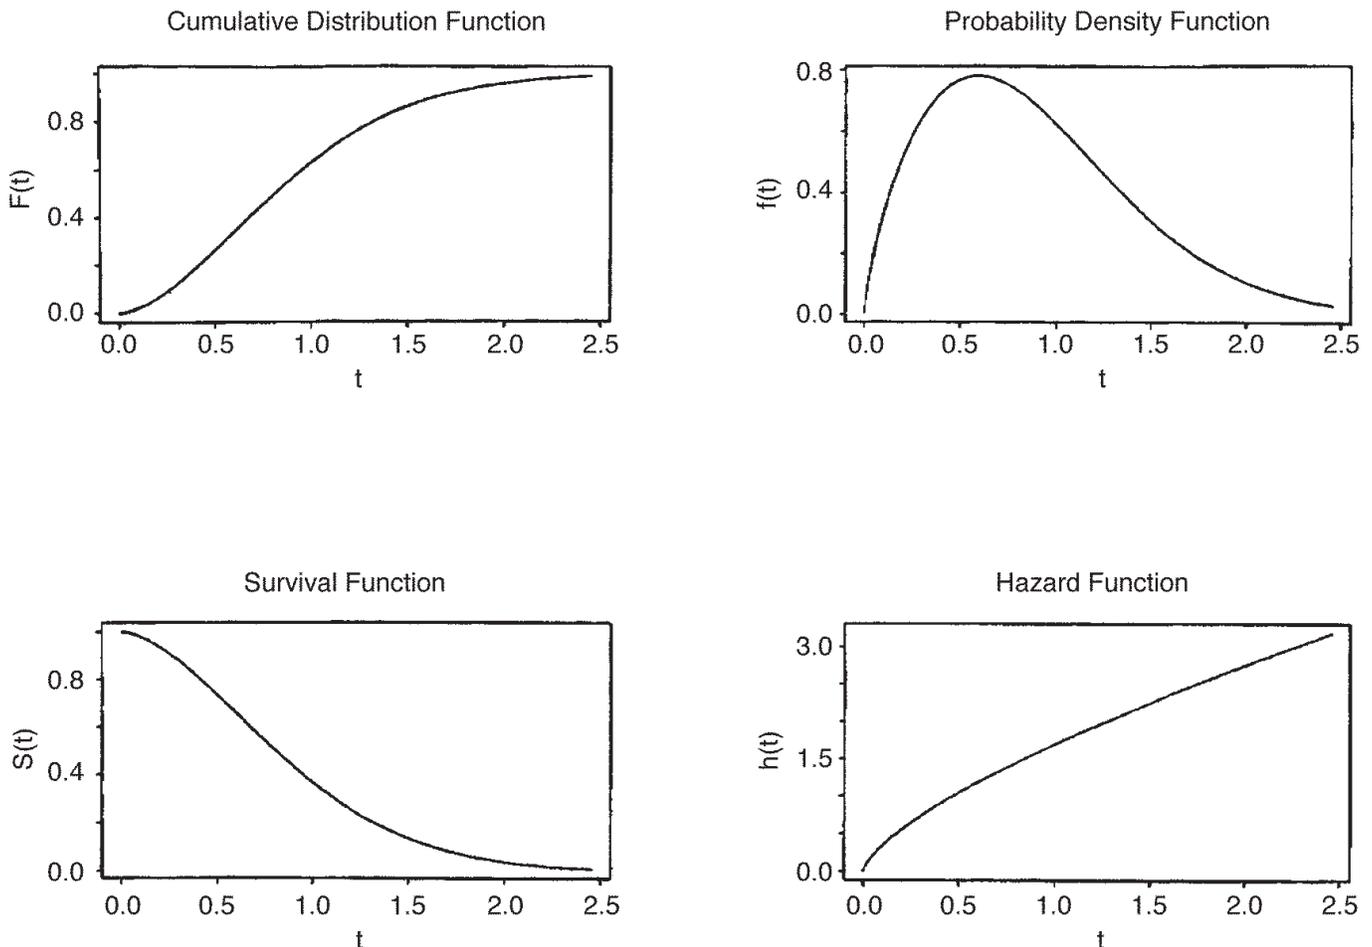
Hazard Function


FIGURE 48.1   Typical time-to-failure cdf, pdf, sf, and hf.

$$h(t) = \lim_{\Delta t \to 0} \frac{\Pr\ (t < T \le t + \Delta t \,|\, T > t)}{\Delta t} = \frac{f(t)}{1 - F(t)}$$

The hf expresses the propensity to fail in the next small interval of time, given survival to time t. That is, for small Δt, $h(t) \times \Delta t \simeq \Pr\ (t < T \le t + \Delta t \,|\, T > t)$. The hf can be interpreted as a failure rate in the following sense. If there is a large number of items [say $n(t)$] in operation at time t then $n(t) \times h(t)$ is approximately equal to the number of failures per unit time [or $h(t)$ is approximately equal to the number of failures per unit time per unit at risk]. Because of its close relationship with failure processes and maintenance strategies, reliability engineers often model time to failure in terms of $h(t)$. The "bathtub curve" shown in Figure 48.2 provides a useful conceptual model for the hazard of some product populations. There may be early failures of units with quality-related defects (infant mortality). During much of the useful life of a product, the hazard may be approximately constant because failures are caused by external shocks that occur at random. Late-life failures are due to wear-out. Many reliability tests focus on one side or the other of this curve.

Other Quantities of Interest in Reliability Analysis.   The mean (also known as the "expectation" or "first moment") of a positive random variable T is a measure of central tendency or "average" time, and it is defined by:

$$E(T) = \int_0^\infty t f(t)\ dt = \int_0^\infty [1 - F(t)]\ dt$$

When the probability density function $f(t)$ is highly skewed, e.g., has a long right tail (as is common in many life data applications), the mean time to failure may differ appreciably from other measures of central tendency like the median time to failure (the time by which exactly half of the population of units will fail). The mean time to failure $E(T)$ is sometimes abbreviated to MTTF.

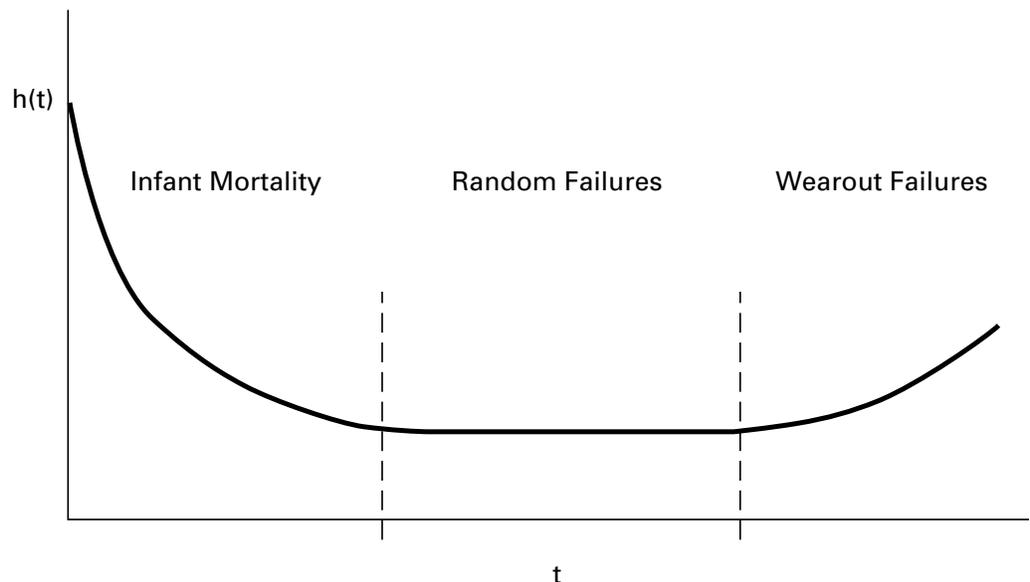
The traditional parameters of a statistical model (mean and standard deviation) are often *not* of primary interest in reliability studies. Instead, design engineers, reliability engineers, managers, and customers are interested in specific measures of product reliability or particular characteristics of the failure-time distribution, e.g., distribution quantiles. In particular, the quantile t_p is the time at which a specified proportion p of the population will fail. Also, $F(t_p) = p$. For example, $t_{.20}$ is the *time* by which 20 percent of the population will fail. Alternatively, frequently one would like to know $F(t)$, the *probability* of failure associated with a particular number of hours, days, weeks, months, or years of usage, e.g., the probability of a product failing (or not failing) during the first 5 years in the field.


FIGURE 48.2   Bathtub curve hazard function.

Common Parametric Time-to-Failure Distributions

The Exponential Distribution.   The exponential distribution cdf is

$$F(t;\, \theta) = 1 - \exp\left(-\frac{t}{\theta}\right) \qquad t > 0$$

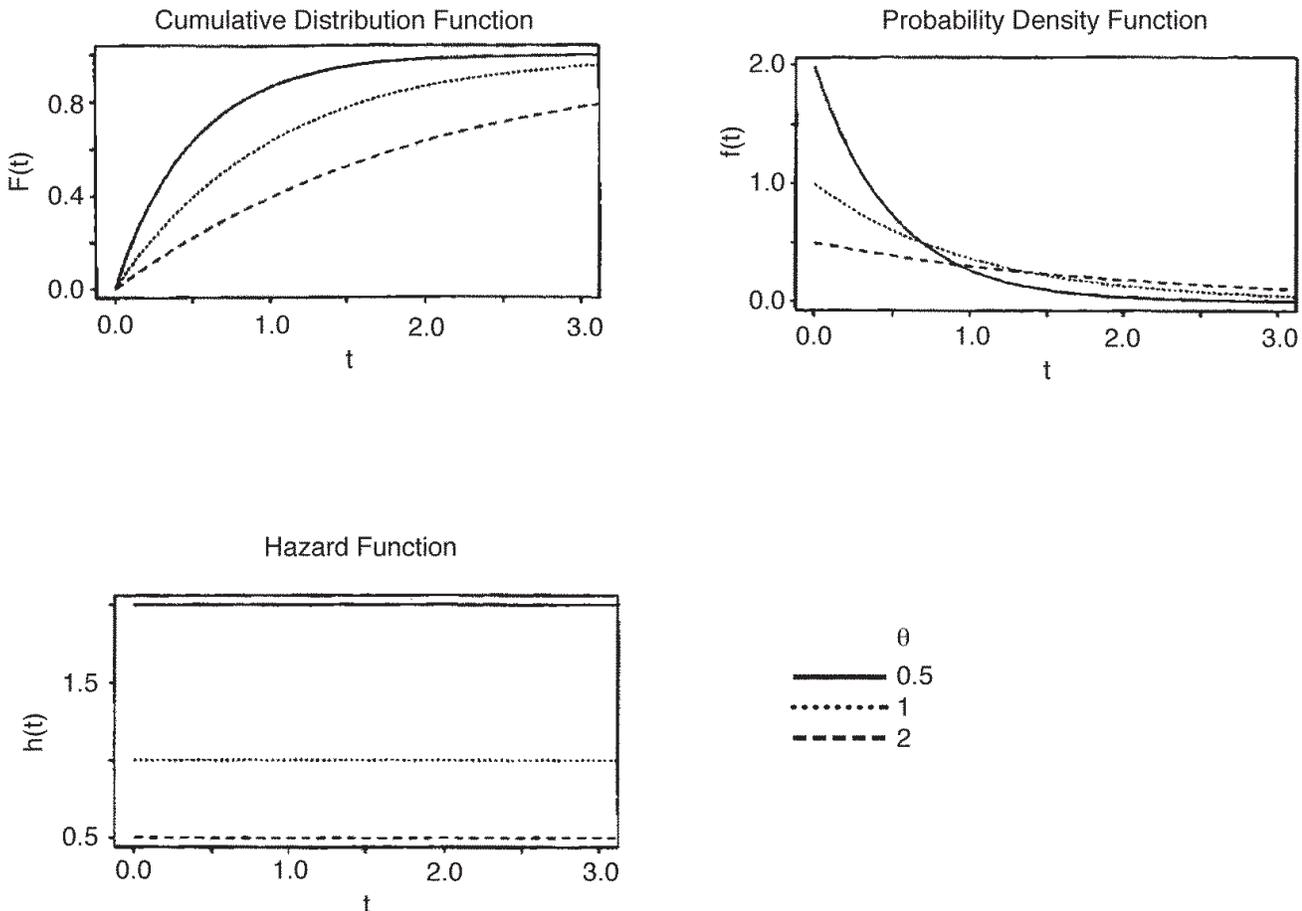
where the distribution's single parameter $\theta > 0$ is a scale parameter. The exponential distribution has no shape parameter and, thus, has only a single unique shape. The exponential cdf, pdf, and hazard function are graphed in Figure 48.3 for $\theta = .5$, 1, and 2. The p quantile of the exponential distribution is $t_p = -\theta \log(1 - p)$. The exponential distribution has the important characteristic that its hazard function $h(t) = 1/\theta$ is constant (does not depend on time t). A constant hazard implies that, for an unfailed unit, the probability of failing in the next interval of time is independent of the unit's age. Physically, a constant hazard implies that units in the population are not subject to an infant mortality failure mode and also are not wearing out or otherwise aging. Thus, this model may be appropriate when failures are induced by an external phenomenon that is independent of product life and past history. An example might be the life in service of a dish in a restaurant, whose end of life is the result of breakage. The exponential distribution is commonly, and sometimes incorrectly, used because of its simplicity. It would *not* be appropriate for modeling the life of mechanical components (e.g., bearings) subject to some combination of fatigue, corrosion, or wear or for electronic components that exhibit wear-out properties over their life (e.g., lasers and filament devices).


FIGURE 48.3   Exponential distribution cdf, pdf, and hf for $\theta = .5$, 1, and 2.

The Weibull Distribution.   The Weibull distribution cdf is

$$F(t; \eta, \beta) = 1 - \exp\left[-\left(\frac{t}{\eta}\right)^{\beta}\right] \qquad t > 0$$

where $\beta > 0$ is a shape parameter and $\eta > 0$ is a scale parameter (which is also approximately the .63 quantile of this distribution). The p quantile of the Weibull distribution is $t_p = \eta[-\log (1-p)]^{1/\beta}$. For example, the Weibull distribution median is $t_{.50} = \eta[-\log (1-.5)]^{1/\beta}$. The Weibull hazard function is $h(t) = (\beta/\eta)(t/\eta)^{\beta-1}$. The exponential distribution is a special case of the Weibull with $\beta = 1$. The practical importance of the Weibull distribution stems from its ability to describe failure distributions with many different commonly occurring shapes. As illustrated in Figure 48.4 with $0 < \beta < 1$, the Weibull hazard function is decreasing and with $\beta > 1$, the Weibull hazard function is increasing. Thus the Weibull distribution can be used to describe either decreasing hazard caused by infant mortality or increasing hazard due to wear-out, but *not* both. The Weibull distribution is often used as a model for the life of insulation and many other products as well as a model for strength of materials. For some applications there is theoretical justification for its use.

The logarithm of a Weibull random variable, $Y = \log(T)$, follows a smallest extreme value distribution so that

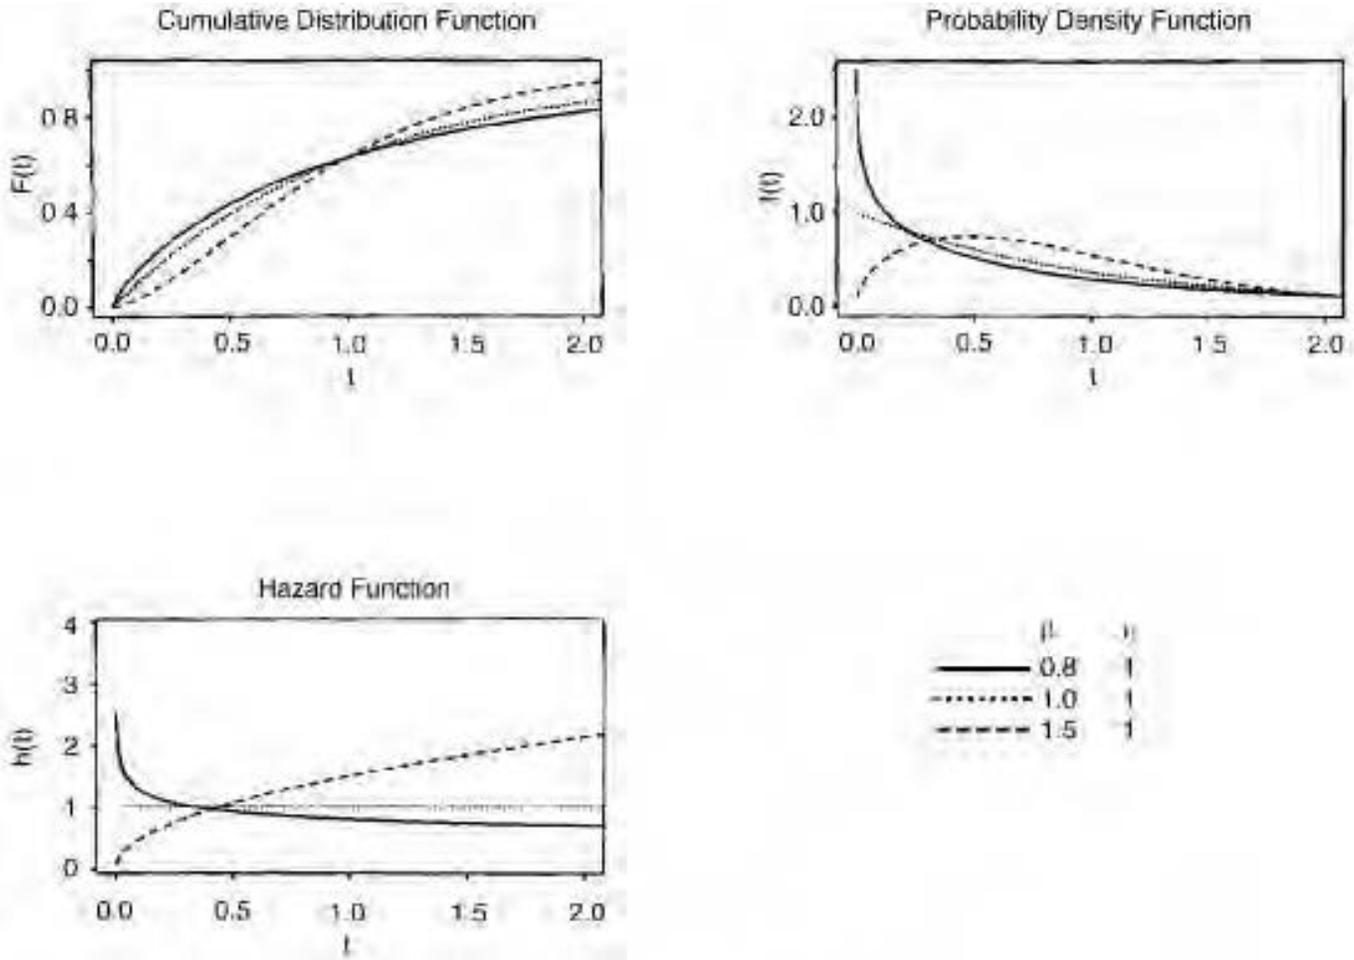
$$\Pr [\log(T) \le \log (t)] = F (t; \mu, \sigma) = \Phi_{sev}\left(\frac{\log (t) - \mu}{\sigma}\right)$$


FIGURE 48.4   Weibull distribution cdf, pdf, and hf for scale parameter $\eta=1$ and shape parameter $\beta=.8$, 1.0, and 1.5.

where $y = \log(t)$, $\Phi_{sev}(z) = 1 - \exp[-\exp(z)]$, $\mu = \log(\eta)$ is a location parameter with $-\infty < \mu < \infty$, and $\sigma = 1/\beta > 0$ is a scale parameter. The relationship between the Weibull and the smallest extreme value distribution is similar to the relationship between the normal and lognormal distributions and the relationship will be used later in this section in explaining methods for failure-time regression analysis and accelerated test modeling.

The Lognormal Distribution.   The normal distribution, though playing a central role in other statistical applications, is infrequently appropriate as a time-to-failure model. This is because failure can occur at times shortly after 0 hours, but they cannot be negative. Logarithms of failure times, however, are often described well by a normal distribution. This is equivalent to fitting a lognormal distribution. The lognormal cdf is

$$F(t;\ \mu,\sigma) = \Phi_{nor}\left[\frac{\log(t) - \mu}{\sigma}\right] \qquad t > 0$$

where Φ_{nor} is the cdf for the standard normal distribution (see Section 44). The parameter $\exp(\mu)$ is a scale parameter and the median of the distribution, $\sigma > 0$ is a shape parameter. The p quantile of the lognormal distribution is $t_p = \exp[\mu + \Phi_{nor}^{-1}(p)\,\sigma]$, where Φ_{nor}^{-1} is the inverse of the standard normal distribution. The relationship between the lognormal and normal distributions is often used to simplify the use of the lognormal distribution.

The lognormal distribution is commonly used as a model for the distribution of failure times. As shown in Figure 48.5, the lognormal hazard function always starts at 0, increases to a maximum, and then approaches 0 for large t.

Following from the central limit theorem (described in Section 44), application of the lognormal distribution could be justified for a random variable that arises from the product of a number of identically distributed independent positive random effects. For example, it has been suggested that the lognormal is an appropriate model for time to failure caused by a degradation process with combinations of random rate constants that combine multiplicatively. Correspondingly, the lognormal distribution is widely used to describe failure times due to fatigue and in microelectronic applications.

Other Life Distributions.   For more details for these and other distributions that can be used to describe life distributions, see Chapter 8 of Hahn and Shapiro (1967) and Chapters 4 and 5 of Meeker and Escobar (1998).

Multiple Failure Modes.   In more complex situations (e.g., products that have *both* infant mortality and wear-out modes, as in the bathtub curve situation, which was described earlier) the data cannot be fit by any of the preceding models. This is often the case when there is more than one failure mode. In such cases, if the individual failure modes can be identified, it is usually better to do the evaluations separately for each of these modes and then combine the results to get total system probabilities. See Chapter 5 of Nelson (1982) or Chapter 15 of Meeker and Escobar (1998) for examples.

ANALYSIS OF CENSORED LIFE DATA

This subsection illustrates simple, but powerful, methods for analyzing life data. The first example uses data from a laboratory life test. The second example illustrates the analysis of multiply censored data from a field tracking study. In both cases we proceed as follows:

1. Analyze the data graphically, using a nonparametric procedure (one that does not require any assumptions about the form of the underlying distribution) plotted on special probability paper. Such plots also allow us to explore the adequacy of possible distributional models.

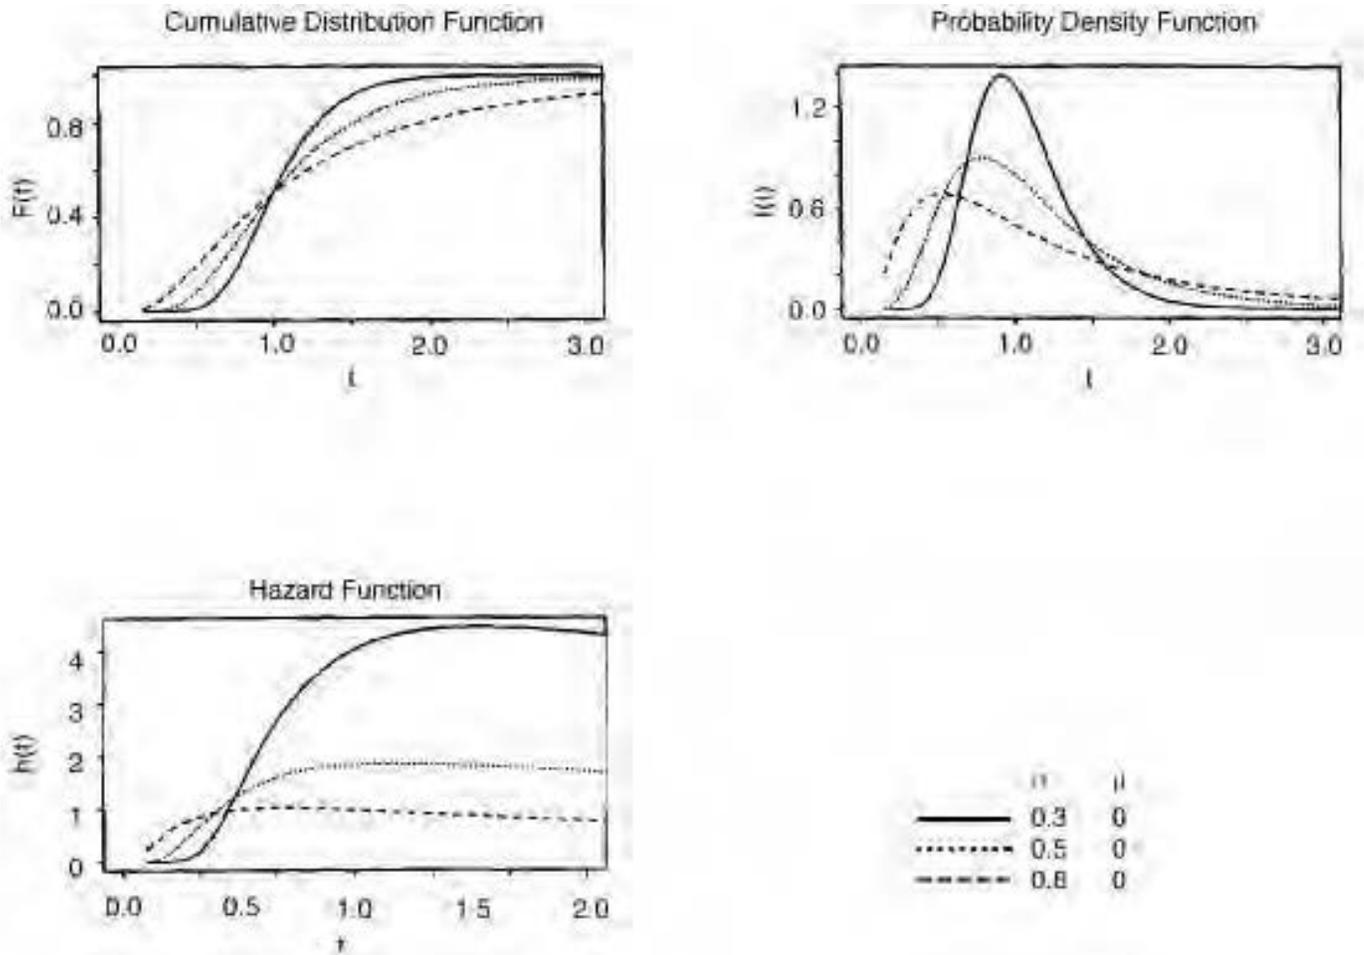
2. If a parametric distribution provides an adequate description of the available data, estimate the distribution parameters.


FIGURE 48.5 Lognormal distribution cdf, pdf, and hf for scale parameter $\exp(\mu) = 1$ and for shape parameter $\sigma = .3, .5,$ and $.8$.

3. Using these parameter estimates, estimate the distribution quantiles of interest, population proportion failing at specified times, hazard function values, and appropriate confidence intervals on some or all of these estimates.

Simple Life Test Data (with Single Censoring).

For sample life test data with n observations, continuous or very frequent monitoring for failures, and all censoring at the end of the observation period (typical for some laboratory life tests), a nonparametric estimate of $F(t)$ can be computed as

$$\hat{F}(t) = \frac{\text{number of failures up to time } t}{n} \tag{48.1}$$

This is a step function that jumps by an amount $1/n$ at each failure time (unless there are ties, in which case the estimate jumps by the number of tied failures divided by n). This estimate requires no assumption about the form of the underlying distribution. The estimate can be computed only up to the censoring time, and not beyond.

Example: Chain Link Fatigue Life. Parida (1991) gives the results of a load-controlled high-cycle fatigue test conducted on 130 chain links. The 130 links were randomly selected from a population of different heats used to manufacture the links. Each link was tested until failure or until it had run for 80 thousand cycles, which ever came first. There were 10 failures—one each at 33, 46, 50, 59,

62, 71, 74, and 75 thousand cycles and two at 78 thousand cycles. The remaining 120 links had not failed by 80 thousand cycles. Figure 48.6 shows the step-function nonparametric estimate of $F(t)$ for these data.

Probability Plotting.   Comparing data in plots like Figure 48.6 with theoretical cumulative distributions like those shown in Figures 48.3, 48.4, and 48.5 is difficult, because the human eye cannot easily compare nonlinear curves. Probability plots display data on special *probability scales* such that a particular theoretical cumulative distribution is a straight line when plotted on such a scale. For example, taking the log of the Weibull quantile gives the straight line $\log(t_p) = \log(\eta) + (1/\beta) \log [-\log(1-p)]$. Thus, appropriately plotting the data on probability paper, and assessing whether the plot reasonably approximates a straight line, provides a simple assessment of the adequacy of an assumed model. In addition, probability plots are commonly used to estimate

- Distribution quantiles
- Probabilities of surviving to specified lifetimes

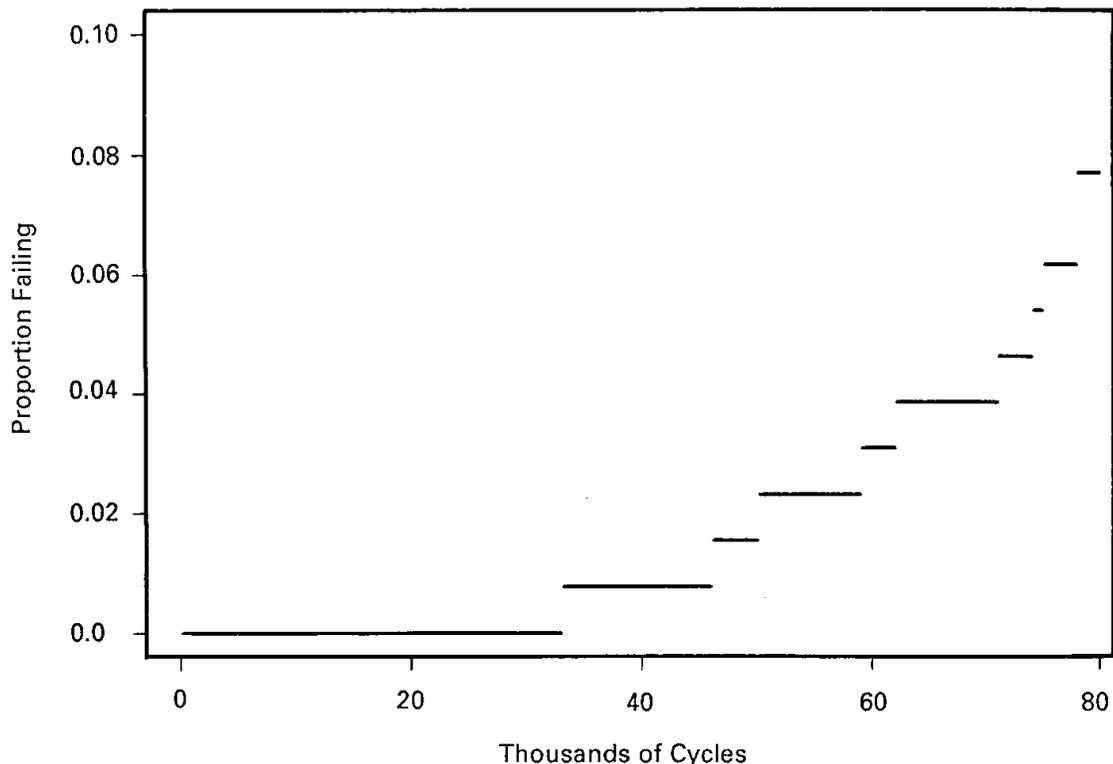
Figure 48.7 is a Weibull probability plot of the chain link failure data. One common method of making a probability plot is to plot the ith largest time (or number of cycles at failure) value on the time axis versus $(i-.5)/n$ on the probability axis for $i = 1,2,\ldots$. This is equivalent to plotting, at each jump in the step function of Figure 48.6, the time of the step versus the point halfway between steps, as shown in Figure 48.7. Drawing a curve through these points allows one to estimate distribution quantiles and survival probabilities, without assuming any distributional model. However, the points plotted on Figure 48.7 fall nearly along a straight line, indicating that the Weibull distribution provides a good fit to the data. Figure 48.7 contains a special "β" scale that allows one to obtain a graphical estimate of the Weibull shape parameter. This is done by drawing a line through the cross mark on the top of the plot, parallel to the line that seems to best fit the data points. Then the graphical estimate of β is read off the "β" scale. In this case, the graphical estimate of the Weibull shape para-


FIGURE 48.6   Nonparametric estimate of $F(t)$ for the chain link failure data.
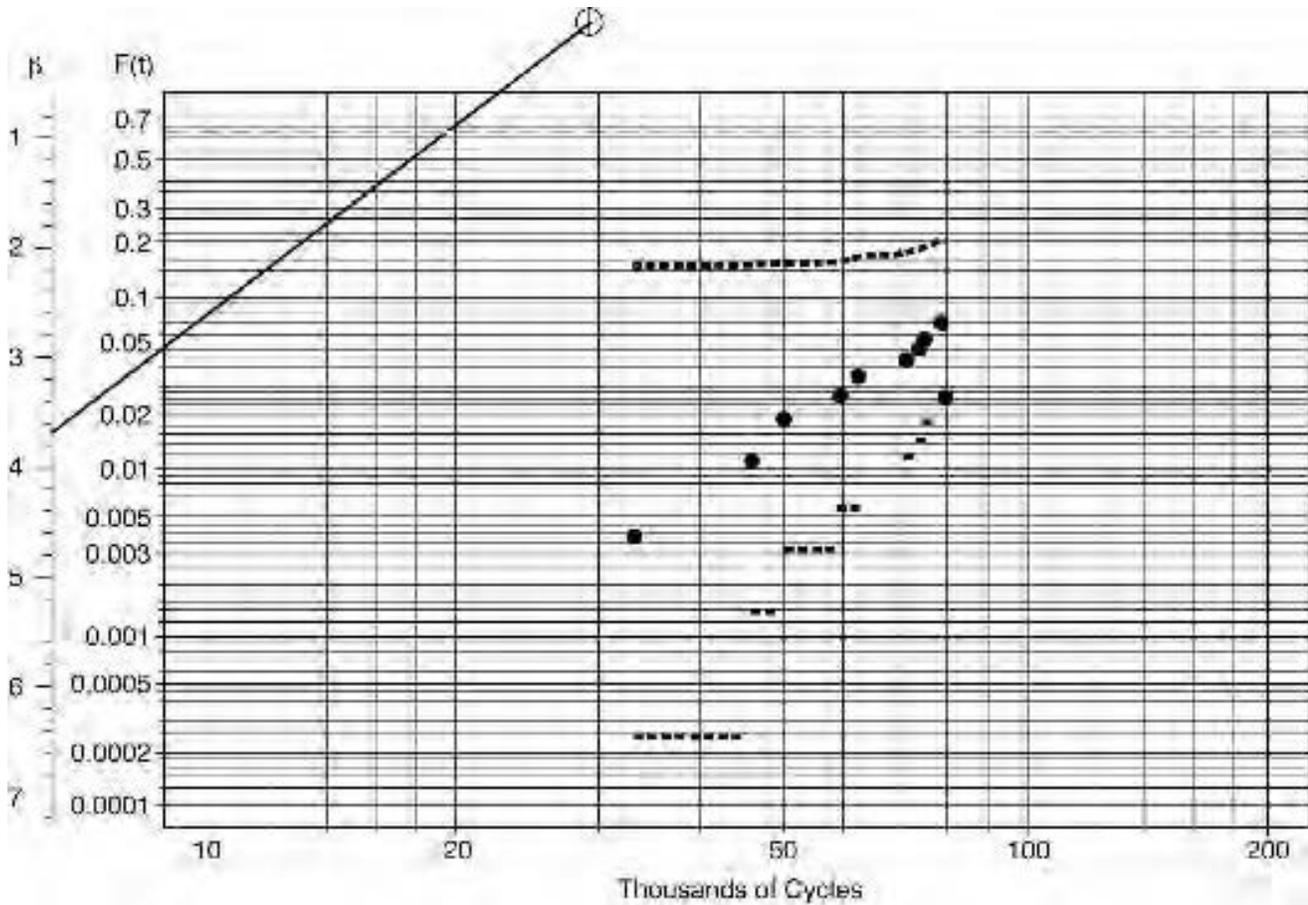

FIGURE 48.7   Weibull probability plot for the chain link failure data with 95 percent simultaneous confidence bands.

meter is $\hat{\beta} \simeq 3.62$. A graphical estimate of the Weibull scale parameter η can be obtained by drawing a line to fit the plotted points and reading off an estimate of the .63 quantile, giving $\hat{\eta} \simeq 185$ in the example. The grid lines on Figure 48.7 are useful for plotting by hand or for reading numbers from the plot. It can be argued that the grid lines interfere with the interpretation of the graph, and their inclusion should be a software option.

The light dotted points on this probability plot are 95 percent simultaneous nonparametric (i.e., without any parametric distribution assumption) confidence bands that help judge the sampling uncertainty in the estimate of $F(t)$. These confidence bands are obtained by using the method described in Nair (1984) and are defined by the inversion of a distributional goodness of fit test. If one can draw a straight line through the confidence bands, as is the case here, then the distribution implied by the probability paper (Weibull for Figure 48.7) cannot be ruled out as a model that might have generated the data.

A similar lognormal plot (not shown here) suggested the data could also have come from a lognormal distribution. The lognormal distribution assumption provides somewhat similar estimates for, say, quantiles within the range of the data, but appreciable differences outside the range.

Maximum Likelihood Estimation.   The maximum likelihood (ML) method provides a formal, objective, statistical approach for fitting a life distribution, using an assumed model, and estimating various properties, such as distribution quantiles and failure probabilities. A probability plot can also be used to show the ML estimate of $F(t)$. In fact, fitting a Weibull distribution using ML is an objective way of fitting a straight line through data points on a probability plot. Computer programs are convenient for this task. Least squares (using standard linear regression methods) can also be used to fit such a line to the plotted points. ML is, however, the preferred method, especially with

censored data, because of its desirable statistical properties and other theoretical justifications. Figure 48.8 is similar to Figure 48.7, but gives a computer-generated Weibull probability plot for the chain link data with the fitted ML line superimposed. The dotted lines are drawn through a set of 95 percent parametric *pointwise* normal-approximation confidence intervals for $F(t)$ (computed as described in Chapter 8 of Meeker and Escobar 1998). For some purposes, the uncertainty implied by the intervals in Figure 48.8 would suggest that more information is needed. The next subsection discusses methods for choosing the sample size to control the width of confidence intervals for Weibull quantiles.

The probability plot in Figure 48.8 might invite extrapolation beyond the range of the observed times to failure in either direction. It is important to note, however, that such extrapolation is dangerous; the data alone do not tell us about the shape of $F(t)$ outside the range of 30 to 90 thousand cycles. Moreover, the confidence intervals, even though they are wider outside the data range, reflect only the uncertainty due to limited data, and assume that the fitted Weibull model holds beyond, as well as within, the range of the data.

Guidelines for Choosing the Sample Size in Life Tests.   Generally, larger samples lead to more precise estimates. This subsection shows how to choose the sample size n to control precision in a simple life test. Certain input information is required, as illustrated in the following example.

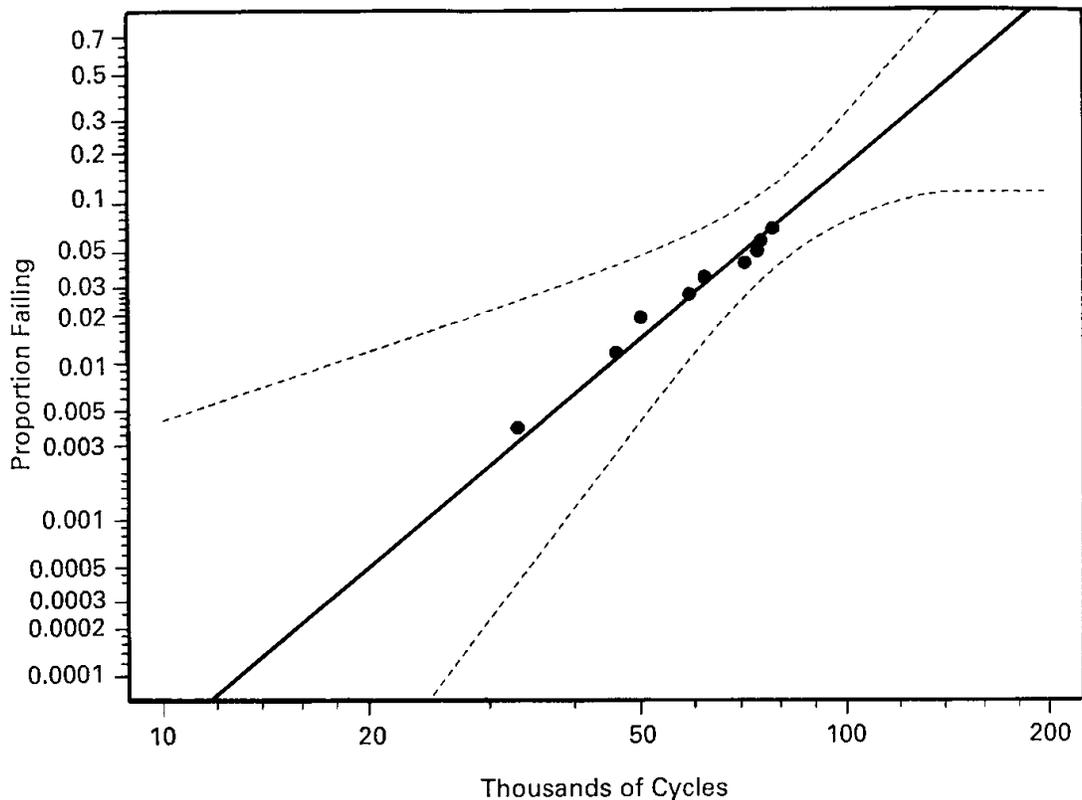
Planning Values for Sample Size Determination.   For purposes of illustration assume that investigators intend to run a life test for a new mechanical device. The test will run for 30 days and the experimenters, from past experience, expect that about 7 percent of the units will fail in that time. From past experience with similar products, they expect the data to fit a Weibull distribution with a shape parameter near $\beta = 3$.


FIGURE 48.8   Weibull probability plot with the Weibull ML estimate and a set of pointwise approximate 95 percent confidence intervals for $F(t)$ for the chain link failure data.

Using Simulation to Evaluate Precision.   The plots in Figure 48.9 compare simulations of ML cdf estimates for the above testing situation (Weibull distribution with $\eta = 30[-\log(1-.07)]^{-1/3} = 71.92$ days and $\beta = 3$) with a fixed censoring time of 30 days for sample sizes $n = 40, 160, 640,$ and 2560; each simulation is based on 30 random samples of size n. In each plot, the thicker, longer line shows the cdf of the assumed underlying "true" population distribution, from which the simulated data were generated. The other lines show the cdf, as estimated from each of the 30 simulations. A comparison of the plots shows that with a small sample size, the estimated line can depart appreciably from the true line. Looking at the horizontal dashed line allows us to see the improvement in precision for estimating the time at which 1 percent of the population will fail as the sample size increases. For example, for $n = 40$, the 30 estimates of t_{01} range from 5.9 to 28.0 days, while for $n = 2560$, the range is 11.2 to 14.2 days. Thus, such simulations allow us to assess the precision that can be expected in the estimates from a planned study and from this choose an appropriate sample size.

Analytical Formula for Sample Size.   If one prefers an analytic approach to find the sample size needed to estimate the quantile t_p of a Weibull distribution with a specified degree of precision, one can use a simple approximate formula, supplemented by a set of curves. Thus, in our example, we might wish to estimate the .01 quantile within 40 percent of its true value with 95 percent confidence. The approximate formula is

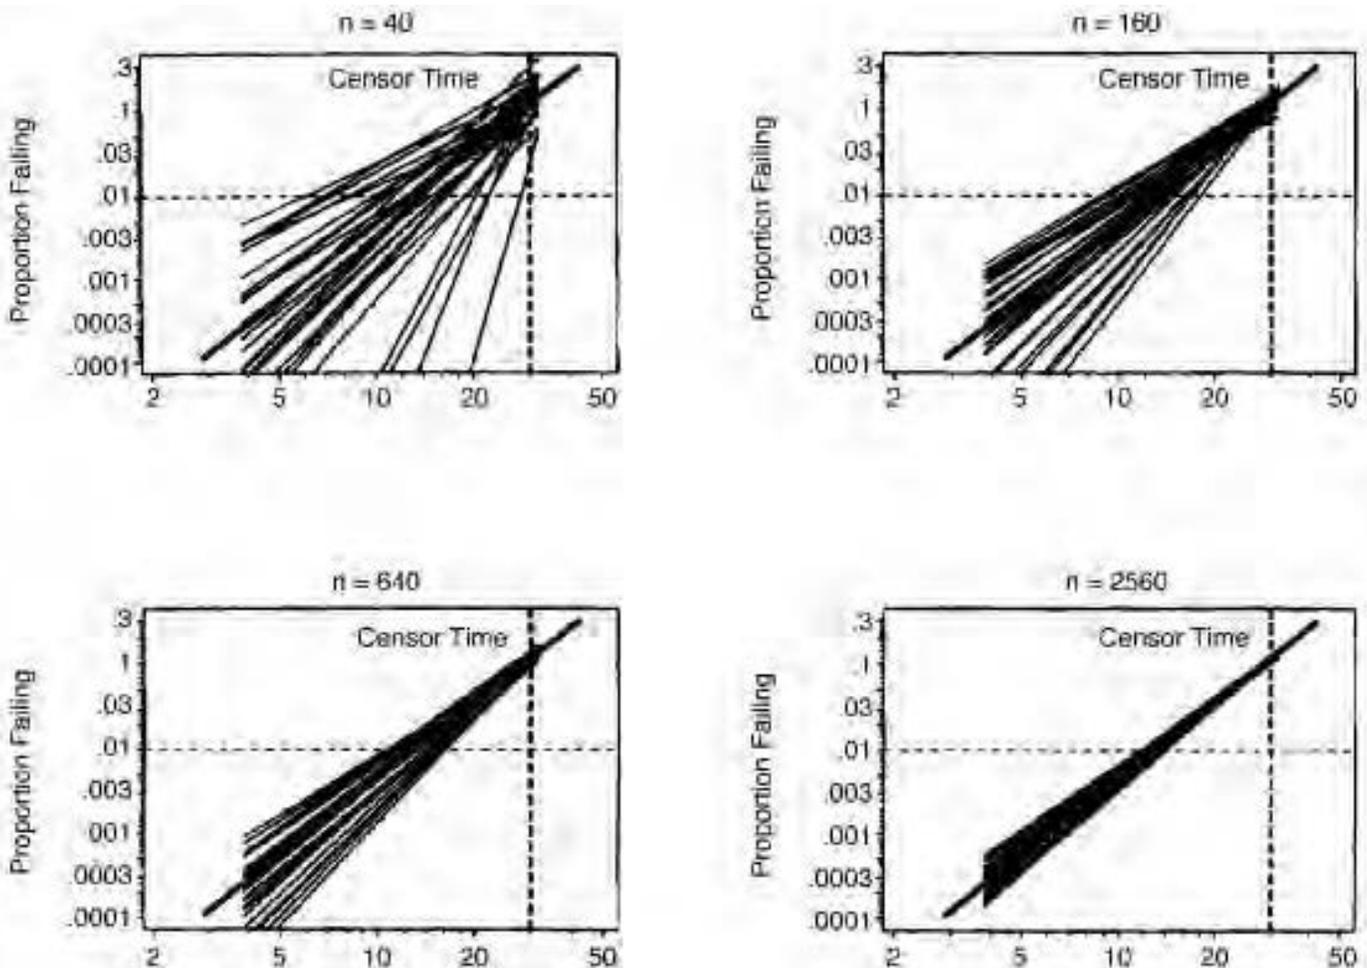
$$n = \frac{z^2_{(1-\alpha/2)}V^{\square}}{[\log(R_T)]^2}$$


FIGURE 48.9   Weibull probability plots showing the cdf, and the estimated .01 quantile as estimated by ML, for 30 simulated samples of size $n=40, 160, 640,$ and 2560 from a Weibull distribution with $\eta=71.92$ and $\beta=3$.

where $z_{(1-\alpha/2)}$ is the $1 - \alpha/2$ quantile of the standard normal distribution, $1 - \alpha$ is the desired level of confidence, $R_T > 1$ is the target precision, and $V^\square$ is the value read from Figure 48.10, multiplied by $(\beta^\square)^2$ where $\beta^\square$ is a "planning value" for the Weibull distribution parameter β. In our example $\beta^\square = 3$. For a 95 percent confidence interval $\alpha = .05$, $1 - \alpha/2 = .975$ so $z_{.975} = 1.96$. Typical values of R_T range from 1.2 to 2, where the desire is to have confidence interval endpoints not more than $100(R_T - 1)$ percent above and below the point estimate for t_p. In our example $R_T = 1.4$. Figure 48.10 gives a plot of the large-sample approximate variance factor $\beta^2 \times V$ for estimating t_p. A smaller variance implies better estimation precision. Each line gives $\beta^2 \times V$ as a function of the quantile p whose value is to be estimated from the life test; in our example $p = .01$. There are different lines for different values of p_c, the expected proportion failing during the life test. In our example, $p_c = .07$. The curves in Figure 48.10 are then used to read $\beta^2 \times V$ using p and p_c and then solve for the value $V^\square$ of V, using $\beta^\square$. If the model and planning values are correct, the actual precision achieved will be smaller than the target precision R_T with probability approximately .5.

For the example, entering Figure 48.10 with $p_c = .07$ and $p = .01$, we read the ordinate $V^\square \times (\beta^\square)^2 \simeq 70$, so $V^\square \simeq 70/(3)^2 = 7.778$. Thus, with $R_T = 1.4$,

$$n = \frac{z_{(1-\alpha/2)}^2 V^\square}{[\log (R_T)]^2} = \frac{(1.96)^2(7.778)}{[\log (1.4)]^2} \simeq 264$$

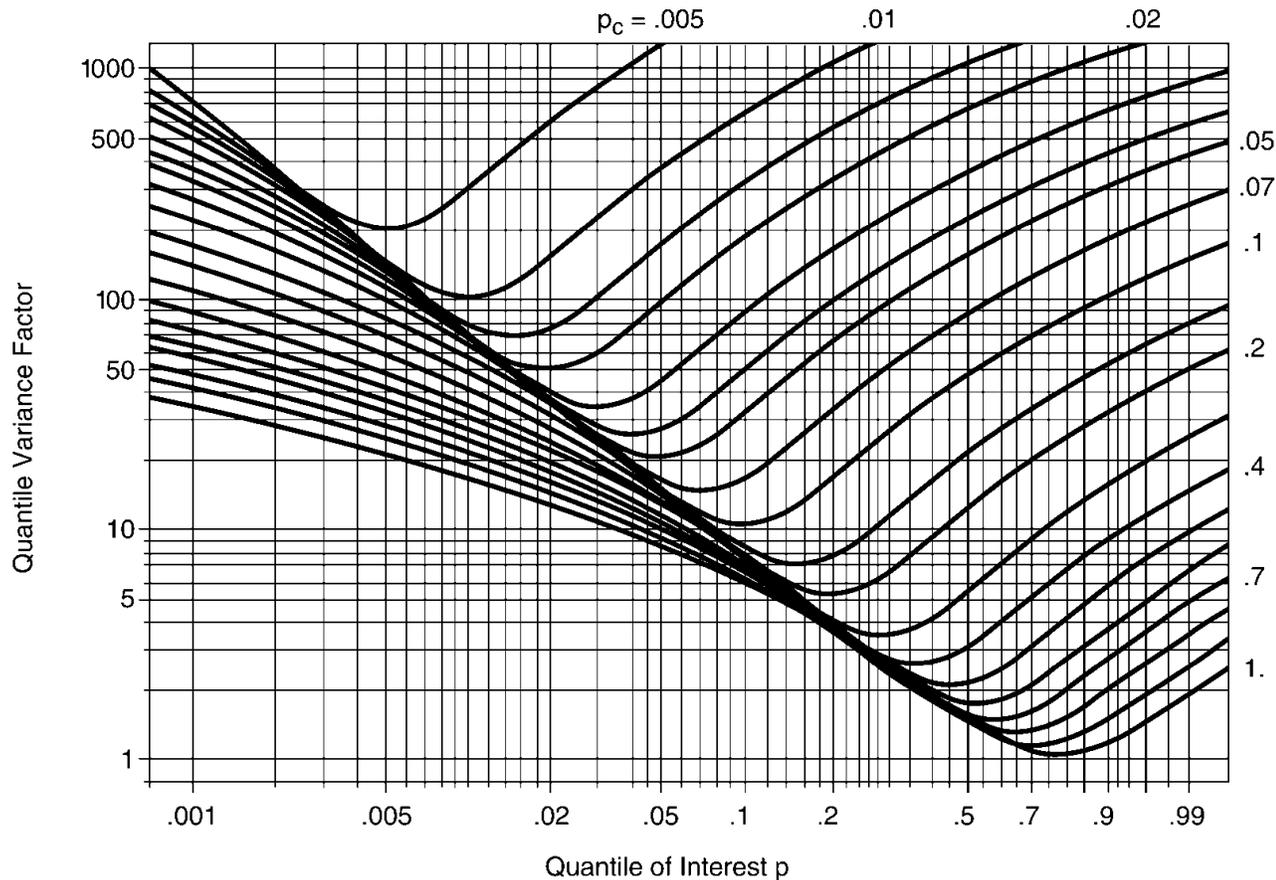
is the number of items that should be tested. In summary, in order to estimate the 0.01 quantile within 40 percent of its true value with 95 percent confidence, we need to test approximately 264 units up to 30 days (under the assumption of a Weibull distribution with shape parameter 3 and an expected 7 percent failures after 30 days).


FIGURE 48.10   Large-sample approximate variance factor $\beta^2 \times V$ for ML estimation of Weibull distribution quantiles as a function of p_c, the population proportion failing by censoring time t_c and p, the quantile of interest.

Analysis of Multiply Censored Data.   Multiple censoring can arise when units go into service at different times or units accumulate varying running times over a particular elapsed time period (likely in the field), or in a variety of other situations (such as the analysis of a particular failure mode, for which units that fail independently due to other modes are taken as still running with regard to the mode under evaluation). In this case, often some running times for unfailed units are less than some failure times. Multiple censoring is encountered frequently in practice, especially in dealing with field life data. For such data, the cumulative failure probability $F(t)$ cannot be estimated directly using (48.1). Instead an alternative estimator, to be described below, is used. The ML estimates and approximate confidence intervals that were previously mentioned still do apply.

Example: Shock Absorber Failure Data.   O'Connor (1985) gives failure data for shock absorbers. At the time of analysis, failures had been reported at 6700, 9120, 12,200, 13,150, 14,300, 17,520, 20,100, 20,900, 22,700, 26,510, and 27,490 km. There were 27 units in service that had not failed. The running times for these units were 6950, 7820, 8790, 9660, 9820, 11,310, 11,690, 11,850, 11,880, 12,140, 12,870, 13,330, 13,470, 14,040, 17,540, 17,890, 18,450, 18,960, 18,980, 19,410, 20,100, 20,150, 20,320, 23,490, 27,410, 27,890, and 28,100 km.

To estimate $F(t)$ with multiply censored data, we use the following nonparametric procedure (i.e., no distribution model assumed). Let $t_1, t_2, \ldots, t_r$ denote the times at which failures occurred, let d_i denote the number of units that failed at t_i, and let n_i denote the number units that are unfailed just before t_i. The estimator of $F(t)$ for all values of t between t_i and t_{i+1} is

$$F(t_i) = 1 - \prod_{j=1}^{i}\left(1 - \frac{d_j}{n_j}\right) \qquad i = 1, \ldots, r \tag{48.2}$$

This is the well-known product-limit or Kaplan-Meier estimator. It can be used only within the range of the failure data. The justification for this estimator is based on the relationship between the cdf and the discrete-time hazard function and is described more completely in Chapter 3 of Meeker and Escobar (1998). Calculations of the estimated cumulative failure probability $F(t_i)$ and the estimated survival probability $S(t_i)$ to 12,200 km for the shock absorber data are illustrated in Table 48.1. This table could have gone up to 27,490 km—the largest failure time.

Figure 48.11 shows the shock absorber data plotted on Weibull probability paper, with the points plotted at each of the failure times at a height halfway between the jumps in the nonparametric cdf estimate in Table 48.1 (extended to 27,490 km). Figure 48.11, like Figure 48.8, also shows the Weibull ML cdf estimate and a set of approximate 95 percent pointwise confidence intervals for $F(t)$. The plot shows that the Weibull distribution fits the data well. A similar lognormal probability plot

(not shown here) did not fit nearly as well. Although the plotted points represent a nonparametric estimate that is *not* based on any assumed distribution, the straight line drawn through the points on Weibull probability paper, by ML, freehand, or some other method is a parametric estimate that, unlike the nonparametric estimate, allows extrapolation in time. Extrapolation outside the range of the data is, however, dangerous because the assumed distribution model, though providing a reasonable fit near the center of the data, may no longer apply beyond the extremes.

Chapter 4 of Nelson (1982) describes hazard plotting, an alternative graphical method of nonparametric estimation for multiply censored data. The two methods are very similar and generally provide similar estimates.

ACCELERATED LIFE TEST MODELS AND DATA ANALYSIS

Estimating the time-to-failure distribution or long-term performance of components of *high-reliability* products is particularly difficult. Most modern products are designed to operate without failure for years, decades, or longer. Thus, we might expect that few units will fail in a test of practical length at normal use conditions. For example, the design and construction of a new communications satellite or a new appliance may allow only 8 months to test components that are expected to be in service for 15 or 20 years. For such applications, Accelerated Life Tests (ALTs) are used widely, particularly to obtain timely information on the reliability of simple product components, materials, and to provide early identification (and removal) of failure modes, thus improving reliability. There are difficult practical and statistical issues involved in accelerating life, especially for a complicated product that can fail in different ways. Here we describe accelerated life tests for components, materials, or products with a single failure mode. Extensions are described in Chapter 7 of Nelson (1990). As previously suggested, the analysis of life data with various independent failure modes often calls

for considering failure modes one at a time, treating failures from other modes as if they are unfailed, and then combining the results.

Often, information from tests at high levels of stress (e.g., use rate, temperature, voltage, or pressure) is extrapolated, through a physically reasonable statistical model, to obtain estimates of life or long-term performance at lower, normal levels of stress. In some cases, stress is increased or otherwise changed during the course of a test (step-stress and progressive-stress ALTs). ALT results are used in the reliability-design process to assess or demonstrate component and subsystem reliability, certify components, detect failure modes, compare different manufacturers, and so forth as *speedily* as possible. ALTs have become increasingly important because of rapidly changing technologies, more complicated products with more components, the pressures for rapid new product introduction, and higher customer expectations for better reliability (in place of a traditional "ship and fix later" approach).

Methods of Acceleration.   Three different methods of accelerating a reliability test are

- Increase the use rate (or cycling rate) of the product. A typical toaster is designed for a median lifetime of 20 years with a usage rate of twice each day. If, instead, we test the toaster 365 times each day, we could reduce the median lifetime (for many potential failure modes) to about 40 days. Also, because it is not necessary to have all units fail in a life test, useful reliability information might be obtained in a matter of days instead of months. This form of acceleration is the simplest to handle, since the methods for a single distribution can generally be applied directly (after making an appropriate time transformation). Thus, this situation will not be discussed further. The key assumption is that the increased use rate will not introduce new failure modes or change the damage per cycle rate for existing failure modes (e.g., due to overheating of cycled components).

- Increase the aging rate of the product. For example, increasing temperature or humidity can accelerate the chemical processes of certain failure modes such as chemical degradation (resulting in eventual weakening) of an adhesive mechanical bond or the growth of a conducting filament across an insulator (eventually causing a short circuit).

- Increase the level of stress (e.g., voltage or pressure) under which test units operate. A unit will fail when its *strength* drops below applied stress. Thus, a unit with degrading strength at a high level of stress will generally fail more rapidly than it would have failed at a low level of stress.

Combinations of these methods of acceleration can also be employed. A factor like voltage will, for some failure modes, both increase the rate of an electrochemical reaction (thus accelerating the aging rate) and increase stress relative to strength. In such situations, when the effect of stress is complicated, there may not be enough knowledge to provide an adequate physical model for acceleration. Empirical models may or may not be useful. See Chapter 2 of Nelson (1990) or Chapter 18 of Meeker and Escobar (1998) for more discussion.

Acceleration Models.   Analysis of accelerated life tests, other than those that just increase the product use rate, requires a physically reasonable model relating acceleration variables like temperature, voltage, pressure, and size to time to failure. One then fits the model to the data to describe the effect that the factors have on failure.

Physical Acceleration Models.   For well-understood failure modes, it may be possible to use a model based on physical/chemical theory that will be capable not only of describing the failure-causing process over the range of the data, but also allow extrapolation to use conditions based on accelerated testing. Usually the actual relationship between acceleration variables and the actual failure mechanism is extremely complicated. Often, however, it is possible to find a physical simplification that will adequately capture and describe the dominant aspect of the process. For example, failure may be affected by a complicated chemical process with many steps, but there may be one rate-limiting (or dominant) step, and a good understanding of this part of the process may provide a model that is adequate for extrapolation. See Meeker and LuValle (1995) and Chapter 2 of Nelson (1990) for examples.

Empirical Acceleration Models.   When there is little understanding of the chemical or physical processes leading to failure, it may be impossible to develop a model based on physical/chemical theory. An empirical model may be the only alternative. However, such a model might provide an excellent fit to the available data, but may be highly incorrect when extrapolated to the use conditions of real interest. In some situations there may be extensive experience with an empirical model and this may provide the needed basis for extrapolation to use conditions.

Some guidelines for the use of acceleration models include:

- Use physical theory as much as possible, and choose accelerating variables (e.g., temperature, voltage, or humidity) that correspond to factors that cause actual failures.

- Investigate previous attempts to accelerate failure modes similar to the ones of interest. There are, for example, many research reports and papers on physics of failure. Chapter 2 of Nelson (1990) or Chapter 18 of Meeker and Escobar (1998) provide examples and references.

- Design accelerated tests to minimize, as much as possible, the degree of extrapolation required [see Meeker and Hahn (1985), Chapter 6 of Nelson (1990), and Chapter 20 of Meeker and Escobar (1998)]. Highly accelerated testing can cause failure modes that would not occur at use conditions. If extraneous failures are not recognized they can lead to seriously incorrect conclusions. Note that product life data can be analyzed, using maximum likelihood methods, even though at some test conditions the majority, or even all, of the test units remain unfailed. This allows us to be much more conservative in establishing testing conditions than would otherwise be the case, (i.e., include tests at or close to the use conditions). See Meeker and Hahn (1985) or Nelson (1990) for details.

- Most accelerated tests are used to obtain information about a single, relatively simple, failure mode (or corresponding degradation measure). If there is more than one failure mode, it is likely that the different failure modes will be accelerated at different rates and, unless this is accounted for in the modeling, testing, and analysis, the resulting inferences could be seriously incorrect.

- In practice, acceleration relationships are difficult to verify in their entirety. The accelerated life test data should be used to look for departures from the assumed acceleration model. It is important to recognize, however, that the available data will generally provide very little power to detect anything but the most serious departures, and typically there is no useful diagnostic information close to use conditions.

- Simple models with the right shape have generally proven to be more useful for extrapolation to use conditions than elaborate multiparameter models. For example, even if there is some evidence of curvature in ALT data, a simple linear model relating the accelerated stress variable to time to failure will generally provide more accurate extrapolation than a fitted quadratic model.

- Sensitivity analyses should be used to assess the effect of perturbing uncertain inputs (e.g., inputs related to model assumptions). For example, it is useful to compare the extrapolations to use conditions with different assumed time-to-failure distributions, or different physically reasonable models relating stress to life.

- Include some test units at conditions at which no failures would be expected during the duration of the test (e.g., at or near use conditions). If failures do, indeed, take place at these conditions it would raise serious concerns about reliability (and suggest that the assumed model is inadequate).

- Accelerated life test programs should be planned and conducted by teams including individuals knowledgeable about the product and its use environment, the physical/chemical/mechanical aspects of the failure mode, and the statistical aspects of the design and analysis of reliability experiments.

The next subsection describes a simple temperature-acceleration model and illustrates the analysis of data from an ALT.

Elevated Temperature Acceleration.   High temperature has been said to be the enemy of reliability. Increasing temperature is one of the most commonly used methods to accelerate failures.

The Arrhenius relationship is a well-known model describing the effect that temperature has on *R,* the rate of a simple chemical reaction. This model for reaction rate can be written as

$$R(\text{temp}) = \gamma_0 \exp\left(\frac{-E_a}{k_B \times \text{temp K}}\right) = \gamma_0 \exp\left(\frac{-E_a \times 11,605}{\text{temp K}}\right)$$

where temp K = temp °C + 273.15 is temperature in the absolute Kelvin scale, $k_B = 1/11,605$ is Boltzmann's constant in units of electron volts per degrees Celsius and E_a is the reaction activation energy in electron-volts. The parameters E_a and γ_0 are generally unknown product or material characteristics. In some simple situations, the failure-causing process can be modeled adequately by such a simple chemical reaction. In such cases, if log (*T*) follows a distribution with a location and scale parameter (so that the time to failure *T* could, for example, be described by a lognormal distribution or a Weibull distribution) with parameters μ and σ then the life distribution can be written as a function of temperature:

$$\Pr(T \leq t; \text{temp}) = \Phi\left[\frac{\log(t) - \mu(\text{temp})}{\sigma}\right]$$

where $\Phi = \Phi_{\text{nor}}$, and $\Phi = \Phi_{\text{sev}}$ (see earlier discussion) for the lognormal and Weibull distributions, respectively, $\mu(\text{temp}) = \beta_0 + \beta_1 x$, $x = 11,605/(\text{temp K})$, and $\beta_1 = E_a$. This is known as the Arrhenius failure-time model. One would then use life data at various accelerated temperatures and the resulting observed times to failure to estimate β_0, β_1, and σ.

Although the Arrhenius model does not apply to all temperature-acceleration problems and will be adequate over only a limited range of temperatures (depending on the particular application), it is used widely in many areas of application. Nelson (1990, p. 76) comments that "…in certain applications (e.g., motor insulation), if the Arrhenius relationship…does not fit the data, the data are suspect rather than the relationship."

Similar life-stress regression relationships have been used for other accelerating variables like voltage, pressure, humidity, cycling rate, and specimen size. See Chapter 2 of Nelson (1990) and Chapter 18 of Meeker and Escobar (1998) for examples and further references.

Planning an ALT.   Usually accelerated life tests need to be conducted within stringent cost and time constraints. Careful planning is essential. Resources need to be used efficiently, and the degree of extrapolation minimized, to the greatest degree possible. Meeker and Hahn (1985), Chapter 6 of Nelson (1990), and Chapter 20 of Meeker and Escobar (1998) describe methods for planning statistically efficient ALTs that meet practical constraints. During the test planning phase of a study, experimenters should try to explore the kind of results that they might obtain as a function of the assumed model and proposed test plan. Simulation methods, such as described in discussion of the guidelines for choosing sample size, also provide useful insights in this process.

Strategy for Analyzing ALT Data.   This subsection outlines a useful procedure for analyzing ALT data when multiple units are life tested at three or more conditions (e.g., three or more temperatures). See, for example, the data in Table 48.2.

The basic idea is to start by analyzing the data at each test condition separately and then to fit a model that ties together the data at the different conditions. Briefly, the strategy, as illustrated in the example that follows, is to:

1. Construct probability plots of the data at each test condition (level of the accelerating factor) separately, to suggest and explore the adequacy of possible distributional models.

2. At each test condition with two or more failures, fit models, as suggested by the previous step, individually to the data using the ML method. Plot the ML lines on a multiple probability plot for each of these conditions. Use the plotted points and fitted lines to assess the reasonableness of assumptions (such as a constant standard deviation at each test condition, e.g., Figure 48.12).

TABLE 48.2 Failure Intervals or Censoring Times and Testing Temperatures from an ALT Experiment on a New-Technology Integrated Circuit Device

Temperature °C	Number of devices	Hours Lower	Hours Upper	Status
150	50		1536	Censored
175	50		1536	Censored
200	50		96	Censored
250	1	384	788	Failed
250	3	788	1536	Failed
250	5	1536	2304	Failed
250	41		2304	Censored
300	4	192	384	Failed
300	27	384	788	Failed
300	16	788	1536	Failed
300	3		1536	Censored

3. Fit a model to the assumed relationship between life and the accelerating variable. Plot the fitted model on probability paper, together with a plot of the data (e.g., Figure 48.13).

4. Perform residual analyses and other diagnostic checks of the model assumptions (as in standard regression analysis). See Chapter 5 of Nelson (1990). (This is not done for the example here.)

5. Obtain the desired estimates and confidence intervals, and assess their reasonableness (e.g., Figure 48.14).

For further examples and further discussion of methods for analyzing ALT data, see Nelson (1990) or Meeker and Escobar (1998).

Example.   Table 48.2 gives the results of an ALT on a new-technology integrated circuit (IC) device. The device inspection process involved an electrical diagnostic test conducted periodically to determine whether or not failure had occurred. This test was expensive because it was manual and required much time on a special machine. Thus, only a few inspections could be conducted on each device. One common method of planning the times for such inspections is to choose a first inspection time and then space the further inspections to be equally spaced on a log scale. In this case, the first inspection was after 1 day with subsequent inspections at 2 days, 4 days, and so on (except for a day when the person doing the inspection had to leave early). Tests were run at 150, 175, 200, 250, and 300°C. Life tests in which failures are recorded only at inspection times lead to interval-censored data (sometimes called "interval" or "read out" data). When a unit fails the test, all that is known is that there has been a failure in the elapsed time since the previous inspection. Interval-censored data require special statistical methods that are described in Chapter 9 of Nelson (1982), Chapter 3 of Nelson (1990), and Chapters 3, 7, and 19 of Meeker and Escobar (1998). Table 48.2 gives the interval in which failure occurred for the devices that failed. Correspondingly, for devices that did not fail, Table 48.2 gives the running time at the last inspection.

At the time of analysis, failures had been found only at the two highest temperatures. After early failures had been observed at 250 and 300°C there was some concern that no failures would be observed at 175°C before the time at which decisions would have to be made. Thus the 200°C test was started later than the others and only limited running time was accumulated by the time of the analysis.

The developers were interested in estimating the activation energy of the suspected failure mode and the long-life reliability of the components. In particular, they wanted to estimate the proportion of devices in the product population that would fail by 100 thousand hours (about 11 years) at the use condition of 100°C.

Figure 48.12 is a lognormal probability plot and estimated ML cdf of the failures at 250 and 300°C along with the ML estimates of the individual lognormal cdfs. The differing slopes in the plot suggest the possibility that the lognormal shape parameter sigma changes from 250 to 300°C. Such a change could be caused by a change in failure mode. Failure modes with a higher activation energy, that might never be seen at low levels of temperature, can appear at higher levels of temperature (or other acceleration factors). An approximate 95 percent confidence interval on $\sigma_{250}/\sigma_{300}$ is [1.01, 3.53] (calculations not shown here), suggests that the difference could be real. These results also suggested that detailed physical failure mode analysis should be done for at least some of the failed units and that, perhaps, the accelerated test should be extended until some failures are observed at lower levels of temperature. However, in the subsequent analyses we shall assume that σ is constant at the different temperatures.

Table 48.3 gives Arrhenius-lognormal model ML estimation results and confidence bounds for the new-technology IC device under the assumed model. Figure 48.13 is a lognormal probability plot of the data at 250°C and 300°C showing the Arrhenius-lognormal model cdf fit to the data. This figure also shows lognormal cdf estimates from the fitted model for the other test temperatures as well as the estimated cdf, and an approximate 95 percent confidence interval at the use condition of 100°C. We note that the upper bound of the 95 percent confidence interval on the proportion failing by 100,000 hours at this temperature is less than .0001 (0.01 percent).

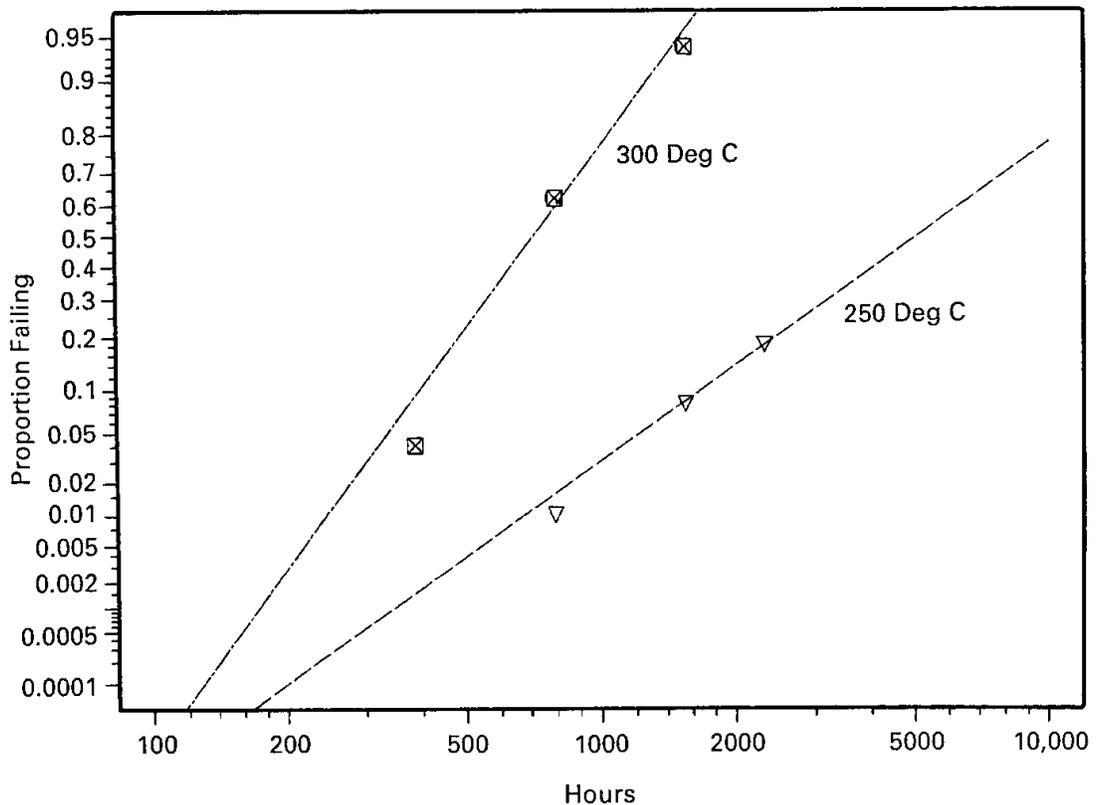
Figure 48.14 is an Arrhenius plot of the lognormal model fit to the new-technology IC device ALT data, showing the times at which 1, 10, and 50 percent of the units are expected to fail as a function of time. This plot shows the rather extreme extrapolation needed to make inferences at the use conditions of 100°C. If the projections are close to reality, it appears unlikely that there will be any failures below 200°C during the remaining 3000 hours of testing, and, as mentioned before, this was the reason for testing additional units at 200°C.


FIGURE 48.12 Lognormal probability plot and estimated ML cdf of the failures at 250 and 300°C for the new-technology integrated circuit device ALT experiment.

TABLE 48.3 Individual Lognormal ML Estimation Results for the New-Technology IC Device*

Parameter	ML estimate	Standard error	Approximate 95% confidence intervals	
			Lower	Upper
β_0	−10.2	1.5	−13.2	−7.2
β_1	.83	.07	.68	.97
σ	.52	.06	.42	.64

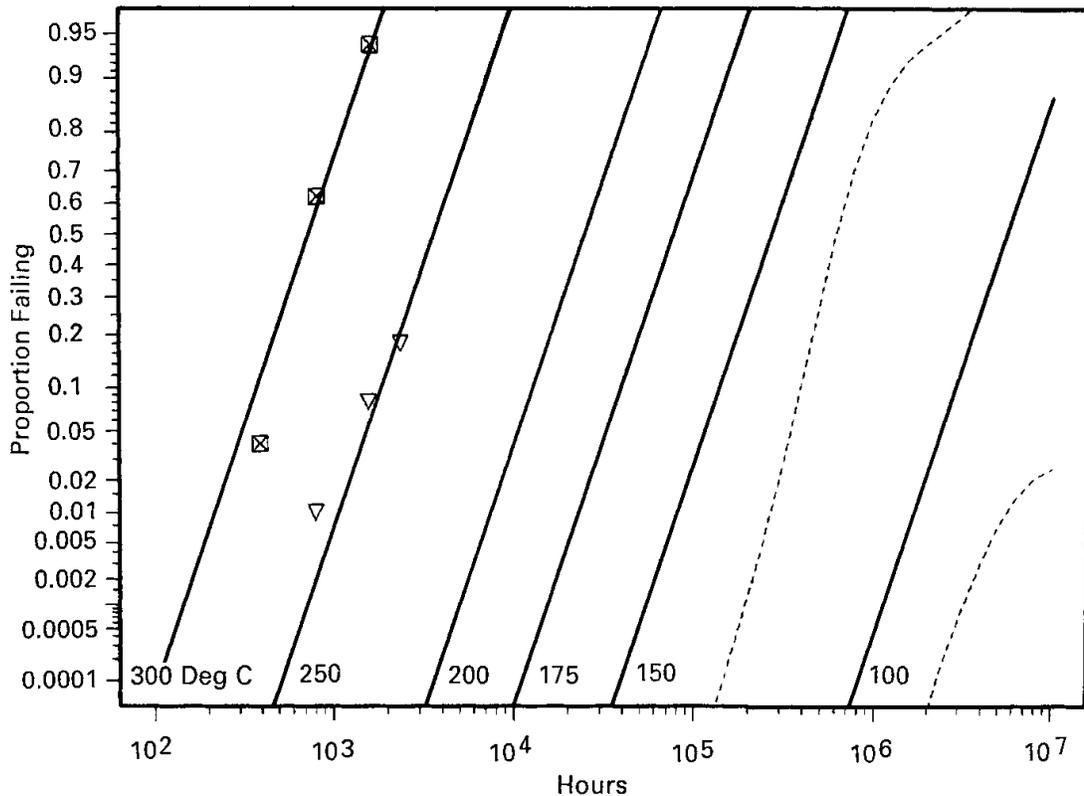
*The loglikelihood is $\mathcal{L} = -88.36$. The confidence intervals are based on the normal approximation method.


FIGURE 48.13 Lognormal probability plot showing the Arrhenius-lognormal model ML estimation results for the new-technology IC device at the test temperatures and (with the approximate 95 percent confidence interval) at 100°C.

SYSTEM RELIABILITY CONCEPTS

The system failure probability $F_T(t)$ is the probability that the system fails before time t. The failure probability of the system is a function of time in operation t (or other measure of use), the operating environment(s), the system structure, and the reliability of system components, interconnections, and interfaces (including, for example, human operators).

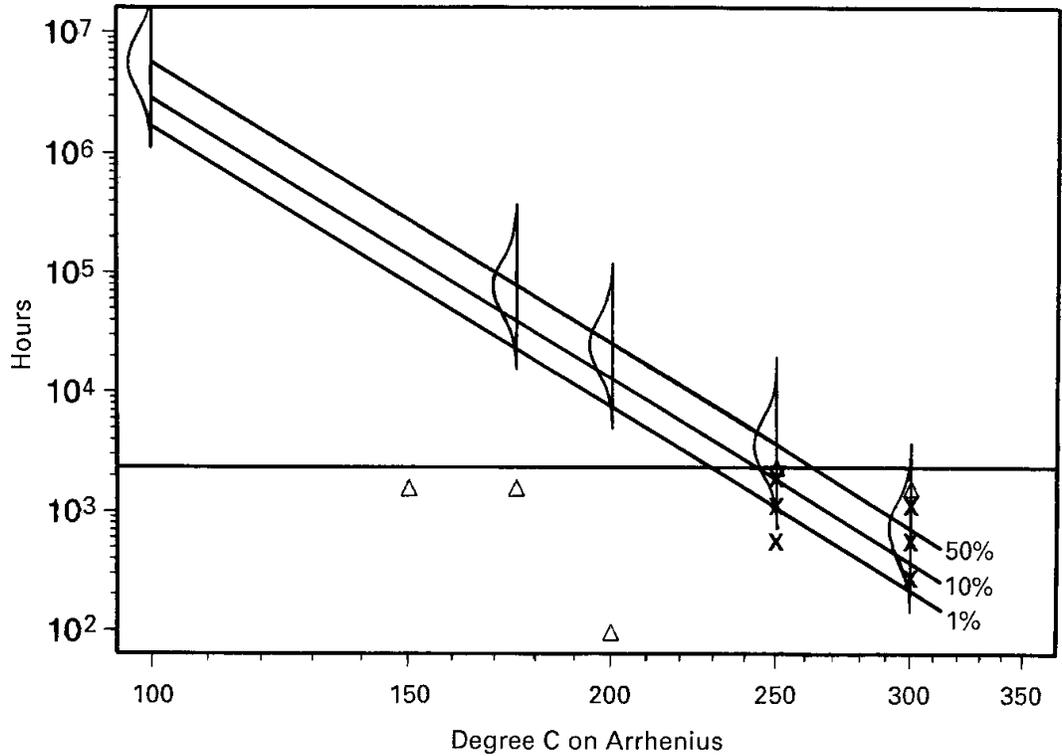
This subsection describes several simple system structures. Not all systems fall into one of these categories, but the examples provide building blocks to illustrate the basics of using system structure to compute system reliability. Complicated system structures can generally be decomposed into collections of the simpler structures presented here. Thus the methods for evaluation of system relia-


FIGURE 48.14 Arrhenius plot showing the Arrhenius-lognormal model ML estimates for the new-technology IC device. Failure and censored observation times are indicated by $\times$ and Δ respectively.

bility can be adapted to more complicated structures. For more information, see texts such as O'Connor (1985), Høyland and Rausand (1994), or Meeker and Escobar (1998).

Terminology for System Reliability.

Consider the time to failure of a system (i.e., all components starting a time 0) with s independent components. The cdf for component i is denoted by $F_i(t)$. The corresponding reliability (or survival probability) is $S_i(t) = 1 - F_i(t)$. The cdf for the system is denoted by F_T. This cdf is determined by the F_i's and the system structure, that is, $F_T(t) = g[F_1(t), ..., F_s(t)]$. To simplify the presentation, this function will be expressed as $F_T = g(F_1, ..., F_s)$.

Systems with Components in Series.

A series structure with s components works if and only if all the components work. Examples of systems with components in series include chains, high-voltage multicell batteries, inexpensive computer systems, and inexpensive decorative tree lights using low-voltage bulbs. For a system with two independent components in a series, illustrated in Figure 48.15, the cdf is

$$F_T(t) = \Pr (T \le t) = 1 - \Pr (T > t) = 1 - \Pr (T_1 > t \text{ and } T_2 > t)$$

$$= 1 - [\Pr (T_1 > t) \ \Pr (T_2 > t)] = 1 - (1 - F_1)(1 - F_2) \tag{48.3}$$

FIGURE 48.15 A system with two components in series.

For a system with s independent components $F_T(t) = 1 - \prod_{i=1}^{s} (1 - F_i)$ and for a system with s independent components, each of which has the same time to failure distribution [for example, multicell batteries $(F = F_i, i = 1, ..., s)$], $F_T(t) = 1 - (1 - F)^s$. The system hazard function, for a series system of s independent components, is the sum of the component hazard functions:

$$h_T(t) = \sum_{i=1}^{s} h_i(t)$$

Figure 48.16 shows the relationship between system reliability $1 - F_T(t)$ and individual component reliability $1 - F_T(t)$ for systems with different numbers of identical independent components in series. This figure shows that extremely high component reliability is needed to maintain high system reliability if the system has many components in series. If the system components are not independent, then the first line of (48.3) still gives $F_T(t)$, but the evaluation has to be done with respect to the bivariate distribution of T_1 and T_2 with a similar generalization to a multivariate distribution for more than two components.

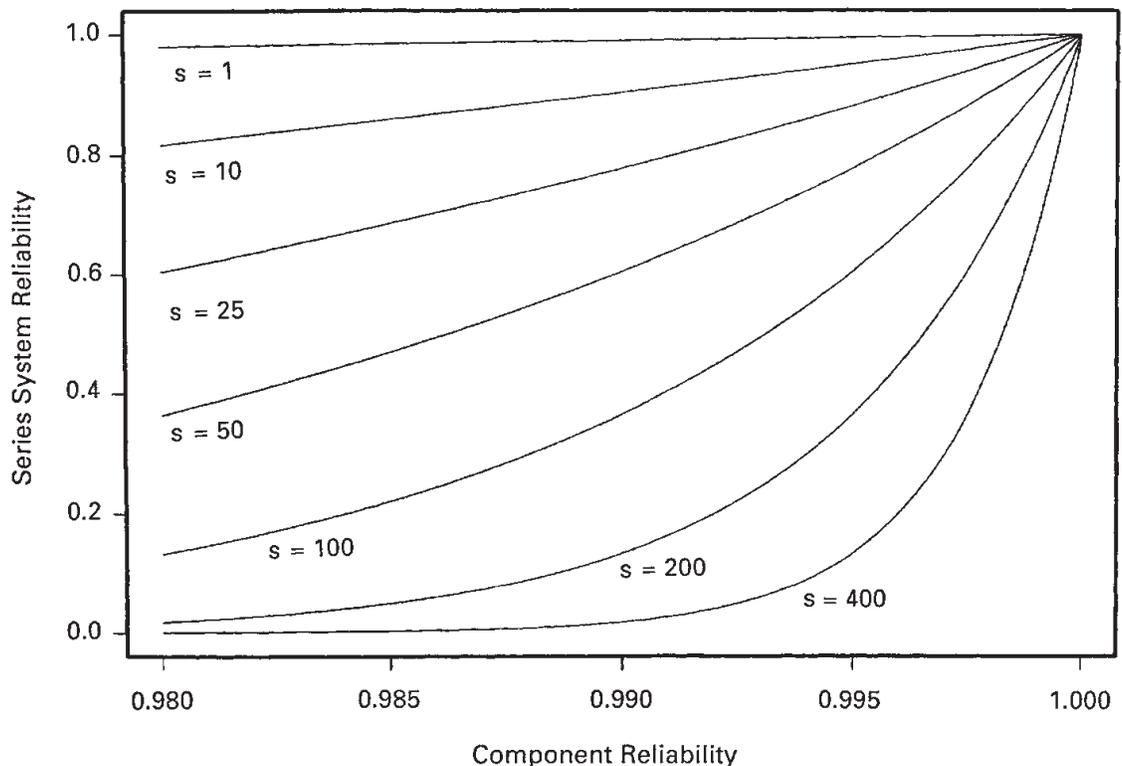
Importance of Part Count in Product Design.   An important rule of thumb in reliability engineering design practice is "keep the part count small," meaning keep the number of individual parts (or components in series) in a system to a minimum. Besides the cost of purchasing and handling of additional individual parts, there is also an important reliability motivation for having a smaller number of parts in a product. For example, the design of a new-technology computer modem uses a higher level of microelectronic integration and requires only 20 discrete parts instead of the 40 parts required in the previous generation. As a specific example, the system hazard function $h_T(t)$ becomes particularly simple if a constant hazard rate (or equivalently, an exponential time-to-failure distribution) provides an adequate model for time to failure for the system components or parts. In this case, as a rough approximation, assuming that all failures are due to part failures, and that the parts have the same hazard function, the new design with only 20 parts will experience only half of the failures of the old design. Allowing that failures can occur at interfaces and interconnections between parts with the same frequency in the new and old designs would further increase the reliability improvement because of the larger number of such interfaces with a higher number of parts. With nonconstant hazard function (more common in practice), and parts with different hazard functions, the idea is similar.


FIGURE 48.16   Reliability of a system with s identical independent components in series.
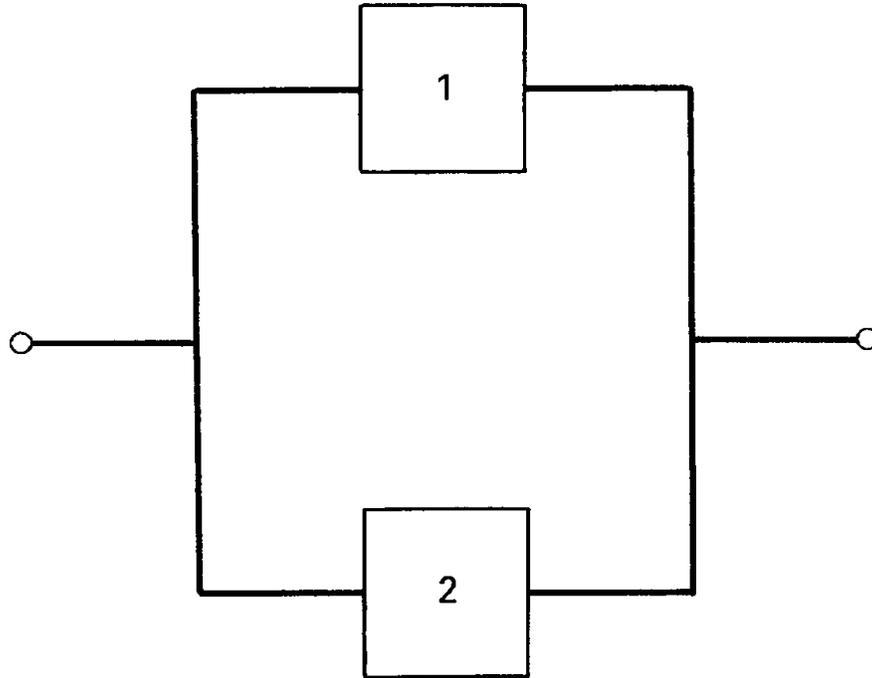

FIGURE 48.17   A system with two components in parallel.

This illustration assumes, of course, that the reliability of the parts in the new system will be the same (or at least similar to) the reliability of the individual parts of the old system, and that the stress in operation on each part remains the same. If the new system uses parts from an immature production process with low part reliability, or the operating stress on individual components is increased, the new system could have lower reliability.

Systems with Components in Parallel.   Parallel redundancy is often used to improve the reliability of weak links or critical parts of larger systems. A parallel structure with s components works if at least one of the components works. Examples of systems with s components in parallel include automobile headlights, RAID computer disk array systems, stairwells with emergency lighting, overhead projectors with a backup bulb, and multiple light banks in a classroom. For two independent parallel components, illustrated in Figure 48.17,

$$F_T(t) = \Pr\,(T \le t) = \Pr\,(T_1 \le t \text{ and } T_2 \le t)$$

$$= \Pr\,(T_1 \le t)\,\Pr\,(T_2 \le t) = F_1 F_2 \qquad (48.4)$$

For s independent components $F_T(t) = \Pi_{i=1}^{s} F_i$ and for s independent identically distributed components $(F_i = F, i = 1, \ldots, s)$, $F_T(t) = F^s$. Figure 48.18 shows the relationship between system reliability $1 - F_T(t)$ and individual component reliability $1 - F(t)$ for different numbers of identical independent components in parallel. The figure shows the dramatic improvement in reliability that parallel redundancy can provide. If the components are not independent, then the first line of (48.4) still gives $F_T(t)$, but the evaluation has to be done with respect to the bivariate distribution of T_1 and T_2. A similar generalization applies for more than two nonindependent components.

REPAIRABLE SYSTEM DATA

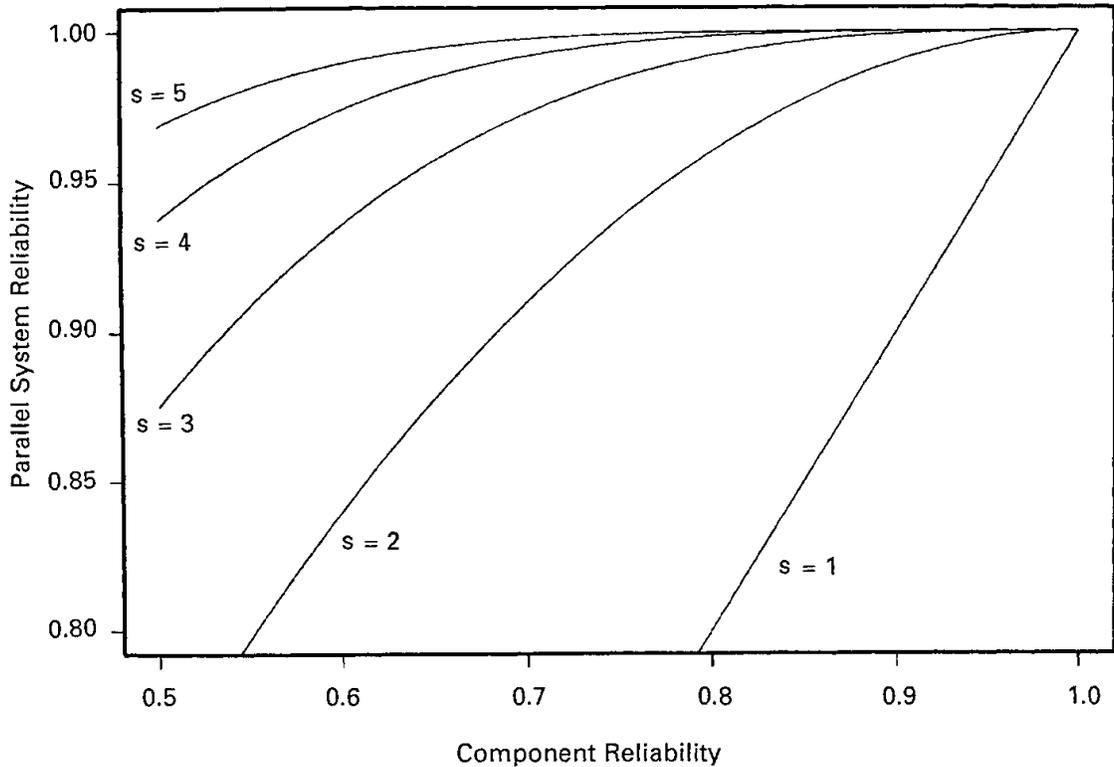
The previous discussion dealt with reliability data analysis for nonrepairable components (or devices). Since a nonrepairable component can fail only once, time to failure data from a sample of


FIGURE 48.18   Reliability of a system with s independent components with identical time to failure distributions, in parallel.

nonrepairable components consist of the times to first failure for each component. In most instances involving nonrepairable components, the assumption of independent and identically distributed failure times is a reasonable one and suitable lifetime distributions (such as the Weibull or lognormal) are used to describe the distribution of failure times. In contrast, repairable system data typically consist of multiple repair times (or times between repairs) on the same system since a repairable system can be placed back in service after repair.

The purpose of many reliability studies is to describe the trends and patterns of repairs on failures over time for an *overall system* or collection of systems. Data consist of a sequence of system repair times for similar systems. When a single component or subsystem in a larger system is repaired or replaced after a failure, the distribution of the time to the next system repair will depend on the overall state of the system at the time just before the repair and the nature of the repair. Thus, repairable system data, in many situations, should be described with models that allow for changes in the state of the system over time or for dependencies between repairs over time.

Repairable system data can be viewed as sequence of repair times $T_1, T_2, \ldots$. The model for such data is sometimes called a "point process." Some applications have repair data on only one system. In most applications there are data from a collection of systems, typically monitored over a fixed observation period (t_0, t_a), where, often, $t_0 = 0$. The observation period often differs from system to system. In some cases, exact repair times are recorded. In other cases, the numbers of repairs within time intervals are reported.

From the repair data, one would typically like to estimate:

- The distribution of the times between repairs, $\tau_j = T_j - T_{j-1}$ $(j = 1, 2, \ldots)$ where $T_0 = 0$
- The number of repairs in the interval $(0, t)$ as a function of t
- The expected number of repairs in the interval $(0, t)$ as a function of t
- The recurrence rate of replacements as a function of time t

These questions lead to the analyses in the following example.

Example: Times of Replacement of Diesel Engine Valve Seats. The following data will be used to illustrate the methods. Repair records for a fleet of 41 diesel engines were kept over time. Table 48.4 gives the times of replacement (in number of days of service) of the engine's valve seats. This is an example of data on a group of systems. The data were given originally in Nelson and Doganaksoy (1989) and also appear in Nelson (1995). Questions to be answered from these data (not all of which are discussed here) include:

- How many replacements can the fleet owner expect, on the average, during the first year of operation of a locomotive?
- Does the replacement rate increase or decrease with diesel engine age and at what rate?
- How many replacement valves will be needed in the next two calendar years for this fleet?
- Can the valve replacement times be modeled as a renewal process (so that simple methods for independent observations can be used for further analysis and prediction)?

Simple data plots provide a good starting point for analysis of system repair data. Figure 48.19 is an event plot of the valve seat repair data showing the observation period and the reported replacement times. Note that the length of the observation period differed from engine to engine.

Initial evaluations of the data suggested some differences in repair vulnerability among locomotives. This is a separate subject of study, and is ignored in the following evaluations.

Nonparametric Model for Point Process Data. For data on a single system, the cumulative number of repairs up to time t is denoted as $N(t)$. The corresponding model, used to describe a population of systems from the same population, is based on the mean cumulative function (MCF) at time t. The MCF is defined as the average or expected number of repairs per system before time

t, i.e., $\mu(t) = E[N(t)]$, where the expectation is over the entire population of systems. Assuming that $\mu(t)$ is differentiable,

$$v(t) = \frac{dE[N(t)]}{dt} = \frac{d\mu(t)}{dt}$$

defines the recurrence rate of repairs per system for the system population. This can also be interpreted as an *average* rate of repair occurrence for individual systems.

Although data on number of repairs (or other specific events related to reliability) are encountered frequently, the methods given here can be used to model other quantities accumulating in time, including continuous variables like cost. Then, for example, if $C(t)$ is the cumulative repair cost for a system up to time t, then $\mu(t) = E[C(t)]$ is the average cumulative cost per system in the time interval $(0, t)$.

Nonparametric Estimation of the MCF.   Given $n \geq 1$ repairable systems, the following method can be used to estimate the MCF. The method is nonparametric in the sense that it does not require specification of a parametric model for the repair-time point process. The method assumes that the sample data are taken randomly from a population of MCF functions. It is also assumed that the time at which we stop observing a system does not depend on the process. Thus, it is important that the time at which a unit is censored is not systematically related to any factor related to the repair time distribution. Biased estimators will, for example, result if units follow a staggered entry into service (e.g., one unit put into service each month) and if there has been a design change that has increased the repair probability of the more recent systems introduced into service. Then newer systems have a more stressful life and will fail earlier, causing an overly optimistic trend over time on the estimated recurrence rate $v(t)$. In such cases, data from different production periods must be analyzed separately or the change in the recurrence rate needs to be modeled as a function of system age and calendar time.

Let $N_i(t)$ denote the cumulative number of system repairs for system i at time t and let t_{ij}, $j = 1, \ldots, m_i$ be the failure (or repair, or other event) times for system i. A simple estimator of the MCF at time t would be the sample mean of the available $N_i(t)$ values for the systems still operating at time t. This estimator is simple, but appropriate only if all systems are still operating at time t. Thus, this method can be used in the diesel engine example up to $t = 389$ days, or up to 578 days if we ignore the data on engine 409. A more appropriate estimator, allowing for multiple censoring, and providing an unbiased estimate of the MCF is described in Nelson (1988), Nelson (1995), Lawless and Nadeau (1995), and Meeker and Escobar (1998). A plot of the MCF estimate versus age indicates whether the reliability of the system is increasing, decreasing, or unchanging over time.

MCF Estimate for the Valve Seat Replacements.   Figure 48.20 shows the estimate of the valve seat MCF as a function of engine age in days. The estimate increases sharply after 650 days, but this is based on only a small number (i.e., 10) of systems that had a total operating period exceeding 650 days. The uncertainty in the estimate for longer times is reflected in the width of the confidence intervals [the computation of the estimate beyond 389 days and the confidence limits is explained in Nelson (1995) and Chapter 16 of Meeker and Escobar (1998)].

Nonparametric Comparison of Two Samples of Repair Data.   Decisions often need to be made on the basis of a comparison between two manufacturers, product designs, environments, etc. Doganaksoy and Nelson (1998) describe methods for comparing samples from two different groups of systems.

OTHER TOPICS IN RELIABILITY

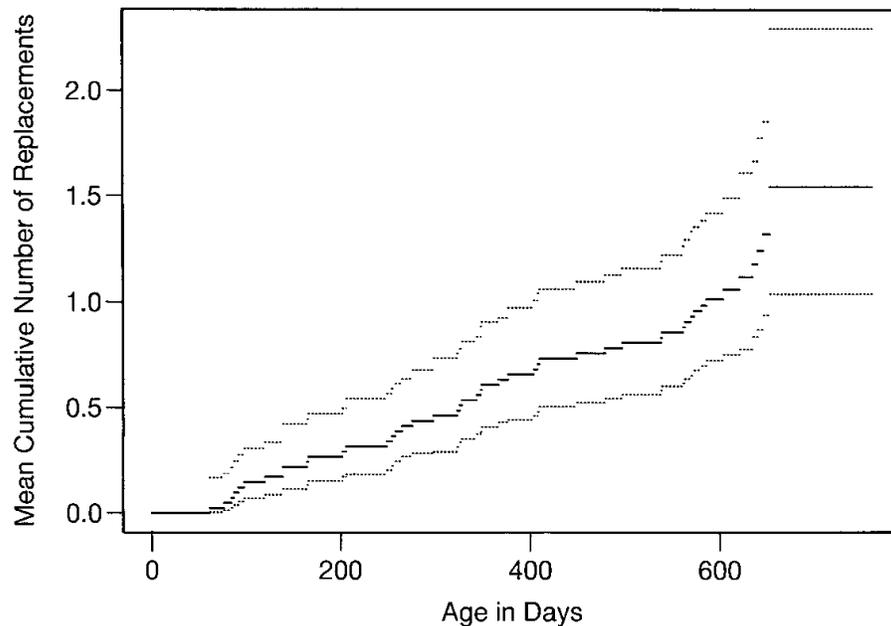
Sources of Reliability Data and Information.   Component and subsystem reliability information is needed as input to reliability models. Such information comes from a number of different sources. For example:


FIGURE 48.20   Estimate of the mean cumulative number of diesel engine valve seat repairs, with a 95 percent confidence interval.

- Laboratory tests are used widely, especially to test new materials and components, when there is little past experience. Such testing is generally expensive and may have limited applicability to product field reliability, but it may provide early warning of reliability problems. Care must be taken to assure that failure modes relevant to field use are obtained and that, if the goal is reliability prediction, the test conditions can be accurately related to actual field conditions. As described earlier in this section, laboratory tests are often accelerated with the goal of getting component reliability information more quickly.

- Carefully collected field data, when available, may provide the most accurate information about how components and systems behave in the field. It is important, however, to ensure that field data are consistently and unambiguously recorded to allow speedy and easy analysis. Field warranty data often contain no information on units that do not fail and may be biased, for example, because units in the harshest environments tend to fail sooner. Also, field data generally come too late to help avoid costly reliability problems.

- Reliability handbooks and data banks can be useful [e.g., Klinger, Nakada, and Menendez (1990) and MIL-HDBK 217F (1991)]. One common complaint about such handbooks, however, is that data become obsolete by the time they are published, or shortly after.

- Expert knowledge is often used when no other source of information is available.

Unless data are collected from carefully planned and conducted studies and properly maintained and analyzed, obtaining unbiased estimates, and quantifying uncertainty may be impossible.

FMEA and FMECA. Products and systems often have complicated designs that are the result of the efforts of several design teams. Management for system reliability requires a global process to assure up front that the product/system reliability will meet customer requirements.

Failure Modes and Effect Analysis (FMEA) is a systematic, structured method for identifying system failure modes and assessing the effects or consequences of the identified failure modes. Failure Modes and Effect Criticality Analysis (FMECA) considers, in addition, the importance of identified failure modes, with respect to safety, successful completion of system mission, or other criteria. The goal of FMEA/FMECA is to identify and possibly remove possible failure modes at a specified level of system architecture. These methods are typically used in product/system design review processes. The use of FMEA/FMECA usually begins in the early stages of product/system conceptualization and design. Then the FMEA/FMECA evolves over time along with changes in the product/system design and accumulation of information about product/system performance in preproduction testing and field experience. FMEA/FMECA is used during the product/system design phase to help guide decision making. It is also used to develop product/system guidelines for system repair and maintenance procedures, to improve system safety, and to provide direction for reliability improvement efforts.

Operationally, FMEA/FMECA begins by defining the scope of the analysis, specified by the system level at which failures are to be considered. FMEA/FMECA can be conducted at various levels in a product or a system. It might be done initially for individual subsystems. Then the results can be integrated to provide an FMEA/FMECA for an entire system comprising many subsystems. For example, an FMEA to study the reliability of a telecommunications relay repeater might consider, as basic components, each discrete device in the electronic circuit (e.g., ICs, capacitors, resistors, diodes). At another level, an FMEA for a large telecommunications network might consider as components all of the network nodes and node interconnections (ignoring the electronic detail within each node).

The next step in the FMEA/FMECA process is the identification of all components that may fail during the life of the product. This is followed by identification of all component interfaces or connections that might fail. In many applications, environmental and human factors–related failures are considered in defining failure modes. Finally the effects of the identified failure modes are delineated. Determining the effect of failure modes and combinations of failure modes uses the detailed specification of the relationship among the product/system components (system structure). Special worksheets and/or computer software can be used to organize all of the information.

MIL-STD-1629A (1980) and books like Høyland and Rausand (1994) and Sundararajan (1991) outline in more detail and provide examples of the procedures for performing an FMEA/FMECA analysis. Høyland and Rausand (1994) also list several computer programs designed to facilitate such analyses.

Fault Trees.   The FMEA/FMECA process described above is sometimes referred to as a "bottom-up" approach to reliability modeling. Fault tree analysis, on the other hand, quantifies system failures using a "top-down" approach. First, one or more critical "top events" (such as loss of system functionality) are defined. Then in a systematic manner, the combination (or combinations) of conditions required for that event to occur are delineated. Generally this is done by identifying how failure-related events at a higher level are caused by lower-level "primary events" (e.g., failure of an individual component) and "intermediate events" (e.g., failure of a subsystem). Information from an FMEA analysis might be used as input to this step. The information is organized in the form of a "fault tree diagram" with the top event at the top of the diagram. Events at different levels of the tree are connected by logic gates defined by Boolean logic (e.g., AND, OR, Exclusive OR gates).

A complete fault tree can be used to model the probability of critical system events. Additional inputs required for this analysis include the probabilities or the conditional probabilities of the primary events. With this information and the detailed system structure specification provided by the fault tree, it is possible to compute critical event probabilities. See O'Connor (1985), Sundararajan (1991), Høyland and Rausand (1994), or Lewis (1996) for examples.

Fault tree diagrams are, in one sense, similar to the reliability block diagrams presented earlier in this subsection. It is generally possible to translate from one to the other. Fault tree analysis, however, differs in its basic approach to system reliability. Reliability block diagrams are structured around the event that the system does *not* fail. Fault tree analysis focuses on the critical top events like loss of system functionality or other safety-critical events. The tree shows, directly, the root causes of these top events, and other contributing events, at all levels within the scope of the analysis. The structure and logic of the fault tree itself provides not only a mechanism for quantitative reliability assessment, but also clearer insight into possible approaches for reliability improvement.

Designed Experiments to Improve Reliability.   Experimental design can be an important tool for reliability improvement. Different kinds of experiments can obtain information for assessing and improving reliability. These include life tests and accelerated life tests, such as those described earlier in this section, to assess the durability or lifetime distribution of materials and components, for which there is one or a small number of identifiable failure modes. Information from such tests is used to make design decisions that will result in acceptable (or better) reliability for the tested components.

At another level one may conduct experiments to define system configurations or operating factors to enhance reliability by making components more robust to varying manufacturing conditions or operating/environmental conditions that might be encountered in service. Generally such experiments also focus on a single failure mode or a few failure modes for a single component or subsystem. Multifactor robust-design experiments (RDE) provide methods for systematic and efficient reliability improvement. These are often conducted on prototype units and subsystems and focus on failure modes involving interfaces and interactions among components and subsystems. Among many possible product design factors that may impact a system's reliability, RDEs empirically identify the important ones and find levels of the product design factors that yield consistent high quality and reliability. Graves and Menten (1996) provide an excellent description of experimental strategies that can be used to help design products with higher reliability. Byrne and Quinlan (1993) describe an experiment to design a flexible push cable that will have long life under varying operating conditions. Tseng, Hamada, and Chiao (1995) describe the use of a factorial experiment to choose manufacturing variables that will extend the life of fluorescent light bulbs. Phadke (1989) describes an experiment to optimize performance, and thus reliability, of a copying machine subsystem.

The need to quickly develop new high-reliability products has motivated the development of other new-product testing methods. The purpose of these testing methods is to rapidly identify and

eliminate potential reliability problems (failure modes or other system weaknesses) early in the design stage of product development. One such testing method is known as STRIFE (*str*ess-l*ife*) testing. The basic idea of STRIFE testing is to aggressively stress and test prototype or early production units (using, for example, temperature cycling, power cycling, and vibration) to force failures. Although it may be useful to test only one or two units, appropriately selected units can provide important additional information on unit-to-unit variation. Bailey and Gilbert (1981) describe an example in which the complete STRIFE test and improvement program was successfully completed in three weeks. Kececioglu and Sun (1995) also describe STRIFE testing and present several interesting case studies. Schinner (1996) provides a detailed description of preproduction "accelerated tests" that can be used to discover or assess the potential impact of product failure modes.

Reliability Demonstration.

Reliability demonstration is used to assess whether product reliability meets specifications. The reliability specification is often stated in terms of the mean or a specified percentile of the life distribution of the product. For example, an industrial purchaser of a component may require that the percentage of failing parts during the first 5 years of service must not exceed 0.5 percent.

Demonstration of product reliability usually involves some type of a life test. The basic considerations in planning a reliability demonstration test are similar to those of acceptance sampling (see Section 46), although some special aspects arise as noted below. A reliability demonstration test plan specifies the number of units to be placed on test, test time, and criteria for successful demonstration. Acceptance test plans involving attribute data [such as MIL-STD-105E (1989) or the corresponding civilian standard ANSI/ASQC (1993*a*) Z1.4] are applicable sometimes to reliability demonstration when the outcome of a test is either a success or a failure, such as in demonstrating start-up reliability of a system. Likewise, standard acceptance test plans for the normal distribution [MIL-STD-414 (1957) or the corresponding civilian standard ANSI/ASQC (1993*b*) Z1.9] can sometimes be used for reliability demonstration when all units are tested to failure, provided distributional assumptions of the plan are satisfied (e.g., logs of failure times are often modeled with a normal distribution). However, special test plans for reliability demonstration are needed in situations where testing is to be terminated before all units fail. Abernethy (1996) describes small-sample Weibull demonstration plans. Special test plans for reliability are also needed to accommodate life distributions other than the normal (such as the Weibull) which are widely used in reliability data analysis.

Reliability demonstration test plans for a wide range of situations have been documented in various handbooks and standards published by the U.S. Defense Department. For example, U.S. Department of Defense (1960), *Quality Control and Reliability Handbook H-108,* provides failure-terminated (test is stopped upon occurrence of preassigned number of failures), time-terminated (test duration is predetermined) and sequential test plans for the exponential distribution. Similar test plans for the Weibull distribution are contained in U.S. Department of Defense (1965) *Handbook TR 7.* Schilling (1982) provides a thorough overview of common test plans used in reliability demonstration.

Screening and Burn-in.

Many products, ranging from electronic components to electronic systems to automobiles, experience reliability problems in the early break-in part of life. Such "infant mortality" failures often occur in a small proportion of units with manufacturing defects. After all or most of these defective units have failed, population failure rates typically reach a low level until wear-out failures begin to occur (see earlier discussion of "bathtub curve"). For some products (e.g., desktop computers), the wear-out phase of life is well beyond the technological life of the product. However, in many applications involving critical systems or where repair is impossible or highly expensive (e.g., satellite systems, undersea systems, and critical aircraft systems), infant mortality failures present an important obstacle to achieving the needed level of reliability.

Manufacturers, in their quality and reliability improvement programs, strive to eliminate or at least reduce the rate of occurrence of infant mortality failures. In such applications, screening or burn-in techniques are often used to identify and remove defective components or to remove products containing defects before they are released to customers.

Burn-in tests can be viewed as a type of 100 percent inspection or screening of the product population. All units are run for a period of time before shipment or installation. To accelerate the process, components such as integrated circuits may be run at high levels of temperature and/or other stresses. The ability to use acceleration is much more limited for systems and subsystems. See Jensen and Petersen (1982) for an engineering approach to this subject. Also, see Nelson (1990, p. 43) for more information and references.

Environmental Stress Screening (ESS) was developed as a means of accelerated burn-in for units at the system or subsystem (e.g., circuit pack) level. ESS uses mild, but complicated, stressing such as combinations of temperature cycling, physical vibration, and perhaps stressful operational regimes (e.g., running computer chips at higher than usual clock speeds and lower than usual voltages) to help identify the weak units. Tustin (1990) gives a motivational description of the methodology and several references. MIL-STD-2164 (1985) provides a useful overview of ESS procedures. Kececioglu and Sun (1995) provide a comprehensive treatment of ESS. Nelson (1990, p. 39) gives additional references, including military standards.

Burn-in and ESS are inspection/screening schemes. In line with the modern quality goal of eliminating reliance on mass inspection, most manufacturers prefer not to do burn-in or ESS. Such methods are also expensive and may not be totally effective. By improving reliability through continuous improvement of the product design and the manufacturing process, it may be possible to reduce or eliminate reliance on screening tests except, perhaps, in the most critical applications.

Reliability Growth.   Reliability of a system continually evolves during its design, development, testing, production, and field use. This ongoing change is referred to as "reliability growth" (although, in fact, reliability may actually improve or deteriorate). Growth usually results from efforts to discover design (or manufacturing) flaws and implement fixes to affect all future manufactured units. Thus, later-generation systems should have better reliability than their predecessors. Sometimes this process is referred to as "test, analyze, and fix" (TAAF). The basic idea is to find and fix reliability problems that had not been found earlier. Reliability growth models and data-fitting methods allow predictions of product reliability due to such improvements. Reliability growth analysis usually involves fitting a reliability growth model (such as the popular Duane plot) to failure data on systems built over time. These empirical models are then used to predict the reliability of future generations of systems. For further information and references on reliability growth, see MIL-HDBK-189 (1981), Klion (1992), Ascher and Feingold (1984), and Chapter 11 of Pecht (1995).

Software Reliability.   State-of-the-art reservation, banking, billing, accounting, and other financial and business systems depend on complicated software systems. Additionally, modern hardware systems of all kinds, from automobiles and televisions to communications networks and spacecraft, contain complicated circuitry. Most of these electronic systems depend heavily on software for important functionality and flexibility. For many systems, software reliability has become an important limiting factor in system reliability.

The Institute of Electrical and Electronic Engineers defines software reliability as "the probability that software will not cause a system failure for a specified time under specified conditions." Software reliability differs from hardware reliability in at least one important way. Hardware failures can often be traced to some combination of a physical fault and/or physical/chemical degradation that progresses over time, perhaps accelerated by stress, shocks, or other environmental or operating conditions. Software failures, on the other hand, are generally caused by inherent faults in the software that are usually present all along. Actual failure may not occur until a particular set of inputs is used or until a particular system state or level of system load is reached. The state of the software itself does not change without intervention.

Software errors differ in their criticality. Those who work with personal computers know that from time to time the system will stop functioning for unknown reasons. The cause is often software-related (i.e., it would not have occurred if the software had been designed to anticipate the conditions that caused the problem). Restarting the computer and the application will seem to make the problem disappear. Important data in the application being used at the time of the failure may or may not

have been lost. Future versions of the operating system or the application software may correct such problems. In safety-critical systems (e.g., medical, air traffic control, or military systems) software failures can have much more serious (e.g., life-threatening) consequences.

For some purposes, statistical methods for software reliability are similar to those used in predicting reliability growth of a system or analyzing data from a repairable system, treated earlier in this subsection. Software data often consist of a sequence of times of failures (or some other specific event of interest) in the operation of the software system. Software reliability data are collected for various reasons, including assessment of the distribution of times between failures, tracking the effect of continuing efforts to find and correct software errors, making decisions on when to release a software product, assessing the effect of changes to improve the software development process, etc.

Numerous models have been suggested and developed to model software reliability data. The simplest of these describe the software failure rate as a smooth function of time in service and other factors, such as system load and amount of testing or use to which the system has been exposed. In an attempt to be more mechanistic and to incorporate information from the fix process directly into the software reliability model, many of these models have a parameter corresponding to the number of faults remaining in the system. In some models, the failure rate would be proportional to the number of faults. When a "repair" is made, there is some probability that the fault is fixed and, perhaps, a probability that a new fault is introduced.

For more information on software reliability and software reliability models, see Musa, Iannino, and Okumoto (1987), Shooman (1983), Neufelder (1993), Chapter 6 of Pecht (1995), or Azem (1995).

APPENDIX I
GLOSSARY OF SYMBOLS AND ABBREVIATIONS

This list is meant to provide a single reference source for symbols and abbreviations commonly used in the literature of the quality sciences, especially in the sections of this handbook. It represents a major update and revision of this appendix for this edition.

a = acceptance number in a sampling plan.

a = combination of factors A, B, C, …, n in a 2^n experiment in which only A occurs at the high level; similarly for $b, c, …, n$.

A = arbitrary origin for grouped data.

A = factor in graphical application of variables sampling plan.

A = unit cost of acceptance (damage done by a defective piece which slips through inspection).

A = a multiplier of σ_0 used to locate the 3-sigma control limits above and below the central line on an X chart.

A_3 = a multiplier of $\bar{s}$ used to locate the 3-sigma control limits above and below the central line on an $\bar{X}$ chart.

A_2 = a multiplier of $\bar{R}$ used to locate the 3-sigma control limits above and below the central line of an $\bar{X}$ chart.

A_c = in sampling acceptance schemes, the acceptance number, i.e., the maximum allowable number of defective pieces in a sample of size n.

ACL = acceptance control limit, i.e., a distance d from APL in the direction of the RPL.

ANOVA = analysis of variance.

AOQ = average outgoing quality, i.e., the long-term average quality of product leaving the inspection department after acceptance sampling and any detailing found necessary is performed.

AOQL = average outgoing quality limit, i.e., an upper limit on the AOQ.

APL = acceptable process level, i.e., a process level which is acceptable and should be accepted most of the time by the plan.

AQL = acceptable quality level, i.e., a specified quality level for each lot such that the sampling plan will accept a high percentage (say 95 percent) of submitted lots having this quality level.

ARL = average run length.

ASN = average sample number, i.e., the average number of units inspected per lot in sampling inspection.

ATI = average total inspection, i.e., average number of items inspected in a lot under a specified acceptance procedure.

b = number of blocks in a randomized or balanced incomplete block experimental design.

$b_1, b_2, \ldots$ = estimates of regression coefficients β_1, β_2, ...

B_3 = a multiplier of $\bar{s}$ used to locate the 3-sigma lower control limit on a chart for σ.

B_4 = a multiplier of $\bar{s}$ used to locate the 3-sigma upper control limit on a chart for σ.

B_5 = a multiplier of σ_0 used to locate the 3-sigma lower control limit on a chart for σ.

B_6 = a multiplier of σ_0 used to locate the 3-sigma upper control limit on a chart for σ.

B_U, B_L = factors for confidence limits on σ using s.

c = number of defects, usually in a sample of stated size.

c = in sampling acceptance plans, the acceptance number, i.e., the maximum allowable number of defective pieces in a sample of size n. (In some sampling tables the symbol Ac is used.)

c = a scale factor given in MIL-STD-414.

c = acceptance number in a sampling plan, also A_c.

$\bar{c}$ = average number of defects per sample in a series of samples.

c_0 = standard or aimed-at average number of defects in a sample of stated size. c_0 may also refer to the population average number of defects per sample.

c_2 = ratio of the expected value of $\hat{\sigma}$ in a long series of samples to the σ of the population from which they were drawn.

c_4 = factor for estimating the standard deviation from $\hat{\sigma} = \bar{s}/c_4$.

c_5 = factor for estimating the standard deviation of s, $\sigma_s = c_5\sigma$, so $\hat{\sigma}_s = c_5\bar{s}/c_4$.

c_{ij} = element in the ith row and jth column of a matrix C.

C = cost of repairing or replacing a defective once found.

C = extra capacity required.

C = correction factor, constant.

C_p = variance of regression predictions.

C_p = capability index for process centered between specification limits.

C_{pk} = performance index.

$\hat{C}_{pk}$ = estimate of C_{pk}.

$C(t)$ = cumulative repair cost for a system up to time t.

C_1, C_2 = adjusted cumulative sum for tabulation method.

$ChSP$ = chain sampling plan.

CIM = change-in-mean-effect in Evolutionary Operations.

CSP = continuous sampling plan.

d = the difference to be detected in a test divided by the measure of variability.

d = the difference in readings in a paired sample.

d = the number of defectives.

d = lead distance in cumulative sum charts.

d_i = number of defective units in ith sample.

d_i = signed differences.

$\bar{d}$ = the average difference in readings in a paired sample.

d' = deviation, in cells, from the assumed origin of a frequency distribution.

d_2 = ratio of the expected value of $\bar{R}$ (in samples of size n) to the σ of the population, i.e., $\bar{R} = d_2\sigma$.

D = largest deviation of actual percent cumulative frequency from theoretical percent cumulative frequency.

D = in a cumulative sum control chart, the least amount of change in the average that it is desired to detect.

D_1 = a multiplier of σ_0 used to locate the 3-sigma lower control limit on a chart for R.

D_2 = a multiplier of σ_0 used to locate the 3-sigma upper control limit on a chart for R.

D_3 = a multiplier of $\bar{R}$ used to locate the 3-sigma lower control limit on a chart for R.

D_4 = a multiplier of $\bar{R}$ used to locate the 3-sigma upper control limit on a chart for R.

D_i = cumulative number of defective units at the ith sample.

df = degrees of freedom, the number of independent comparisons possible with a given set of observations (also called DF).

DF = degrees of freedom, the number of independent comparisons possible with a given set of observations (also called df).

DPU = defects per unit.

e = the base of the natural logarithm, a constant whose value is 2.71828+.

e = simple event.

e_{ij} = the experimental error associated with the measurement Y_{ij}.

$\bar{E}$ = maximum allowable error in estimate (desired precision).

$E(T)$ = expectation of T; also mean time to failure.

E_2 = a multiplier of $\bar{R}$ to determine the 3-sigma control limits on a chart for individuals.

EVOP = evolutionary operation.

f = frequency; generally, the number of observed values in a given cell of a frequency distribution.

f = sampling rate in continuous sampling.

f = in Skip Lot sampling, the fraction of lots to be inspected after the initial criteria have been satisfied.

$f(t)$ = probability density function (pdf).

F = ratio of two estimates of variance or the distribution of this ratio.

F_{CALC} = calculated value of F.

F_{TAB} = tabulated value of F.

F' = ratio of two sample ranges or the distribution of this ratio.

$F(t) = Pr(T \le t)$ = cumulative distribution function (cdf).

$F_T(t)$ = system failure probability.

$\hat{F}(t)$ = empirical estimate of distribution function.

$F(t, \theta)$ = exponential distribution function with mean θ.

$F(t, \eta, \beta)$ = Weibull distribution function with shape parameter η and scale parameter β.

$F(t, \mu, \sigma)$ = normal distribution function with location parameter μ and scale parameter σ; $F(t, \theta, \sigma) = \Phi_{NOR}[(t - \mu)/(\sigma)]$.

g = a numerical factor used in calculations for the Weibull distribution.

G = grand total of all observations.

GLD = generalized lambda distribution.

h = multiplier for two-stage testing, confidence interval, and testing of the best.

h = a parameter of cumulative sum sampling plans.

$h_T(t)$ = system hazard function

$h(t)$ = hazard function; $h(t) = f(t) / (1 - F(t))$

h' = a parameter of cumulative sum sampling plans.

h_1, h_2 = intercept values in a sequential sampling plan for process parameter.

H: = hypothesis.

i = cell interval; for grouped data, the distance from a point in one cell to a similar point in the next cell.

i = in Skip Lot sampling, the number of successive lots to be found conforming to qualify for skipping lots either at the start or after detecting a nonconforming lot.

i = number of successive acceptable units in continuous sampling.

i = number of lots having samples with no defectives in chain sampling.

I = cost of inspecting one piece.

I_m = minimum inspection per lot.

I = the square identity matrix.

I = identity symbol.

k = number of sampling levels in continuous sampling plans.

k = a parameter of cumulative sum sampling plans.

k = number of treatments or levels of the factor to be investigated.

k = acceptance constant for variables plan.

k = block size in a balanced incomplete block or Youden square design.

k = number of factors in a $2k$ design.

k = number of points required for a lattice design for $m + 1$ equally spaced values and q components.

k = number of populations for intervals of fixed width and precision.

k = number of predictor variables in regression.

k = sample number.

k = tolerance interval factor for the normal distribution using s.

K = the difference between a particular value and the average in units of standard deviation. $K = (X - \mu)/\sigma$. Also called z.

K = in Evolutionary Operation, a factor used in determining the error term. Converts range into estimated standard deviation.

K_1, K_2 = factors for tabulation method cumulative sum chart.

K_1, K_2 = tolerance interval factors for the normal distribution using the range.

$\mathcal{L}$ = likelihood.

L = a numerical factor used in calculations for Evolutionary Operations.

L = loss function.

L = multiples of the standard deviation.

L = lower specification limit for a quality characteristic.

L,E = constants in a balanced incomplete block or Youden square design.

$L(N)$ = notation for orthogonal array with N runs.

LACL = in variables sampling plans, the lower acceptance control limit.

LCL = lower control limit on a control chart.

LQ = limiting quality.

LTPD = lot tolerance percent defective, i.e., the level of defectiveness that is unsatisfactory and therefore should be rejected by the sampling plan.

LSD = least significant difference.

m = number of occurrences.

m = number of levels in the primary (A) factor in a staggered nested design.

m = number of levels of a factor.

m_R = true mean of ranges.

M = in MIL-STD-414, an acceptance limit.

M = a numerical factor used in calculations for Evolutionary Operation.

MAR = maximum allowable range.

MCF = mean cumulative function, the expected number of repairs per system before time t.

ML = maximum likelihood.

MS = mean square.

MSB = mean square between treatments.

MSD = maximum standard deviation for variables sampling plan.

MSE = error mean square.

MSI = mean square for interaction.

MS (RES) = residual mean square.

MSW = mean square within treatments.

MTBF = mean time between failures.

n = number of articles or observed values in a sample or subgroup. Also, the number of trials of some event.

n_i = number assigned to each treatment.

n_0 = in a response surface experimental design, the number of center points.

n_0 = initial sample size.

n_1 = in double sampling, the number of pieces in the first sample.

n_2 = in double sampling, the number of pieces in the second sample.

n_a = attributes sample size.

n_0, n_s = sample sizes for variables plans with known and unknown standard deviation.

n_T, n_N = sample sizes for a TNT sampling plan.

$\bar{n}$ = average sample size.

$n!$ = $n(n-1)(n-2)\cdots(1)$, where n is a positive integer; $n! = 1$ for $n = 1$ and for $n = 0$.

np = number of defective articles in a sample of size n.

$n\bar{p}$ = average value of np in a set of sample size n.

N = number of articles in a lot or population.

N = number of experimental units.

N = number of data pairs in regression.

OC = operating characteristic, a plot describing the risks in a sampling plan.

p = fraction nonconforming, i.e., the ratio of the number of nonconforming units to the total number of nonconforming and conforming units.

p = probability of occurrence of an event.

p = fractionalization element in a 2^{k-p} experiment design.

P^* = confidence level.

$p(\%)$ = in variables sampling plans, estimate of two-sided percent defective.

P_1 = in sampling plans, the acceptable fraction nonconforming.

P_2 = in sampling plans, the rejectable fraction nonconforming.

P_0 = aimed-at or standard values of the fraction of nonconforming articles; also, the true value of p in a lot or population being sampled.

$\bar{P}$ = average fraction nonconforming, i.e., the total number of nonconforming units found in a set of samples divided by the total number of units in the samples.

p_b = break-even value of fraction nonconforming for which cost of inspection of $1/p_b$ units is equal to cost of damage done by one nonconforming.

p_c = expected proportion failing.

p_k = upper tail p value corresponding to $z = $ k.

$P_{n_0}(t)$ = probability for testing if two measures are equal in two stages.

$p_L(\%)$ = in variables sampling plans, estimate of percent defective below the lower specification limit.

$p_U(\%)$ = in variables sampling plans, estimate of percent defective.

P = the population percentage included between statistical tolerance limits.

P_a = probability of accepting a given lot. Also, the probability of accepting a hypothesis.

$P(A)$ = probability of occurrence of event A.

$P(B|A)$ = conditional probability of B, given A has occurred.

P_r = the probability of lot rejection.

PC = PRE-Control.

PE = pure error.

P_s = probability of survival. The probability of failure-free operation for a time period equal to or greater than t. This is identical with R, reliability.)

q = $1 - p$, the probability that a particular event will not happen in a single trial.

q = in experimental design, number of components in a mixture.

Q = quadratic loss function.

$Q_r(X_r)$ = statistic for Quisenberry Q chart for the mean with known σ.

$Q(R_r)$ = statistic for Quisenberry Q chart for process variation with known σ.

Q_L, Q_U = quality indices used in MIL-STD-414.

r = the number of occurrences of some event, e.g., the number of defectives in a sample, the number of occurences of the less frequent sign in a test of hypothesis. Also, the distribution of this statistic.

r = the sample correlation coefficient.

r = number of replications.

r = rejection number in a sampling plan.

$r_{10}, r_{11}, r_{21}, r_{22}$ = criteria for testing outliers.

R = range of a set of n numbers, i.e., the difference between the largest number and the smallest number.

R = operating ratio (p_2/p_1) of a sampling plan.

$\overline{R}$ = mean of several ranges.

R_e = the rejection number, i.e., the number of defective pieces in a sample of size n which causes rejection of the lot.

$R(t)$ = reliability; proportion of population surviving to time t; also called R.

REG = regression.

RES = residual.

RPL = rejectable process level, i.e., a process level which is rejectable and should be rejected most of the time by the plan.

RQL = rejectable quality level.

RSM = response surface methodology, an experimental approach used to optimize many different kinds of industrial unit processes and systems.

R^2 = the proportion of variation explained by a regression model. Also the square of the sample multiple correlation coefficient.

s = sample estimate of σ (standard deviation of population); e.g., s is the sample estimate of the standard deviation of individual values, $s_{\overline{X}}$ is the sample estimate of the standard deviation of sample means.

s = $\sqrt{\Sigma(x - \overline{x})^2/(n - 1)}$.

s = in sequential sampling plans, a constant computed from the values of the APL and the RPL.

s^2 = sample estimate of σ^2 (variance of a population); e.g., s^2 is the sample estimate of the variance of individual values, $s_{\overline{X}}^2$ is the sample estimate of the variance of sample means.

s_0 = standard deviation for a standards given control chart.

s_d = standard deviation of differences.

s_{XY} = covariance between X and Y.

S_m = test statistic in cumulative sum sampling plans.

$S(t)$ = $\Pr(T > t)$ = survival function; $S(t) = P_s = 1 - F(t)$, also known as reliability function.

SE = standard error.

SKSP = Skip Lot sampling plan.

SN = signal-to-noise ratio.

SPC = statistical process control.

SS = sum of squares; e.g., SSE is sum of squares for error.

SS(LF) = sum of squares due to lack of fit.

SS(PE) = sum of squares due to pure error.

SSB = between-treatments sum of squares.

SSC = column sum of squares.

SSE = error sum of squares.

SSI = interaction sum of squares.

SSR = row sum of squares.

SSR = residual sum of squares.

SST = total sum of squares, also TSS.

SSW = within-treatments sum of squares.

t = a specified period of failure-free operation.

t = number of treatments in a randomized block design.

t = statistic used to compare sample means or the distribution of the statistic.

t' = statistic used to compare sample means when the population standard deviations cannot be assumed equal. $t' = (\bar{X}_1 - \bar{X}_2)/\sqrt{s_1^2/n_1 + s_2^2/n_2}$

t = number of standard deviation units.

t_c = censoring time.

t_p = pth quantile of T.

T = in sequential sampling, the cumulative sum of an appropriate statistic against the sample number n.

T = in cumulative sum control charts, the reference value.

T = tolerance.

T = observation total.

T = total test time.

T' = sum of ranks for two-sample Mann-Whitney test.

T_L = $(\bar{X} - L)/s$, a statistic used in MIL-STD-414.

T_U = $(U - \bar{X})/s$, a statistic used in MIL-STD-414.

T^2 = a statistic used to test population means on two characteristics (called Hotelling's T^2).

TSS = corrected total sum of squares.

u = defects per unit.

$\bar{u}$ = total number of nonconformities in all samples divided by the total number of units in all samples, i.e., the average number of nonconformities per unit.

U = symbol used for statistics (for testing hypotheses) that follow a normal distribution.

U = upper specification limit for a quality characteristic X.

UCL = upper control limit on a control chart.

ULL, LLL = parameters for lot plot sampling.

v = factor in graphical application of variables sampling plan.

v = factor in variables sampling plans for known variability.

var (Z_t) = variance of exponentially weighted moving average.

w = cell width.

w = the ranges of the n observations on each treatment.

W = importance weights.

x = a vector of elements.

x' = the transpose of the x vector.

$x_1, x_2,...$ = observed value of some variable, usually a quality characteristic.

$\overline{X}$ = arithmetic mean, the average of a set of numbers $X_1, X_2, X_3, ..., X_n$ is the sum of the numbers divided by n.

$\overline{X}_0$ = an aimed-at or standard value of a quality characteristic. Also used to represent the true but often unknown mean of a universe being sampled.

$\overline{\overline{X}}$ = mean of several $\overline{X}$ values. Often called the grand average.

X = a matrix of elements.

$\tilde{X}$ = median value of X.

y = density or frequency function.

y_1, y_2 = acceptance and rejection values in sequential sampling.

Y = response characteristic.

Y = observed value of a variable.

Y_i = the yield for run number i.

Y_{ij} = the observation on the ith treatment in the jth block.

$\overline{Y}$ = average of values of Y variable.

$\overline{Y}_0$ = in response surface methodology, the average of the center points.

$\hat{Y}$ = the predicted value for Y.

z_{1-Pa} = normal z value for caluclating OC curve.

z_p = z value for fraction p in the upper tail of the normal distribution.

Z = normal distribution coefficient.

Z_t = statistic for exponentially weighted moving average plot.

α (alpha) = probability of rejecting the hypothesis under test when it is true. (Called the type I error or level of significance.) In acceptance sampling, α = the producer's risk.

α = scaling parameter of the Weibull distribution.

β (beta) = probability of accepting the hypothesis under test when it is false. (Called the type II error.) In acceptance sampling, β is the consumer's risk.

β_0, β_1 = acceptable and unacceptable mean life.

$\beta_1, \beta_2,...$ = in regression, the unknown parameters of the model.

β = shape parameter of the Weibull distribution.

$\beta^2 V$ = large sample approximate variance factor for Weibull estimation.

β_i = a term peculiar to a given block. It is the amount by which the response of a given treatment in the ith block differs from the response of the same treatment averaged over all blocks, assuming no experimental error.

γ (gamma) = confidence level.

γ = location parameter of the Weibull distribution.

Γ (gamma) = the gamma function.

δ (delta) = width of confidence interval.

δ = in a cumulative sum control chart, standardized shift in mean it is desired to detect, $\delta = D/\sigma$.

δ^* = distance between true value and hypothesized value.

ϵ (epsilon) = a random error term of a linear function.

η (eta) = scale parameter of the Weibull distribution.

η = group means, grand mean.

θ (theta) = mask angle for cumulative sum chart (one-half total angle of mask).

θ = in reliability, mean life.

θ = in cumulative sum control charts, an angle on the mask used in the chart.

λ (lambda) = failure rate, i.e., the proportion of failures per unit time.

λ = weighting factor for exponentially weighted moving average.

μ (mu) = the population mean (average), e.g., the mean of a lot, the mean time between failures, or the mean life. (μ_0 is the acceptable value of the mean and μ_1 is the unacceptable value of the mean.)

μ_0 = a standard value for μ.

ν (nu) = degrees of freedom.

$\nu(t)$ = recurrence rate of repairs per system.

ξ (xi) = transformation value.

π (pi) = the constant 3.14159+.

σ (sigma) = the population standard deviation; e.g., σ is the standard deviation of indiviual values, $\sigma_{\bar{x}}$ is the standard deviation of sample means. (Some literature uses σ' in place of σ.)

$\bar{\sigma}$ = mean of several standard deviations.

$\hat{\sigma}$ (sigma hat) = estimate of population standard deviation computed from a sample of size n; $\hat{\sigma} = \sqrt{\Sigma(x - \bar{x})^2/n}$.

σ_0 = a standard value for σ.

σ_p = standard deviation of proportions.

σ_R = standard deviation of sample ranges.

σ_w^2 = within component of variance, estimated by s_w^2.

σ_b^2 = between component of variances, estimated by s_b^2.

σ^2 = population variance, error variance.

Σ (sigma) = a mathematical sign meaning "take the algebraic sum of the quantities which follow."

τ_d (tau$_d$) $=$ $(\bar{X}_1 - \bar{X}_2/[\frac{1}{2}(R_1 + R_2)]$, a statistic used to test the hypothesis about μ_1 and μ_2. Also, the distribution of the statistic.

τ_1 $=$ $(\bar{\bar{X}} - \mu_0)/R$, a statistic used to test the hypothesis about μ_0. Also the distribution of the statistic.

τ_j $=$ time between repairs.

ϕ_i (phi) $=$ in a randomized block experimental design, a term peculiar to the ith treatment, constant for all blocks regardless of the block in which the treatment occurs.

ϕ^2 $=$ quantity for determining sample size in analysis of variance.

$\Phi^{-1}(p)$ $=$ inverse of distribution function giving value of random variable having cumulative probability p.

Φ_{SEV} $=$ smallest extreme value distribution function.

Φ_{NOR} $=$ normal distribution function.

$\Phi(p)$ $=$ distribution function.

χ^2 (chi^2) $=$ $(n - 1)s^2/\sigma_0^2$ or the distribution of this ratio.

∞ $=$ infinity.

See Appendix III for a listing of standards covering symbols and other matters.

APPENDIX II
TABLES AND CHARTS

For more extensive tables see Owen, D. B. (1962). *Handbook of Statistical Tables.* Addison-Wesley, Reading, MA. 1962

Table A Factors for Computing Control Chart Lines*

Observations in Sample, n	Chart for averages — Factors for control limits			Chart for standard deviations — Factors for central line		Chart for standard deviations — Factors for control limits				Chart for ranges — Factors for central line			Chart for ranges — Factors for control limits

*The above table is a copy of Table 27 in *ASTM Manual on Presentation of Data and Control Chart Analysis.* (1976). ASTM Publication STP15D. American Society for Testing and Materials, Philadelphia, pp. 134–135. Used with permission.

Notes: For $n > 25$, $A = 3/\sqrt{n}$, $A_3 = 3/c_4\sqrt{n}$, $c_4 \cong 4(n-1)/(4n-3)$; $B_3 = 1 - 3/c_4\sqrt{2(n-1)}$, $B_4 = 1 + 3/c_4\sqrt{2(n-1)}$,

$$B_5 = c_4 - 3/\sqrt{2(n-1)}, \ B_6 = c_4 + 3/\sqrt{2(n-1)}$$

FORMULAS

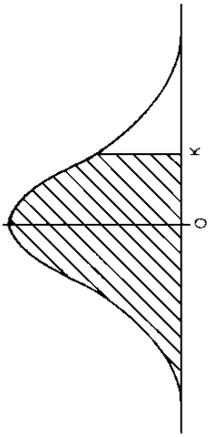
Purpose of chart	Chart for	Central line	3-Sigma control limits
For analyzing past inspection data for control ($\overline{\overline{X}}$, $\overline{s}$, $\overline{R}$ are average values for the data being analyzed)	Averages	$\overline{\overline{X}}$	$\overline{\overline{X}} \pm A_3\overline{s}$, or $\overline{\overline{X}} \pm A_2\overline{R}$
	Standard deviations	$\overline{s}$	$B_3\overline{s}$ and $B_4\overline{s}$
	Ranges	$\overline{R}$	$D_3\overline{R}$ and $D_4\overline{R}$
For controlling quality during production ($\overline{X}_0$, σ_0, R_0, are selected standard values; $R_0 = d_2\sigma_0$ for samples of size n)	Averages	$\overline{X}_0$	$\overline{X}_0 \pm A\sigma_0$ or $\overline{X}_0 \pm A_2R_0$
	Standard deviations	s_0 or $c_4\sigma_0$	$B_5\sigma_0$ and $B_6\sigma_0$
	Ranges	R_0 or $d_2\sigma_0$	$D_1\sigma_0$ and $D_2\sigma_0$


TABLE B Normal Distribution*

Proportion of total area under the curve from $-\infty$ to $K = \dfrac{X - \mu}{\sigma}$. To illustrate: when $K = +2.0$, the probability is 0.9773 of obtaining a value equal to or less than X.

TABLE K*   Distribution of F

Values of F corresponding to certain selected probabilities (i.e., tail areas under the curve). To illustrate: The probability is 0.05 that the ratio of two sample variances obtained with 20 and 10 degrees of freedom in numerator and denominator, respectively, would have $F = 2.77$ or larger. For a two-sided test, a lower limit is found by taking the reciprocal of the tabulated F value for the degrees of freedom in reverse. For the above example, with 10 and 20 degrees of freedom in numerator and denominator, respectively, F is 2.35 and $1/F$ is $1/2.35$, or 0.43. The probability is 0.10 that F is 0.43 or smaller or 2.77 or larger.

CHART N   Confidence Limits for Fraction Defective*

Enter the horizontal scale with the sample fraction defective. Rise vertically to the upper and lower curves for the stated sample size. Read the corresponding upper and lower confidence limits on the vertical scale. To illustrate: If a sample of 50 is 20% defective, the 95% confidence limits on the population fraction defective are 10 and 35%.

TABLE V One-Sided and Two-sided Statistical Tolerance Limit Factors k for a Normal Distribution*

Factors k such that the probability is γ that at least a proportion P of the distribution will be less than $\overline{X} + ks$ (or greater than $\overline{X} - ks$) where $\overline{X}$ and s are estimates of the mean and standard deviation computed from a sample size of n. Two-sided factors cover $\overline{X} \pm ks$.

n	$\gamma=0.90$				$\gamma=0.95$				$\gamma=0.99$			
$P=$	0.90	0.95	0.99	0.999	0.90	0.95	0.99	0.999	0.90	0.95	0.99	0.999

APPENDIX III

SELECTED QUALITY STANDARDS, SPECIFICATIONS, AND RELATED DOCUMENTS

This list is limited to documents likely to be of general interest. August Mundel collected, organized, and assembled the material to bring this appendix up to date. There are many other standards that refer to the control and measurement of specific quality, reliability, etc., of specific products. In general, these have not been listed.

The U.S. Department of Defense has, for the most part, given up the maintenance and use of its own standards and is letting other organizations inherit, revise, and republish the standards. There is still a vast amount of information in the U.S. MIL standards not available elsewhere. These standards can, for the most part, be obtained and are therefore listed.

The list is based on the original summary by B. A. MacDonald and M. V. Petty entitled "List of Quality Standards, Specifications and Related Documents," (February 10, 1987, unpublished). Much of the other material is the result of the Standards Column of *Quality Engineering* magazine, edited by August B. Mundel, where the data from MacDonald and Petty has also been published.

The following list is divided into three parts as follows:

System and program requirements	Statistical techniques and procedures	Inspection and test methods
Definitions	Definitions, symbols, formulas	Definitions, units of measurement
Quality	Analysis of data	Inspection and test methods and
Reliability	Control charts	requirements
Maintainability	Acceptance sampling	Evaluation of inspection and test
Software		systems
Safety		Precision and accuracy
Certification programs		
Other		

In some cases, the official document designation includes abbreviations or other notations:

Amd.: Amendment

Chg not: Change notice

Supp: Supplement

'79: 1979

Following the complete listing, addresses are given for the organizations issuing the documents.

APPENDIX IV
QUALITY SYSTEMS TERMINOLOGY

The following terms and definitions are selected from those given in the American National Standard ANSI/ASQC A8402-1994, *Quality Management and Quality Assurance—Vocabulary*. The reader is urged to consult the full standard for the full vocabulary list and for valuable notes and comments associated with individual terms. The document is available from American Society for Quality, 611 East Wisconsin Avenue, Milwaukee, WI 53202. In many cases, the authors of specific sections have used slightly different or expanded definitions of some terms. The following terms and definitions are provided for general understanding and use.

Conformity: Fulfillment of specific requirements.

Customer: Recipient of a product provided by the supplier.

Dependability: Collective term used to describe the availability performance and its influencing factors: reliability performance, maintainability performance, and maintenance-support performance.

Design review: Documented, comprehensive, and systematic examination of a design to evaluate its capability to fulfill the requirements for quality, identify problems, if any, and propose the development of solutions.

Deviation permit: See *Production permit.*

Entity: Item which can be individually described and considered.

Grade: Category or rank given to entities having the same functional use but different requirements for quality.

Inspection: Activity such as measuring, examining, testing, or gauging one or more characteristics of an entity and comparing the results with specified requirements in order to establish whether conformity is achieved for each characteristic.

Objective evidence: Information which can be proved true, based on facts obtained through observation, measurement, test, or other means.

Procedure: Specified way to perform an activity.

Process: Set of interrelated resources and activities which transform inputs into outputs.

Process quality audit: See *Quality audit.*

Product: Results of activities or processes.

Product quality audit: See *Quality audit.*

Production permit (*Deviation permit*): Written authorization to depart from the originally specified requirements for a product prior to its production.

Quality: Totality of characteristics of an entity that bear on its ability to satisfy stated and implied needs.

Quality assurance: All the planned and systematic activities implemented within the quality system, and demonstrated as needed, to provide adequate confidence that an entity will fulfill requirements for quality.

Quality audit: Systematic and independent examination to determine whether quality activities and related results comply with planned arrangements and whether these arrangements are imple-

mented effectively and are suitable to achieve objectives. *Note:* The quality audit typically applies to, but is not limited to, a quality system or elements thereof, to processes, to products, and to services. Such audits are often called "quality system audit," "process quality audit," product quality audit," "service quality audit."

Quality control: Operational techniques and activities that are used to fulfill requirements for quality.

Quality loop/quality spiral: Conceptual model of interacting activities that influence quality as well as the losses incurred when satisfactory quality is not achieved.

Quality management: All activities of the overall management function that determine the quality policy, objectives, and responsibilities, and implement them by means such as quality planning, quality control, and quality improvement within the quality system.

Quality plan: Document setting out the specific quality practices, resources, and sequence of activities relevant to a particular product, project, or contract.

Quality planning: Activities that establish the objectives and requirements for quality and for the application of quality system elements.

Quality policy: Overall intentions and direction of an organization with regard to quality, as formally expressed by top management.

Quality surveillance: Continual monitoring and verification of the status of an entity and analysis of records to ensure that specified requirements are being fulfilled.

Quality system: Organizational structure, procedures, processes, and resources needed to implement quality management.

Quality system audit: See *Quality audit.*

Requirements for quality: Expression of the needs or their translation into a set of quantitatively or qualitatively stated requirements for the characteristics of an entity to enable its realization and examination.

Requirements of society: Obligations resulting from laws, regulations, rules, codes, statutes, and other considerations.

Service: Result generated by activities at the interface between the supplier and the customer and by supplier internal activities to meet the customer needs.

Specification: Document stating requirements.

Supplier: Organization that provides a product to the customer.

Traceability: Ability to trace the history, application, or location of an entity by means of recorded identifications.

Verification: Confirmation by examination and provision of objective evidence that specified requirements have been fulfilled.

Waiver: Written authorization to use or release a product which does not conform to the specified requirements.

APPENDIX V
QUALITY IMPROVEMENT TOOLS*

INTRODUCTION

Ishikawa's classic *Guide to Quality Control* (1972) is generally credited as the first training manual of problem-solving tools specifically presented for use in quality improvement. In the Japanese original, the book was a training reference for factory workers who were members of quality control (QC) circles. To the "seven tools" of that volume (flow diagrams, brainstorming, cause-effect diagrams, Pareto analysis, histograms, and scatter diagrams), we here add three more. Two are implied but not dealt with in detail in the Ishikawa work—data collection and graphs and charts. The third, box plots, is of more recent origin (Tukey 1977), but has proved itself a worthy complement or substitute for histograms under certain conditions. There are many other useful tools; this list is not exhaustive, nor could it or any list be so. But the list here is a useful starting place for quality improvement activity. Quality improvement teams that have mastered these tools are well prepared for most of the problems they are likely to face.

As presented by Juran Institute in the course *Quality Improvement Tools,* the tools are integrated with a structured quality improvement process (Figure V.1). Each tool is described and instructions for the tool's use are presented. In addition, the process steps in which the tool is used are identified. This information is captured in an application map in matrix form (Figure V.1), with each column corresponding to a tool, and each row corresponding to a process step. At each intersection is a symbol indicating the frequency of use of that tool at that process step (frequent, infrequent, and very rarely).

The process map is a valuable guide to problem-solving teams in these ways:

1. It reminds the team that there is a structured order to the problem-solving process and helps keep the team on track.

2. At a given step, if the team is at a loss what to do next, one of the frequently used tools may suggest the next action.

3. At a given step, using a tool indicated as rarely used is a signal to the team to reconsider its course of action. A convenient example is the use of brainstorming (which is an effective way to develop a list of theories, ideas, and opinions of group members) to test theories (which always requires data, not the opinions of the team members).

The tools are briefly described and illustrated here. A more thorough treatment is available from a number of texts, including the course notes for *Quality Improvement Tools* or from *Modern Methods for Quality Control and Improvement* by Wadsworth, Stephens, and Godfrey (1986).

---

*In response to inquiries from users of previous editions of this handbook, the editors include this introduction to some of the more important and popularly used quality improvement tools. Material in this appendix is adapted from material provided in the course *Quality Improvement Tools* presented by Juran Institute, Inc., Wilton, CT.

FIGURE V.1   Applications for quality improvement tools. (*Juran Institute.*)

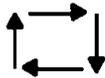
THE TOOLS

Flow Diagram.   A graphic representation of the sequence of steps needed to produce some output. The output may be a physical product, a service, information, or a combination of the three. The symbols of a flow diagram are specific to function and are explained in Figure V.2. Figure V.3 shows the use of these symbols in the flow diagram of an airline ticketing process.

Brainstorming.   A group technique for generating constructive and creative ideas from all participants. Use of this tool should provide new ideas, or new applications and novel use of existing ideas. The technique is outlined in Figure V.4.

Cause-Effect ("Fishbone") Diagram.   Developed by Kaoru Ishikawa, this tool is frequently called the Ishikawa diagram in his honor. Its purpose is to organize and display the interrelationships of various theories of root cause of a problem. By focusing attention on the possible causes of a specific
The *activity symbol* is a rectangle that indicates a single step in the process. A brief description of the activity is shown inside the rectangle.

The d*ecision symbol* is a diamond that designates a decision or branch point in the process. The description of the decision or branch is written inside the symbol, usually in the form of a question. The answer to the question determines the path that will be taken out of the decision symbol. Each path is labeled to correspond to an answer.

The *terminal symbol* is a rounded rectangle that identifies the beginning or the end of a process. "Start" or "End" is shown inside the symbol.


Flow lines are used to represent the progression of steps in the sequence. The arrowhead on the flow line indicates the direction of the process flow.

The *document symbol* represents written information pertinent to the process. The title or description of the document is shown inside the symbol.

The *data base symbol* represents electronically stored information pertinent to the process. The title or description of the data base is shown inside the symbol.

The *connector* is a circle used to indicate a continuation of the flow diagram. A letter or number is shown inside the circle. This same letter or number is used in a connector symbol on the continued flow diagram to indicate how the processes are connected.

These basic symbols are arranged to show the actual sequence of steps in a process, running consistently from top to bottom or left to right on the page. As we have seen, decision diamonds can lead us to branch back and repeat an earlier step.

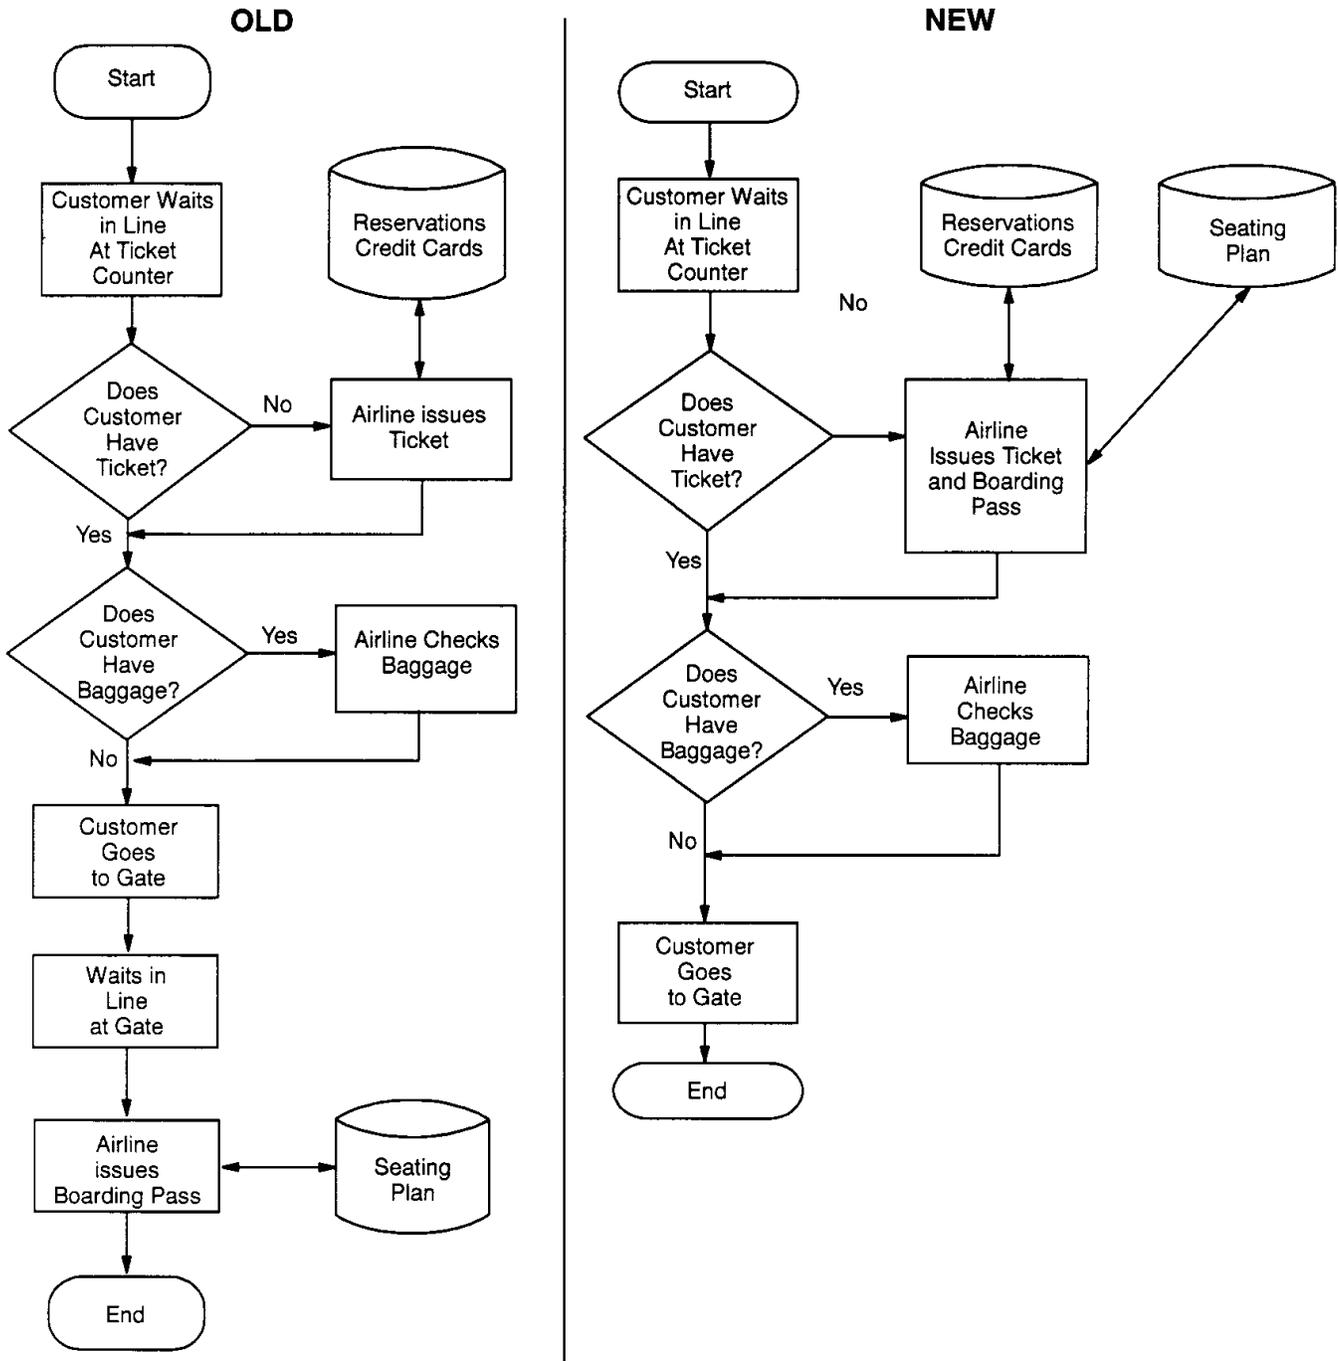
FIGURE V.2   Symbols used in flow diagramming.


FIGURE V.3   Before and after flow diagrams of an airline ticketing process. (*Juran Institute.*)

- Good ideas are not praised or endorsed. All judgment is suspended initially in preference to generating ideas.
- Thinking must be unconventional, imaginative, or even outrageous. Self-criticism and self-judgment are suspended.
- To discourage analytical or critical thinking, team members are instructed to aim for a large number of new ideas in the shortest possible time.
- Team members should "hitchhike" on other ideas, by expanding them, modifying them, or producing new ones by association.

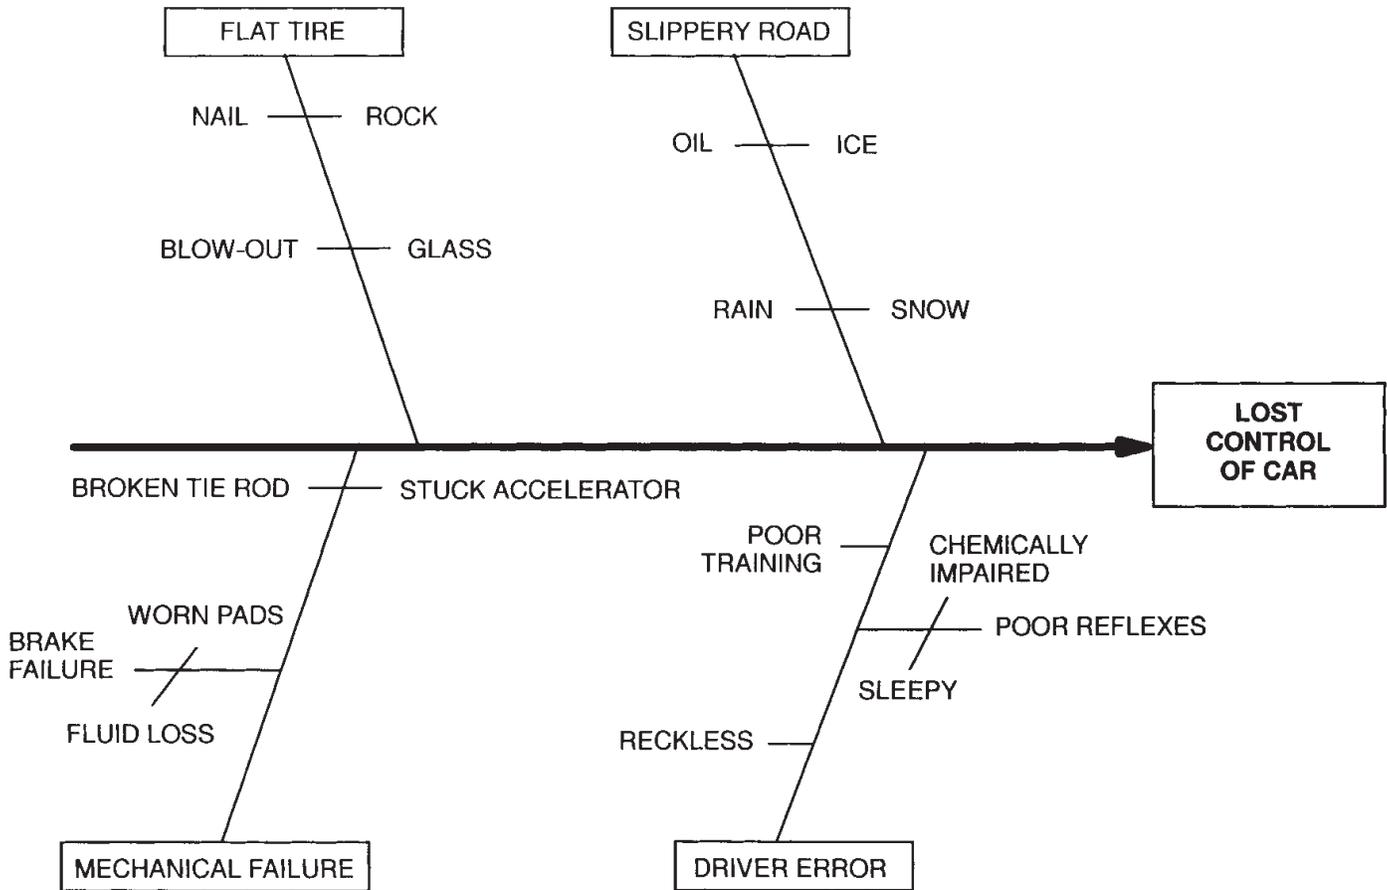
FIGURE V.4 Brainstorming technique. (*Juran Institute.*)


FIGURE V.5 Cause-effect diagram for lost control of car. (*Juran Institute.*)

problem in a structured, systematic way, the diagram enables a problem-solving team to clarify its thinking about those potential causes, and enables the team to work more productively toward discovering the true root cause or causes. Figure V.5 is an example.

Data Collection.   The gathering of the objective data needed to shed light on the problem at hand, and in a form appropriate for the tool selected for the analysis of the data. Types of data collection include check sheets (providing data and trends), data sheets (simple tabular or columnar format), and checklists (simple listing of steps to be taken). Figures V.6 and V.7 are examples.

Graphs and Charts.   A broad class of tools used to summarize quantitative data in pictorial representations. Three types of graphs and charts that prove especially useful in quality improvement are line graphs, bar graphs, and pie charts. A *line graph* connects points which represent pairs of numeric

data, to display the relationship between two continuous numerical variables (e.g., cost and time). In Figure V.8 each pair of data consists of a year and the cost of poor quality recorded in that year. The cost of poor quality is shown as a function of the year. A *bar graph* also portrays the relationship between pairs of variables, but only one of the variables need be numeric (Figure V.9). A *pie chart* (Figure V.10) shows the proportions of the various classes of a phenomenon being studied that make up the whole.

Stratification.   This is the separation of data into categories. It is used to identify which categories contribute to the problem being solved and which categories are worthy of further investigation. It is

• Read temperature to nearest degree off meter number 5.   Date: _____ *6-7-88* _____

an analysis technique that helps pinpoint the location or source of a quality problem. It may be necessary to stratify the data in many different ways. Figures V.11 and V.12 illustrate stratification of data related to field failure of an electronic component. The first stratification is by supplier, the second by shipper. The analysis reveals that the problem relates to shippers (specifically a new shipper), not suppliers. Stratification is the basis for the application of other tools, such as Pareto analysis and scatter diagrams.

Pareto Analysis.   This is a tool used to establish priorities, dividing contributing effects into the "vital few" and "useful many." A Pareto diagram includes three basic elements: (1) the contributors

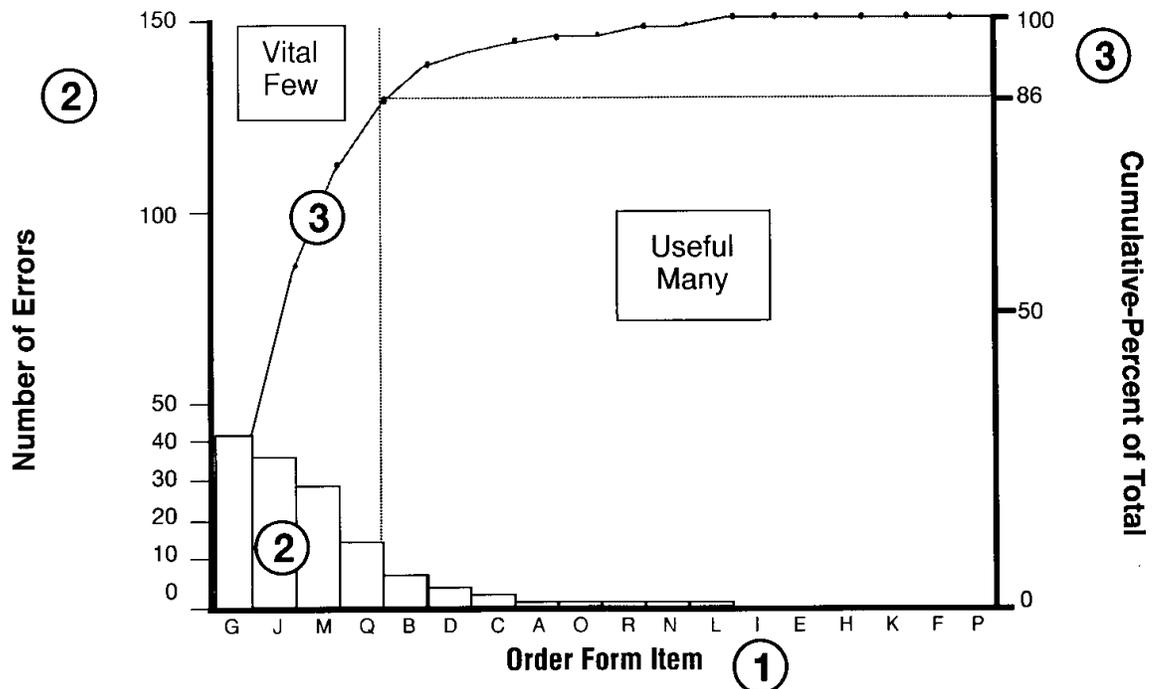

FIGURE V.14   Pareto diagram of errors on order forms. (*Juran Institute.*)

to the total effect, ranked by the magnitude of contribution; (2) the magnitude of the contribution of each expressed numerically; and (3) the cumulative-percent-of-total effect of the ranked contributors. Figure V.13 shows a Pareto table. Figure V.14 shows the same data in a Pareto diagram. Note the three basic elements as reflected in each figure.

Histogram.
This is a picture of the distribution of a set of measurements. A histogram is a graphic summary of variation in a set of data. Four concepts related to variation in a set of data underlie the usefulness of the histogram: (1) values in a set of data almost always show variation, (2) variation displays a pattern, (3) patterns of variation are difficult to see in simple numerical tables, and (4) patterns of variation are easier to see when the data are summarized pictorially in a histogram. Analysis consists of identifying and classifying the pattern of variation displayed by the histogram, then relating what is known about the characteristic pattern to the physical conditions under which the data were created to explain what in those conditions might have given rise to the pattern. The data in Figure V.15*a* shows days elapsed between an interdepartmental request for an interview and the actual interview. In Figure V.15*b,* the histogram helped a team recognize the unacceptable range of time elapsed from request to interview. It also provided the team with a vivid demonstration of a human-created phenomenon—the rush at day 15 to get as many requests completed within the 15-day goal. The histogram directed the team's attention toward steps to reduce the duration (and with it the spread) of the process.

Scatter Diagram.
This is a tool for charting the relationship between two variables to determine whether there is a correlation between the two which might indicate a cause-effect relationship (or indicate that no cause-effect relationship exists). Figure V.16 shows scatter diagrams used to explore three potential causes for clerical errors. Potential causes, chosen from a cause-effect diagram are: fatigue, working with a mixture of alphabetic and numeric keyboard characters, and distracting background noise. The diagrams indicate the alphanumeric mixture appears to be the most likely root cause of the clerical errors.

Box Plot.
This is a graphic, five-number summary of variation in a data set. The data are summarized by: the smallest value, second quartile, median, third quartile, and largest value. The box plot can be used to display the variation in a small sample of data or for comparing the variation in

a large number of related distributions. The box plot (sometimes called a "box and whisker chart") can be useful even when the number of data points is too small to produce a meaningful histogram. In analyzing the performance of two copy-repair contractors, a potential customer created the analysis in Figure V.17. It is based on 10 repair calls each to contractors A and B. Figure V.17*a* and *b* shows the response time of two copy machine contractors as raw data and as "ordered" (sequenced) data. Figure 17*c* shows the same data as a box plots. The comparison of the two plots favors contractor B: B's median response time is less than A's and exhibits less variation.
